Under the box-car method of handling, such freight must load in a car to a transfer and then either load to another transfer or into a straight car. In any event there is delay and additional expense, with possibilities of claims for loss and damage, etc.

In the container method it is entirely feasible to have each of

these small towns either daily or on a certain number of days per week load a container car with six containers, each of the six containers for a different destination, but the destinations to be the same in the six cars, and then stop the cars at the first proper point and reassort the containers so that when the cars leave this first point there will be six containers in each car, but each car will have its six containers loaded for the same point. In other words, there will be a straight car for each of six points, and the cost of such rehandling is very small in comparison with the cost of ordinary transfer handling. Further, the load per car would be very much in excess of any load possible from the transfer, so that it may fairly be said that all expense incident to the container method is more than absorbed by the economies made possible.

### Containers for Bulk Freight

The containers for handling bulk freight, such as brick, limestone, sand, and other bulk materials, present a somewhat different situation in that the handling costs involved in the ordinary transportation methods as against the handling costs involved in the container method must serve as a basis of comparison. The brick containers have dimensions approximately half those of the merchandise containers, and they have inside dimensions of width 4 ft. 1 in., height 7 ft. $4^3/_4$ in., length 6 ft. $11^3/_4$ in. and outside dimensions of width over guides 4 ft. $8^3/_4$ in., height over lifting brackets 8 ft. 4 in., approximately, length 7 ft. $2^1/_2$ in., and a capacity of 210 cu. ft., and an average light weight of 2,300 lb.

They were designed purposely of these dimensions to accommodate 3000 ordinary Hudson River brick thrown in at random, as this number represented the ordinary truckload of brick. The containers are of substantial construction, with special devices for opening the bottom doors by dropping them and for closing them after the brick had come out, a rain- or snow-deflecting top, and with lifting eyes on the four corners. In addition, through special devices the containers can be opened or closed while suspended from the crane. It may be mentioned that this particular size is not in any way necessary as the size can be varied to suit particular conditions, but so far it has been shown to meet a variety of uses as will be outlined later.

For many years the method of handling brick has been in water-borne barges, or in box cars, stacked, or in open tops, thrown in. The first method is possible only in the season of navigation and presents great expense in handling at the point of making the brick, because so many human handlings are involved, and there are similar expenses in unloading from the barge to the truck. The second method presents similar expense in human handling at both ends of the line, and the third perhaps more so owing to the hardship in unloading a gondola car by human hands. In addition the breakage was large and the truck cost out of all proportion owing to the waiting time while the trucks were being loaded.

Therefore a container which would allow the mechanical placement of the brick from the kiln into such a container on a count basis of 3000 brick, their transportation mechanically to the car if the container is not being loaded while on the car, and their transportation in large volume to the point of destination to be unloaded in about one-tenth of the time necessary for a similar number of brick from the barge or the car, appeared to present an opportunity not to be lightly disregarded.

After much experimentation the L.C.L. bulk container was developed to hold 3000 brick each, with 12 units or 36,000 brick per car, which is a load of approximately 132,000 lb. per car. This is about double the largest car handled by the railroad, and it is possible to unload the whole car in actual practice in less than an hour as against at least two days by hand unloading for half the quantity or four days for a similar quantity. The rates charged for transporting are substantially those charged for rail transportation on a similar basis.

Data developed by the Brick Association independently of the railroad showed that there was a motor-truck efficiency in the handling at destination of at least two to one on a 3000-brick basis, and as trucks have been developed for handling 6000 brick the motor-truck efficiency will be nearer four to one, which means that on a basis of a truck costing $30 per day and with container-car brick the truck could handle four times as many brick in a given length of time or do the work of four trucks.

Incidentally while mention is made of unloading a brick container in less than five minutes in actual performance at a given installation where there are two gantry cranes and spanning tracks holding 23 container cars, 293 containers have been unloaded in one day of eight working hours, or 18 containers for each crane per hour, an average of less than $3^1/_2$ min. per container. The speed was limited only by the ability of the trucks to get into position and into and out of the yard.

On a large volume of this traffic this means double the load and at least double the efficiency in unloading time, or an efficiency of at least four to one for the brick container as against the ordinary box car, but it further means that if such tonnage were transported in box cars there would be necessary four times the amount of track room for handling a given volume of tonnage; and as obviously at any center capable of receiving such traffic it would be impossible to produce at any cost four times the available track room, it may fairly be said that new terminals are created without any material increase of capital expenditure for such terminals other than the cost of the cranes and of their operation.

These of course are furnished in common practice for handling heavy freight, but even charging such cost of operation and such cost of installation against the undertaking on a basis of two-thirds daily use, the figures represent for all items of cost, installation, operation, maintenance, and amortization on a 10-year basis, about 23 cents per container.

Bear in mind also that to the railroad the ability to handle such large loads in one car instead of two cars represents a considerable economy both as to road-haul costs and terminal-switching costs at both ends, together with capital investment, economies as to cars, and maintenance on the cars, all of which would more than overcome any direct expense properly to be attributed to the container method of handling.

The bulk container as applied to brick has been discussed in detail, but in actual practice it is also being applied to bulk lime, a leakproof bottom and a leakproof top being supplied. Whereas the bulk lime had formerly been transported in box cars on a basis of 40,000 lb. to a car, it is now being transported in containers on container cars on the basis of 130,000 lb. pei car at the same rates as charged per ton in the box car, or better than three to one in favor of the container car.

From the standpoint of the consignee there is a saving of at least 50 cents a ton in unloading costs and in trucking costs as well, and from the standpoint of the railroad there is a high revenue per car realized, together with the economies incident to the brick traffic already described.

Refuse quarry stone is also being regularly transported in large quantities from a rail quarry to the lakes, the containers being taken out on barges and dumped into the crib for making a breakwater. The success of this is so marked that the operations will be largely extended during the coming season. There are other types of containers for handling bulk sand, gravel, and in fact any rough articles, also for handling building tile, cement, hollow tile, interior finish, fireproofing, sewer pipe, etc., of which time and space will not permit detailed discussion.

The container has been emphasized because such special em-

phasis seemed desirable. In the use of the containers overhead cranes have played a large part, but the use of overhead cranes is not limited to the container in any way, for in the experience of the particular railroad with which the author is connected they have been developed for handling in a large way boxed automobiles at water terminals in New York (Weehawken) for gradually replacing the pillar or fixed crane. It is interesting to note that experience has shown that a relatively light-capacity crane will take care of a very large percentage of freight for which cranes must be used, and that in the few cases where very heavy pieces must be handled it is usually better practice to call out a locomotive crane for short usage rather than tie up an investment in a high-capacity crane where it is not used except to a limited degree. This leads to the belief that 10-ton cranes and 20-ton cranes will perhaps, with some few exceptions, become standard for this use.

The electric lift truck is also used with the container, but is also an increasingly important development apart from it. As applied to the container the lift truck can pick up the container, take it from a truck into a warehouse, place it where desired, pick it up again and put it back on the truck, and either put it on the car or do so with the help of the crane. The future will prove the degree to which the two methods are best suited. My opinion leans to a preference for the crane lifting where a large number of units to be handled in the shortest possible time are involved, and for the lift truck where there are a few units and more time is available, but the two together present the perfected method of handling. Lift trucks are also used in shop work, in handling materials, in the stores department for similar work, in our baggage service, and in many minor useful operations.

### Motor Trucks

The use of motor trucks might well deserve a paper by itself and can be outlined only very briefly. It has early been recognized that the motor truck in its development and possibilities presented the aspect not of a competitor but rather of something to be used by the railroad in its activities, and the difficulty has been to determine just wherein that use properly lay. There has been much talk and much written concerning motor-truck competition, but in a true sense this has been, I think, a most unfortunate phrase, for rather the motor truck should be considered an ally of the railroads; and those developing the motor truck should be as truly anxious as those working for the best interests of the railroads to come to some mutual understanding as to the proper functions and uses of the two agencies.

It may be said that each side has gone too far, and to a degree that is true, but as the years of usage develop experience and perhaps saner judgment. I think it will be readily agreed that the motor truck should not be used in long hauls over the road except in special cases, as this field lies properly within the sphere of railroad activity. On the other hand, for the relatively short hauls, for terminal work, for interchange involving hauls of not in excess of 35 miles, the motor truck should, and I think will, come into its proper sphere.

Speaking with a somewhat intimate knowledge of the endeavors of one railroad in the use of motor trucks, I may say that it has increasingly made use of this agency during the past five years or more and that its use is an extension of what was formerly done by horse-drawn trucks, starting with consolidation, as between freight stations in the larger centers, extending to certain trucking in place of handling by water, then to trucking between stations and eliminating way-freight service or other train service, trucking for interchange between railroads at various terminals, trucking across country between parallel lines of the same railroads situated 8 or 10 miles apart, rather than hauling by rail around long distances to get to the other division, and in some cases in place of trap and ferry-car service, etc.

The railroad, however, has not endeavored in any way to do more than use the trucking agency which presented itself on the basis of contracts with outside truckmen, and has not undertaken to operate trucks itself. By so doing it has perhaps stimulated public good-will in the towns where such operations have been perfected rather than having incurred any public ill-will, and in addition it has made use of going organizations and has endeavored to have a type of equipment used which would result in the lowest proper rates to be charged for the service rendered. In certain phases tractor and trailer equipment seems to be the best, in others straight trucks, and in still others a combination of the two, but it is not felt that it is competent to pass upon these features or the features of the mechanical part other than as it affects the service or the rates which it pays for such service.

Motor trucking as used by the railroad started from nothing and developed in various phases without very many preconceived plans, and the effort of the railroad has been, as it assumed relatively large proportions in its trucking activities, to work to some common ground of understanding and to some general basis wherein trucking activities would be found to be justified or unjustified as compared with rail operation, and in doing this it has had to establish the factors favorable and unfavorable to trucking operation in a given sphere of activity. Its studies have so far progressed as to set down in a formula such factors, weighing one against the other and then coming to a decision, so that each trucking activity conforms to a general plan while perhaps presenting special features of its own.

The efforts in trucking have been improved service, recognizing the obligation to the public, actual monetary economics where practical, better use of facilities, and the elimination of duplicate service, which makes for economy. Where all these factors and many minor ones could be combined the result is plain, but there are many trucking activities in which the results, while intangible and difficult to set down in black and white, are nevertheless important, all of which must be considered.

Many of the other railroads are pursuing similar activities in trucking, and the experience of the large trucking manufacturers has been of great assistance in avoiding serious errors to as great a degree as is practicable. The future in trucking can best be judged by the past. It is becoming stabilized and will be, in my opinion, largely increased in practical use by the railroads as a whole.

There are many other activities with the railroads in the handling at terminals and along the way which contribute to the general success of railroad operation and the satisfaction of service by the public, but I have endeavored to cover only some of the activities which it seems to us do contribute to improvement in service, in methods, and where possible the lowering of costs to the public, together with better returns for the real owners of the railroads.

## Discussion

F. J. Shepard, Jr.[2] Our experience during several years shows large savings of time and money by handling materials in larger units through labor-saving machines in connection with present railroad equipment.

In 1926 we built for a paper manufacturer 1200 paper-clamping platforms of a returnable type. These are used in shipping coated stock from the mills at Lawrence, Mass., to the printer at Washington. Each platform handles a 4600-lb. load of 40 × 60-in. sheets, the equivalent of four cases as formerly packed. Lift

[2] Chief Engineer, Lewis-Shepard Co., Boston, Mass. Assoc-Mem. A.S.M.E.

trucks place 12 to 14 platform loads in each box car, and they are removed in the same manner at destination. The empty platforms are returned to the mill in carload lots at a low freight cost.

Briefly, the following results have been obtained: A saving of four packing cases at \$2.50 per case for each platform load of paper; loading time cut to one-sixth as 12 platforms are placed in the car in $1^1/_2$ hours with hand-lift trucks; unloading time decreased from 22 man-hours to 6 man-hours; the unpacking of cases eliminated as the paper is used directly from the platforms after removing the clamping tops; spoilage materially reduced, as when the paper was in cases, the five or six lower sheets were badly creased and could not be used.

It is estimated that the \$30,000 worth of platforms paid for themselves in the first nine months. The use of returnable platforms is advantageous where a mill is serving a large user with a standard-size sheet. A cheaper, non-returnable type is used in shipping to smaller users and jobbers, with a like saving in cost over boxing.

In the handling of L.C.L. freight at the new Monon freight house at Indianapolis the use of hand-lift trucks and platforms cut the handling cost from 73 cents per ton to 48 cents. Approximately 250 tons per day is handled through this house on 500 platforms and 16 hand-lift trucks.

Another advantage was in the orderliness of the freight house and the ease of dispatching goods to different cars. Incoming goods for various destinations are placed on separate platforms and are moved into the cars in loads of from 1500 to 3000 lb. Shipments received as late as 4 o'clock in the afternoon are on their way by 5:30 p.m.

The use of materials-handling machines in loading the present railroad equipment to capacity is also resulting in large savings.

An automobile-body manufacturer in the East in shipping to Detroit was loading five bodies on a box-car floor. By using portable elevators in connection with a special lifting dolly and special decking frames the number of bodies per car was increased to 10, which halved the freight per body to destination. The saving amounted to about \$4000 a day after allowing for extra labor and the cost of the special equipment used in double-decking the bodies and return freight on decking frames.

Charles H. Bigelow.[3] In handling the accessories for automobiles we have gone into this matter of containers extensively. In one plant in shipping forgings we first tried loading them in the car, then later we used containers that could be handled by a lift truck. These containers could be built up in tiers by putting on extensions and bolting them down. We are now shipping the materials in these containers by loading them into the car with lift trucks, and then they are taken out at the other end and emptied, and the containers are brought back. In other cases we are shipping the parts packed in the car without containers or boxing, by crating right in the car. They are unloaded at the automobile factories and practically go right on to the conveying line. This handling with containers has made a big saving. We have tried different plans of making up crates for these accessories, but some of the crates are not so successful. The corrugated-iron box has worked out very well as a conveyor.

In connection with lift trucks we use both electric and gasoline trucks. The electric lift trucks have advantages on a smooth floor, but if they get into snow in the yard there will be trouble. Gasoline lift trucks are now on the market that will work better on a rough surface and will do harder work and stand more abuse.

[3] Plant Engineer, Spicer Mfg. Co., South Plainfield, N. J. Mem. A.S.M.E.

George E. Hagemann.[4] A question came up about the cost of electric-truck operation and the chance for the public utility to sell power for charging the batteries to businesses using electric trucks. At the 1927 A.S.M.E. annual meeting in New York a paper[5] was presented giving in considerable detail the costs of operating electric trucks. This paper was by C. B. Crockett and H. J. Payne, who are connected with the Society for Electrical Development, Inc., an association which has contact with practically all electric manufacturers in the country, and consequently has access to reliable data.

The question of freight handling is not altogether a railroad proposition, but is taking on more distinctly a manufacturing aspect. In the old days the railroad was considered as an unfriendly outside organization, one which occasionally smashed things, delayed merchandise, and sent shipments to the wrong places. This has all been changed. The railroads are giving efficient service. They have cooperatively worked with manufacturers to the extent that now the railroad is, in effect, an adjunct of the manufacturing plant, a huge storeroom of incoming supplies that spreads all over the country and happens to be on wheels. As such, it fits into the comprehensive industrial plan of reducing handling costs.

After all, when we talk about materials handling we should consider that as much of the handling part as possible should be lopped off. The whole object of the A.S.M.E. Materials Handling Division is not to develop ways and means of more handling, but of less handling; that is, when something gets on the move, keep it on the move, and do not handle it any more than is positively necessary. "Handling," from its derivation, implies handwork somewhere down the line, and we want to get away from that as much as possible.

We can profitably study what many outstanding manufacturing companies of this country are doing today to reduce manual labor in their plants and get rid of most of the transfer-and-stop procedure between processing operations. Instead of taking a part or material up at one place, moving it a few feet, and setting it down, then somebody else picking it up, doing something on it, moving it a few feet, and so on, and having, say, a hundred men on the payroll engaged in nothing but moving material around, plants have transferred these men to productive work and have installed equipment which will move the product automatically. Not only that, but often the equipment is of a type which permits the man to work on the material or part while it is moving. In some cases the man moves along with the work, such as for instance on foundry conveyors, where he steps on the conveyor and pours castings while the conveyor is on the move.

These developments in keeping materials in motion have gone beyond the industrial plant and now extend to the shipping field. The railroad is today considered by many large corporations really as part of their storeroom facilities. A company ordering materials may place a commitment to cover a long period, but will specify when and how the shipments are to be made. In order not to have large shipments coming in all at one time, they may route the materials over as many as three or four different lines, to space their arrival over one or more days' intervals. I believe the freight rate is about the same. The intervals of a day or more between the time of arrival of shipments at the plant are planned so that the bulk of the materials may be taken directly to the point of use in the factory. The Goodyear Tire and Rubber Company, the Nordyke-Marmon Company, the Ford Motor Company, and many other plants formerly carried large

[4] Managing Editor, *Manufacturing Industries*, New York, N. Y. Mem. A.S.M.E.

stocks in their storerooms. Now, instead of jamming the storerooms with materials that would lie there a long time, then taking them out and sending them to the different manufacturing departments, these companies schedule the arrival of materials so that they can be taken directly to the point where manufacturing starts, thus eliminating one handling. Within a few days these materials are probably out of the plant in the form of finished products.

Materials handling must be looked on as a part of the flow-of-work program. Walter R. Clark, works manager of the Bridgeport Brass Company, says he thinks the time has come to take materials handling out of the overhead column in factory accounts and put it in the production column, because where a man is moving material from one place to another, or where equipment is moving it, while no actual processing operation may be done, nevertheless one cannot separate the transfer of the material from the work of production. The men who are moving the material, or the equipment which is moving it, are vital adjuncts to production line.

How does this bigger conception of material handling affect the railroads? They are asked to transport material which a manufacturer receives from his supplier and which is considered practically in the plant when it is started from the shipper. Hence efficient service from the railroads enables the manufacturer to cut his inventories. It is claimed by the Ford Company, for instance, that they have just about a week's supply of material on hand. If the railroads delay shipments, however, such companies are "out of luck." Many companies are adopting this same plan, considering that when material leaves the shipper's plant it is practically within the control of the receiver, the railroad acting as an outside agent for the receiver. This plan makes the railroad, in effect, a moving storehouse and a part of the flow-of-work line in the manufacturing plant. That is why it is so important to have the railroads cooperate with manufacturing plants so that there is no tie-up of materials in transit.

When we tie this program in with motor-truck delivery of freight where plants have no railroad sidings, we have a chance to introduce further improvements. Instead of having material land at the railroad yard and sending a truck for it during the day, with all the delays incident to street traffic, if the motor truck, run either by the railroad or by some private agency, could get that material at midnight and leave it at the door of the plant in care of the watchman or a night crew, a most perplexing street-traffic problem would be solved. The plan would also help solve an important shipping problem.

In other words, we are getting down to the plan of having a thin but continual flow of materials through manufacturing operations at all times, and the railroad is almost as much a part of this program in the manufacturing plant today as the materials-handling service within the plant itself. The motor truck is likewise a part of the program, bringing in materials to keep the production lines fed in plants without railroad sidings. We all know what happens to schedules in any plant if the production line stops even for a few minutes.

Hence we must look at materials handling as a cycle extending from the time the shipper puts goods on railroad cars, or is ready to put them on, until that material arrives at the plant of the receiver, is put through his processes, and is ready to go to the consumer. It is therefore vitally important for the manufacturing plants and the railroads to get together and work out a comprehensive program of rapid, uninterrupted transportation service, because such a plan means lower costs, better production, and more successful meeting of domestic and foreign competition.

A. L. Struven.[6] We are interested in shipping via rail and lake, and we are working on the design of steamships to handle unit containers. We expect to handle take-off cars at our terminals at the Great Lakes and place in ship without any stevedoring cost; and I hope within another year we shall have some of these ships on the lakes.

### Author's Closure

Answering the inquiry of M. D. Lees,[7] the unloading of containers can be done in either of two ways. At present it is by lift cranes. The Eastman Kodak Co. at Rochester is perhaps one of the largest users of containers. They are taken to the place of business on a truck and either left on the truck while being loaded or taken off as desired. The Eastman Kodak Co. has a contract with a truckman who takes the containers to a crane at the railroad, where the lifting from the truck to the cars is done at no expense to the shipper. When the car gets to the other end of the line, the containers are lifted by a railroad crane and placed on a truck and taken either to a steamship line or to the place where the local delivery is to be made.

Another method by which a new form of car, still in the experimental stage, will be used, will make it possible to take the containers off the car without a crane but by a lift truck. Up to the present most of the loading and unloading has been to and from the truck, as the usual place of business, such as an office building or loft, is not adapted to receiving such a large container. At a factory having a platform the container is unloaded on to the platform.

Charles Schroeder[8] has asked how the containers would be removed from this freight car—by a lift truck, or by the truck running on the deck of a freight car. The lift truck is run under the container while on the car. Elevating the lift truck raises the container, which is then backed off the platform and put on to a specially devised truck. It is taken to the place of business on the truck and removed from it by means of another lift truck. The sunken rail is not used because the container is on feet.

In answer to a question as to the method of holding containers on the trucks, there are several methods. In trucking containers around New York City streets, they are sometimes held by cables which hook into eyes on the side of the containers. There is also a truck which has a hook on the side of the platform to engage the bottom of the container. A third plan is to have no fastening at all, and in places other than New York the containers are never fastened. The weight of the container load, between 5 and 6 tons, is sufficient to hold it on. An assembly of a tractor and trailer, the latter with a body holding three containers, has also been devised.

Answering James A. Jackson[9] as to the saving in cost effected by containers and other types of handling equipment, figures are available which give the experience of the shipper and the railroad.

S. J. Kirsch[10] inquires about the materials used for containers. The International Motor Company is using a container made of a light metal, but this is only for handling materials between the plant in Plainfield and another plant in New Brunswick. It is a lift-truck body which can be pushed off the chassis at the terminals. It is not used at all in railroad practice, nor can it be. Incidentally it is an adaptation of the so-called L.C.L. container mentioned in the paper for use on a truck.

A container made of duralumin could not be used profitably in railroad service owing to the expense and to the doubt as to its durability. One is being tested in service, but it is not stiff enough to support the weight. There is also one of aluminum, but so far the experience of seven years points to a steel container with a special laminated-wood floor.

C. L. Freeman[11] asks if electric lift trucks could be used in place of hand lift trucks. With containers it is planned to use electric lift trucks exclusively. Hand lift trucks will not do.

Answering George W. Kelsey[12] in reference to ownership, all the containers are owned by the railroad companies. The shippers own no part of them. In other words, a low-side gondola car with a battery of six merchandise containers or twelve bulk containers is considered a piece of railroad equipment. There is no expense to the shipper for the use of the containers.

In reply to Monberg Nelsen,[13] the method of loading and unloading containers on or off a car is by a lift crane, where the volume is such as to make it more economical, or, as is now being worked out, by the use of an electric lift truck. In handling brick, the unit cost of crane operation with two cranes handling over 290 containers a day, including the cost of the two cranes and the track work, with amortization on a ten-year basis, and a crane operator, is about 19 cents per container. Amortization on a ten-year basis is probably much too low as the cranes will last much longer, and it is believed that the containers will also. No experience with the containers is available as a guide because they have been in use only six or seven years. The original containers, with one exception, are all in service, so that it is reasonably certain that their life will be ten years at least.

Cartons are packed into containers just as any package would be packed in a freight car, but with the exception that it is not necessary to use the kind of package required in a freight car. For instance, for a manufacturer in Rochester who makes carbon paper, a shipment of 8000 lb. of carbon paper, when put in shape to ship in a box car, makes 9200 lb. of freight, the added 1200 lb. being the boxes. The boxes cost $1.50 apiece, and there are eight of them. This manufacturer now packs the carbon paper in brown paper and saves the cost of the boxes and also saves the freight on the boxes.

The brick containers, or any bulk containers, such as those for crushed stone, sand, or any material that can be emptied through the bottom of the container, obviously would not have feet, as it is necessary for a crane to lift them in order to open and close the unloading device. The merchandise containers have feet and can be used either with a lift truck or a crane, whichever is more desirable.

John A. Grove[14] asks if it is possible to make a container for sand so tight that it will handle clay or any very fine material. Bulk lime, which is probably as fine a material as any, is now being handled. It goes almost to a fine dust and is handled with an absolutely watertight bottom and top, so that there is no sifting at all. Although clay is at present put in bags to keep it from sifting out, an experimental container is under way. Fine sand is shipped in it. The lime container will handle clay because it is absolutely watertight. As to the use of containers now being sufficiently general to specify receipts of clay by means of containers, this depends upon the location of the plant and the shipping point. Mr. Grove is shipping from Georgia, and there are no containers in Georgia at present. There is no reason why these containers should not be used in Georgia. A manufacturer inquired recently about shipping gum, pitch, or tar in Georgia. We have devised an absolutely leakproof container in which he is going to ship this semi-fluid product, and in which he will reship it after refining.

It was brought out in the discussion that Montgomery Ward & Co. put their L.C.L. freight in cars for different transfer points, loading about six cars a day. It has been asked if it is possible for them to separate the contents of a car into different containers for the different railroads. Ultimately it is expected that this will be done. It is expected that companies making large shipments can load a container, making it a unit, and on one car put containers for six different destinations. These are to be taken to a transfer point for containers, and there transferred. Instead of subjecting the railroads to an L.C.L. expense of 62 cents a ton average, there would be a cost of 4 cents a ton for transferring the containers. In other words, the railroads will save the difference, and the shipper will get the benefit of a straight shipment in a container as in straight cars, and the use of less expensive packages than are required today for protection under the official classification requirements of container shipping. The container method of shipping is doing away with official classification requirements of every nature and description.

Executive Committee: L. C. Morrow, *Chairman*, Carlos de Zafra, *Secretary*, W. F. Dixon, J. H. Connolly, J. W. Hook, and W. W. Tangeman

ECONOMIC factors call forth the development of methods and equipment in any industry. It is equally true that pronounced advancement in production methods and equipment design affects economic trend. It is difficult to separate the two—to say where one leaves off and the other begins. Consider that important influence upon machine-shop practice during the past eighteen months—the almost universal recognition that successful competition depends quite as much upon the use of modern equipment as upon good management. Whether such recognition has done more to stimulate design than the new products of an inspired industry have done to obtain the recognition is a moot question, and for that matter is relatively unimportant. It is enough that the recognition does exist and that the metal-working industries have the advantage of lower production costs for the user, and increased equipment markets for the builder, of modern machine-shop equipment. It is significant that sales have been few among those equipment builders who have not modernized their product from the design point of view.

### Economic Factors Influencing the Metal-Working Industries

Similarly, there is a cooperative effect of the requirements of the equipment user and the inventive ability of the equipment builder that is revealed in more productive machines and tools with consequent mutual benefit in a business way. This condition is especially marked in connection with the automotive industry, wherein the search for ever lower production costs is a result of keen competition and the necessity for extremely large markets. It is not confined to the automobile builder, however, but extends firmly into any metal-working plant devoted to products made on mass production, and to a lesser extent into even the small-quantity, jobbing, and repair shops.

Because of the large markets required for our metal products it is advantageous that Europe is progressing toward economic stability. There have been worth-while improvements in business from England and Germany, and considerable improvement from France. Czechoslovakia remains a very good market, considering its size. South American consumption has increased. These statements apply to metal-working equipment and to automobiles.

Foreign markets are worth emphasis at this time because of the recession in the machine-shop-equipment business domestically during 1927—a recession not serious, but noticeable, and one that served to emphasize the over-capacity of the equipment shops, which has resulted in the extension of the lines of individual builders, thus multiplying the points of competition. To offset such expansion there have been few consolidations.

Other general factors affecting the metal-working industries are hand-to-mouth buying, increased commissions to dealers in some divisions of the industry, the requirement for sales engineers who are skilled in processing, the necessity for more accurate cost-accounting methods, and progress in standardization.

Hand-to-mouth buying has reduced inventories in some quarters and increased them in others. It has benefited the equipment builder in that respect, but has, at the same time, placed the premium of getting the business upon the ability to make prompt delivery. Thus the manufacturer with few lines and still fewer variations has had an advantage.

Increased commissions to dealers have raised the cost of sales, but have also spurred the dealers to increased efforts. Moreover, since not all of the increased cost could be passed to the consumer, on account of keen competition, the equipment builder has found it to his advantage to look to his own production methods and shop equipment.

The demand for sales engineers who are skilled in processing is a natural outcome of the search for better methods compelled upon the part of the user by competition.

More accurate cost-accounting methods must necessarily accompany campaigns directed at the lowering of costs. Despite the fact that in principle, modern equipment has decided advantages over equipment several years old, there are cost-accounting problems that must be solved to the satisfaction of the guardian of the purse strings. For example, how much shall be allowed for depreciation and how much for replacement in view of the evident shorter economic life and increase in cost of equipment of advanced design, greater productive capacity, and better quality? This matter of cost accounting has assumed such large proportions that equipment builders are actually undertaking to educate equipment users in its fundamentals.

Standardization, not alone in metal products but in entirely disconnected lines, has influenced machine-shop practice. We are in an era of standardization and simplification that is reflected in all products. It is bound to have—and has had—an appreciable influence upon methods and equipment. The progress in the field dominated by the machine shop has had some notable examples of successful standardization. Akin to this movement and to the process of simplification is the elimination of waste, the outstanding results of which are already known, but which is being carried further by reductions in the cost of product by the substitution of pressed-metal and welded parts for those formerly made by more expensive methods.

### Progress as Indicated by Changes in Machine Tools

Most of the progress in machine-shop practice is indicated by the changes in machine tools. The first machine-tool exposition under the National Machine Tool Builders' Association, held in Cleveland in September, was therefore an index of such progress. The exposition was important also as further establishing a delayed buying period that had already become noticeable as a result of the expositions of the American Society for Steel Treating. The exposition of this year was the largest collection of machine tools featuring new design—and under power—ever displayed. Its influence upon the designing engineers of the builders and the production engineers of the users was most pronounced. It was a mart as well as a display. It thoroughly impressed the users of machine tools as to the extent and the solidarity of the machine-tool industry, and doubtless served to convince the machine-tool builder anew of the importance of his industry to civilization.

Progress in machine-shop practice, aside from the generalities just dealt with, can be shown best by a consideration of the details of changes in design of machine tools.

The demand of the machine user for greater strength, greater

rigidity, and constantly higher speeds of production has been met by the builder with increase in weight, strengthening of critical sections, and a substitution of sturdier materials, especially in the more universal use of heat-treated alloy steels. Though the removal of great volume of metal is not of necessity a part of modern high-production methods, the ability of a machine to do so is, in a measure, a test of its capacity to withstand the shocks of high-pressure work without lowering its standard of accuracy and precision.

Anti-friction bearings have been incorporated extensively into the design of machine tools on rotating shafts, and in some cases on spindles, particularly on the spindles of drilling and grinding machines. Even on milling machines their use is quite common. At least one lathe builder uses them regularly on the spindle, and another supplies them as optional equipment. No standard practice in the application of anti-friction bearings has appeared. Some builders use only ball bearings, others only roller bearings, still others use both. On many machines the plain bearing has practically disappeared.

### Machine Drives

It is becoming more common practice to connect the rotor shaft of the electric motor direct to the first driving shaft of the machine through some form of compensating coupling. In many of the machines having movements of adjustment in several directions a corresponding number of motors is used, each motor driving the particular unit upon which it is mounted without reference to or connection with the other parts of the machine.

The unit-drive method has led to the wider control of power traverse and power setting by push button, a control that has been developed to a point of great precision. Electric clamping, controlled by push button, also has been adopted when practicable, particularly for clamping the columns of radial drills.

In spite of the growth of the method of driving through direct connection of motor to driving shaft, the method of transmitting power by means of a short belt or some form of silent chain remains the most popular. It permits considerable latitude in the matter of speed ratios, works well upon even very short center distances, and operates without noise. A check-up of half of the machines at the machine-tool exposition showed that approximately 57 per cent were so driven. Another drive suitable for short center distances, and finding favor, is the multiple V-belt type. There are now several applications, and the indications are that its use will increase.

While the automobile-type disk friction clutch is more generally used, there exists a difference of opinion, some designers tending toward the positive clutch.

One of the greatest advances made has been in positive lubrication. In many machines all important bearings are oiled from a central reservoir by means of force-feed pumps. Both the circulating system, in which a continuous flow of oil to the bearing and back through a filter to the reservoir, and the intermittent system that supplies a drop of oil to each bearing at stated and easily regulated intervals, are used. Flood lubrication is rather generally applied to gear boxes. Pressure-gun greasing is used on many tools for isolated rubbing points. Full force-feed oiling of a whole machine has been accomplished; either a circulating or a "one shot" system is used for the purpose. An oil purifier, of the type used on automobiles, has been applied to at least one make of machine.

The hydraulic medium for transmitting power has been adopted to a surprising extent. It has been applied to the auxiliary feed and traverse movements, where it is of especial value because of its flexibility, easy control, and low liability to derangement and breakage. Particularly rapid strides have been made in applying this type of feed to drilling machines, grinders, and broaching machines, although other types, including milling machines, have been so equipped. Of the two hydraulic drives in common use, the cylinder-and-piston type is the more frequently applied, although in some of the larger machines, having long traverse movements, a hydraulic motor is connected directly to a pinion in mesh with a rack on the moving part. In this way there are no limiting factors in respect to length of movement inherent in the drive.

### Developments in Design

Other developments that apply to the machines of individual type, or to the machines of individual builders, can be described sufficiently by name only:

The actual and contemplated adoption of hardened steel ways.

The increased use of interlocking devices on control mechanisms.

The increased use of safety devices, shear pins, slip frictions and similar devices.

Changes in plâner control to secure more rapid acceleration.

Dynamic braking on voltage control.

Further trend toward automaticity.

Use of progressive assembly in building large machine tools.

Increased use of ground taps and very accurately finished chasers.

Contour planing and turning, using thin sheet templets, and with automatic electric control of the tool.

Cold-rolling of thin sheets and strips, by means of rolls of small diameter, without annealing.

### Development of Machine Tools for Use in the Automotive Industry

Development of machine tools used particularly in the automotive industry deserves special mention, because of the influence of the industry upon machine-tool design in general, and because the automobile industry furnishes the greatest single market for machine tools. The developments have not been startling, in the way of new processes of a revolutionary nature, but changes have been constant, all tending in the direction of increased production and improved quality.

In machines such as the knee-type miller, there has been adaptation of the standard machine to special uses by means of additional spindles at whatever angle or in whatever position fitted the particular job in hand. In a somewhat similar way the special drilling head, with its spindles built to handle a particular job, and that job only, is being used in place of large multiple-spindle machines in which the spindles have to be adjusted for each set-up.

For certain types of drilling there has been considerable development along the line of three- and four-way drilling machines with enough spindles to drill all the holes in a transmission case or similar unit.

Turret lathes, both hand-operated and semi-automatic, are being more widely used. They have been improved by being provided with more substantial spindles and bearings, more convenient controls, and better lubrication.

The use of the grinding method of machining continues to increase, being particularly noticeable in connection with flat work and in honing. There is a noticeable tendency toward the adoption of the rigidly mounted hone, with the object of correcting out-of-roundness and taper. The latest types of machines on which the rigid honing heads are used provide automatic collapse and expansion of the heads. Originally designed for and used in the finishing of cylinder bores, the rigid-hone head is now being applied to the finishing of smaller holes, one example being piston-pin holes less than one inch in diameter.

A late addition to the line of crankshaft machinery is a lathe

in which the shaft can be driven from the center while both ends are turned. A bearing is used between each two throws of the crankshaft.

### Advances in Grinding Practice

Outside the automotive field, as well as within, the grinding process has been making great headway. New abrasives and new types of wheels have done much in the way of production. New bonds have permitted greatly increased speeds. Grinding of machine ways is an accomplished fact. Spindles are being subjected to an extra-fine grinding operation that gives a surface comparable to the best in automotive practice; considerably longer life is expected to result. Semi-automatic and full-automatic machines that put the work in place, perform the operation, and pass the finished piece on to the next machine are coming into the grinding field. In line with the general trend, more attention has been given to securing accuracy with a minimum of the operator's attention, even within remarkably close tolerances. Centerless grinding has made great strides, both in machine design and from the point of view of increased knowledge of the possibilities by the method. Semi-automatic, multiple-spindle, cylinder grinding has been developed. Worm-grinding machines have been introduced. Segmental grinding-wheel chucks have been placed on the market.

### Processes and Machines of the Year

Certain processes and certain types of machines have come to the front during the past year.

Arc welding has been developed to the point where it is making possible the use of structural shapes and slab steel instead of cast iron and steel for motor and generator parts, for machine bases and for other products. Hydrogen-arc welding has been introduced as a practical process, and the shop equipment for its use has been developed. Welding machines as a whole have been developed, so that the process is much less dependent than formerly upon human skill, thus placing the process within the positive group, adaptable to production.

Jig-boring machines have been much improved during the year. The advances in design have been very favorably received and, in spite of prices relatively high in comparison with those of other kinds of equipment, have found a ready market. Their advent has placed many older and less accurate machines in the obsolete class.

A new method of dimensioning chamber sizes in rifle barrels and a standard method of making and checking chamber and barrel gages within 1/200 of 0.001 in. have been discovered. By the use of this method duplicate chamber plugs may be made by several gage makers, without variation among the gages of more than 1/4 of 0.0001 in. in diameter and with a variation of 0 in length.[1] It is obvious that these methods may be applied to gages for other classes of work, and may be instrumental in obtaining the extreme accuracy toward which the machinery industries are tending.

The casting of locomotive frames with cylinders integral by a middle-western manufacturer has given rise to a need for large machine tools to finish these castings. To perform the necessary machining there has been built a large milling machine to perform in one setting the operations that formerly required a large planer, a large slotter, and a cross-cutting planer. The redesign has effected a material saving in cost.

Equipment for producing accurate gears has progressed in design. The process of burnishing after cutting, and sometimes after hardening, is prominent. Additional equipment for inspecting gears also has been made available. One manufacturer has devised a machine for inspecting a gear and at the same time making a record of any inaccuracies, which can be analyzed to determine the characteristics of the gear.

Finishing of machine tools, other machines, and miscellaneous metal products is undergoing development. Finishing of machines by the spray method, usually involving the use of lacquers, has been adopted by several manufacturers. To some extent conveying equipment has entered into this process. The anodic oxidation of duralumin is one of the new finishes used on products.

The processes involved in heat treating have received marked attention during the year. Certain nomenclature has been adopted as standard. Time and temperature control has been made more exact. Steels and their treatments have been improved. Among the hardness-testing instruments introduced is one that measures the load required to cause a diamond ball to be impressed a given and constant distance into the material being tested, with provision for correction for errors due to contraction of the parts in the machine and the diamond when under strain.

Among the individual machines introduced during the year that point the way to what may be expected, are:

An "offset" milling machine, making use of a circular table on which the parts being milled surround a cutter of large diameter, the centers of the cutter spindle and the table spindle being eccentric. The object of this design is to engage a large proportion of the cutter with the work.

A push-broaching machine for broaching flat surfaces usually milled.

A turret lathe that has an ingenious hydraulic chuck-operating device actuated by the coolant pump, and using the coolant as the liquid medium.

An automatic vertical turret lathe.

### Standardization—Research

Standardization, though influential, did not progress as rapidly as it should have during the past year in the machinery industries. The outstanding accomplishment was the standardization of spindle noses and arbors of milling machines. Aside from its value as providing standards, it demonstrated what can be done in standardization work by an industry or group.

T-slot standards, adopted during the year, were heartily welcomed. Their full effect will not be felt for some time.

Other standards have been adopted, and progress has been made toward the determination of still others. Announcements from the committees and societies concerned, and by the technical press, have kept those interested informed.

Partial standardization of the principal dimensions of a.c. and d.c. motors has been accomplished in foreign countries. To some extent individual domestic manufacturers have progressed along the same line, making certain dimensions constant for a.c. and d.c. motors, but as a group the motor manufacturers have done little.

Of research work within the industry, there has not been a great deal. Progress reports issued from time to time have given information concerning the work on gears being conducted at Massachusetts Institute of Technology under the auspices of the American Gear Manufacturers' Association and The American Society of Mechanical Engineers. Studies have been in progress concerning oils and cutting tools. Study of dynamic and static balance has resulted in widening the field for balancing equipment beyond the balancing of automobile cranks and flywheels to the rotating parts of all kinds of machinery.

The activities of the Special A.S.M.E. Research Committee on Mechanical Springs during the year covered the organization of a financial cooperative group, the preparation of the bibliography for publication, and the layout of experimental work

[1] A demonstration of this method was made by E. Pugsley at Frankford Arsenal and in New York City before the Technical Committee of the S.A.A.M.I.

for the year 1927–1928. The personnel of the financial group numbers forty-five, twelve of whom are spring manufacturers and the remainder spring users. Each of these firms contributed an average of about $150 to the research fund. The committee is now starting the experimental phase of its program, several candidates for the position of Research Fellow, who will conduct the tests, having been interviewed. Copies of the bibliography will soon be available.

It is hoped that more will be accomplished by research during 1928. A committee for the purpose of instigating projects for research has been formed by the Machine Shop Practice Division. Machinery has been provided for getting the work under way after the committee has made its recommendations as to the work to be done, the laboratories available, and the personnel desired. It is expected that the value of the results to be obtained will then be so evident as to greatly assist in the collection of funds.

### The Outlook for 1928

No one can predict with certainty what will be done during 1928. We may expect, however, to see progress along several lines, among them:

Still further use of hydraulic feeds and drives, anti-friction bearings, heat-treated alloy steels, pressed-steel and welded parts, automatic lubrication, safety devices, and automatic operation.

Development and adoption of more standards—for example, standards for nomenclature, initial machine speeds, motor speeds, electric-motor mounting dimensions, machine-tool capacity and performance, belt pull, and so on.

It is likely that foreman training, already well to the front, will be a subject of both experiment and progress during the coming year. It is gratifying that the foremen themselves are realizing the importance of their positions and are making persistent efforts to better fit themselves for their work.

There is still a feeling on the part of some members of the industry that skilled mechanics are no longer being made in quantities sufficient for the good of the industry. Other members feel that the supply is keeping pace with economic law—that the transfer of skill from man to machine has made relatively few mechanics necessary. No matter which viewpoint may prove to be the better, it is essential that the industry train boys for shop positions. From the ranks of these boys there will always emerge a number of skilled mechanics, who can be at least a nucleus on which to build in case of emergency. Others of the boys will become foremen. All of which indicates that attention should be given to apprentice training. There should be devised a system that will cause each manufacturer to contribute his share of skilled workmen and foremen to the industry.

There are predictions that at some time in the future we may expect radical improvement in cutting tools, an improvement which will cause the new tools to be so much more productive than those of today that the increased production will be comparable to that resulting from the introduction of high-speed steel. Whether such improvement will appear during the next year or within the next few years, is conjectural. The advent of a material, or a process, that would have such an effect would revolutionize machine-shop practice.

The activities of the Executive Committee of the Machine Shop Practice Division for the year consisted of the holding of sessions at the Spring Meeting and Annual Meeting; holding a joint meeting with the Metropolitan Section, at Newark; holding a National Meeting at New Haven in connection with the annual machine-tool exposition; the formation of a survey committee to instigate projects for research; and the preparation of this progress report. It is hoped that the service rendered to the machinery industries by these activities has been commensurate with the effort expended by the speakers and the Executive Committee.

L. C. Morrow, *Chairman.*

# The Development of Machine Tools from a User's Viewpoint

By F. C. Spencer,[1] Chicago, Ill.

*The author bases his paper on the experiences and practices of the Hawthorne Works of the Western Electric Company, whose development organization is charged with the selection of machine tools. This organization has adopted five standards which affect the design of machine tools: namely, minimum floor-space requirement; elimination of accident hazards by properly designed guards; reduction of physical effort by convenient operating arrangements; cleanliness; and appearance. The effect of these standards on labor is next brought out and is followed by a review of the motor-drive program which has eliminated all but individually motorized machines with motors generally located in the machine base. Examples of several individually motor-driven machines are given. There then follows an account with some details of construction of the development of better and safer punch presses, and machines for drilling small holes in thin metal. The paper ends with a discussion of the possibilities of the hydraulic drive and the importance of giving special attention in the design of all new machine tools to the matter of safety, maintenance, and facility of operation.*

WITHIN recent years the development of machine tools has progressed with great rapidity, and this has been particularly true of developments tending to increase the suitability of standard machine tools for manufacturing purposes. Much of this progress has resulted directly from the economic necessities of the machine-tool user. It is the purpose of this paper to consider the question of machine-tool development as it has been influenced by the user's demands, and especially in the light of the experiences of the Western Electric Company.

The term "machine tool," which was formerly employed to designate only such machines as were used in the tool room and machine shop, is now interpreted more broadly to include many machines which are built solely for production purposes. It is with machine tools of the latter class, such as screw machines, milling machines, drill presses, and punch presses, and particularly with their development, that the user is mostly concerned.

If we look backward and consider the machine-tool equipment available from ten to twenty years ago, we shall find that the manufacturing requirements of that period were met, not so much by improvements in the design of the machine tools themselves, as by the use of clever tooling, ingenious handling methods, and special-purpose machines designed by users to meet their particular needs. Very few machine tools designed for performing specific kinds of operations were available. In fact, for several years prior to the last decade the machine-tool industry seemed to be inclined to perpetuate the designs it had been building for years, and to make only minor changes in details from time to time. Furthermore, machines were neither designed nor built for high-production service, and consequently when so used were short-lived and costly to maintain. One reason for this may be found in the fact that the machine-tool builder has never been faced with requirements large enough to warrant quantity-production methods, and there has, therefore, been little incentive for him to speed up machinery or to build machines capable of high speeds.

During the last ten years, however, many improvements have been incorporated in machine tools of practically all types. In some instances radical changes have been made, but many of the improvements have been simply adaptations of features already "proven in" by years of service in other types of equipment. For example, it is not unusual today to see featured in machine-tool advertisements such statements as "roller bearings," "ball bearings," "wick oiling," "continuous pressure oiling," "hydraulic control," and "built-in motor drive," although only a few years ago these entirely practical features, which mean so much in the matter of obtaining continuous high-speed production, were conspicuously absent.

Many new types of production machinery have been originated within the last decade, and the demand for these indicates clearly the opportunity for the development of equipment more adaptable for certain kinds of machining operations than the general-purpose machine tool. It is being appreciated that the more nearly a general-purpose machine approaches a special-purpose machine, the more efficient and the more valuable for manufacturing purposes it becomes.

During this same period many of the larger users have taken an active part in machine development, and many improvements have resulted from suggestions originating with them. This has been true to a large extent of the automotive industry. C. F. Kettering[2] has very clearly stated the attitude of the machine-tool user in that field as follows: "The economic factor forced us to improve upon the productive machinery in every conceivable manner, never hesitating to scrap even a comparatively new and expensive machine when a still newer one was developed that would speed up production, cut overhead, save human effort, give greater safety to the worker, or improve the product." Today the builder welcomes, and in fact, solicits, suggestions, a condition quite different from that which prevailed fifteen years ago. This collaboration of the user with the builder in machine development is of the utmost importance to the builder, as it must be recognized that he must produce that which the user will buy. The user controls the situation and consequently if improvements are to be made he must assume his share of the development responsibility and cost. In buying additional machinery the user often specifies the production expected, knowing from a careful analysis of the factors involved that the demand is entirely reasonable, although considerably beyond the possibilities of existing equipment. The equipment finally developed is usually capable of greater production than the output specified.

The engineering and design of machine tools is strictly a function of the builder and should remain so. Not all users employ the kind of talent necessary for this work, and those who do usually have a sufficient amount of special equipment to design to keep this talent constantly employed without attempting to alter the designs of standard machines or to develop new types. In order that satisfactory returns may be realized from the investment in machine tools, however, it is imperative

Contributed by the Machine Shop Practice Division and presented at the Annual Meeting, New York, N. Y., Dec. 5 to 8, 1927, of The American Society of Mechanical Engineers.

[2] *American Machinist*, vol. 66, p. 801, May 19, 1927.

that the user assist the builder by furnishing all the manufacturing information necessary to produce machines which his experience has taught him will more adequately meet the requirements of continuous quantity production.

## Development Organization

In the plants of the Western Electric Company a large quantity of medium-sized production machinery is needed to produce the enormous number of parts required every year for the manufacture and maintenance of the telephones and associated equipment of the Bell System. The problem of manufacturing this equipment economically depends for its solution mainly upon the machine tools selected for the job. The magnitude of the problem will be more fully appreciated if it is realized that the telephone equipment manufactured by this company consists of 13,000 different kinds of apparatus assembled from 110,000 different component parts. For several years it has been necessary to purchase or build from two to three million dollars' worth of machinery per year for the purpose of reducing manufacturing costs or for increasing capacity.

The selection of the machine tools for this job is one of the functions of the development organization at Hawthorne. This organization originated some twenty years ago when the demand for telephone equipment, although much smaller than it is today, was constantly increasing year by year. This increasing growth made it necessary to re-analyze each job frequently and to revise manufacturing layouts so that advantage might be taken of the larger requirements to make use of more productive equipment. It became evident that standard manufacturing methods were in many instances not suitable for manufacturing interchangeable parts in large quantities. A few experienced engineers, therefore, were assigned to the job of studying the problem in detail, and from this small beginning grew the present development organization, consisting of several hundred engineers whose function it is to study constantly every factor affecting the cost of production from the raw material to the finished product. About 35 engineers of this group are employed in the study of machining methods and the standardization of machine equipment, and about 85 designers are required to provide the designs for special-purpose machinery and changes in design or additions to standard machines when necessary to meet the requirements of this company.

These engineers develop all machining methods and select the standard machine tools which are required to meet the production schedule. They keep in close touch with builders of standard machines and, because of their more intimate knowledge of manufacturing conditions and requirements, have been of considerable assistance to the builders in developing machines superior to previously existing models.

The Western Electric Company has been a pioneer in this coöperative development work, and the records are replete with accomplishments. Policies governing the design and construction of machine tools of all types have been established.

## Machinery Standards

The standards adopted by this company affect the design of machines with regard to both their economic and humanitarian aspects and include the following:

1 Minimum floor-space requirement
2 Elimination of accident hazards as far as possible by properly designed guards
3 Reduction of physical effort by the provision of convenient operating arrangement
4 Cleanliness, secured by preventing machine and cutting lubricants from leaking or being thrown from the machine
5 Appearance.

To meet established standards satisfactorily, manufacturing machinery must be compact so as to occupy as little floor space as possible; it must be ruggedly designed to insure accuracy; it must be efficiently lubricated to reduce maintenance; all parts must be easily accessible, though moving parts should be enclosed or properly safeguarded to remove accident hazards; and the machines should be arranged for individual motor drives, preferably with the motor located in the base. They must conform to the latest and best practice with respect to materials, bearings, gears, and chains, and the workmanship must be of a high order. All of these requirements are incorporated in most tool-room machines, but until all production machines are built in accordance with these general specifications there will continue to be opportunity for improvement. To insure a standard of high quality the Western Electric Company finds it necessary to dismantle a large percentage of the machines bought so that they can be thoroughly inspected and replacements made or workmanship improved, if necessary, before the machines are placed in service.

## Consideration of Labor in the Design of Machine Tools

It should not be inferred that all of the standards adopted by the Western Electric Company meet the approval of all builders nor even of all users. Machine standards depend largely on the point of view, and the point of view in a manufacturing plant is a limited or a broad one, depending on the type of management. The importance of the economic factor in determining policies is well recognized. However, a management whose policies do not provide attractive as well as safe working conditions has been blind to the economic value of them.

A few years ago when this country was in the midst of great business activity and a shortage of labor was acutely felt in all localities, the company was faced with the problem of maintaining an operating force of approximately forty thousand persons. An analysis of the labor situation in the territory from which the Hawthorne Plant must draw its shop help indicated that there were approximately six hundred thousand persons in the class considered adaptable to the company's lines of manufacture. In this territory are several medium-size plants each drawing its requirements from this supply. It was estimated that the company would be obliged to select its force from about twenty per cent of the total, or one hundred and twenty thousand. Considering the various classes which it is necessary to employ, it is a difficult task to select a force of forty thousand from so small a number. The policy of selecting only the highest type of help was not relaxed, however, and each individual employed was required to pass a physical examination. During this trying period the company was able to keep a satisfactory operating force and to hold the labor turnover remarkably low. There is no question but that the unusually satisfactory operating conditions and shop environment were largely responsible for attracting and holding a high-grade class of employees. The company is convinced that environment has a great deal to do with health and contentment among employees, and consequently helps reduce the labor turnover.

The design of manufacturing equipment is influenced to a large extent by these considerations. Several years ago when the first multi-story buildings were erected at Hawthorne, the only equipment on hand and obtainable was belt driven, and the group method of driving was adopted as being the best available at that time. The belts and overhead shafting, pulleys, and motors obstructed the light, increased the hazard, and made all departments so equipped gloomy places in which to work. A typical belt-driven hand screw-machine department is shown in Fig. 1. Having provided light, airy buildings, the man-

agement was not content to have them filled with this objectionable equipment.

### Motor-Drive Program

Up to 1914 very few machine tools were available with well-designed motor drives. In that year it was decided to motorize the entire plant consisting of about forty-five hundred machines. The plan adopted involved, first, the development of individual motor drives for each type of belt-driven machine considered sufficiently modern and suitable for manufacturing purposes, and the replacement of all types of machines unsuited to such drives; and second, the policy of purchasing only motor-driven machines for additional capacity.

The motorization of the belt-driven machinery involved a great deal of expense for design and construction work but has now been completed. How well this program has succeeded is shown by reference to Fig. 2, which is a photograph of the hand

Fig. 1 Belt-Driven Screw-Machine Department

Fig. 2 Motorized Screw-Machine Department

screw-machine department referred to above after motorization. During these thirteen years progress in the machine-tool industry toward properly guarded machinery and well-designed motor drives has been slow, and consequently it has been necessary to keep several designers and a large force of mechanics on this class of work constantly to take care of the additional equipment bought to increase manufacturing capacity.

The second phase of the plan has presented the most difficult task of the motorization problem—that of persuading the builder to design and build his equipment in such a manner that it could be belt or motor driven at the option of the purchaser. In 1914, when the plan was launched, builders were not inclined to regard individual motor drives seriously, and the only arrangements offered were makeshifts. It has frequently been necessary to hold up purchases of additional equipment until a sufficient quantity could be ordered to induce the builder to furnish the design wanted. This is well illustrated by the development of the motorized milling machine.

The problem of motorizing belt-driven milling machines was

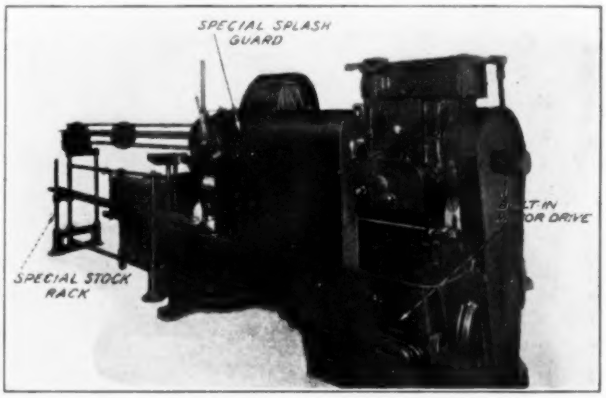

Fig. 3 Small Multiple-Spindle Screw Machine with Built-In Motor Drive

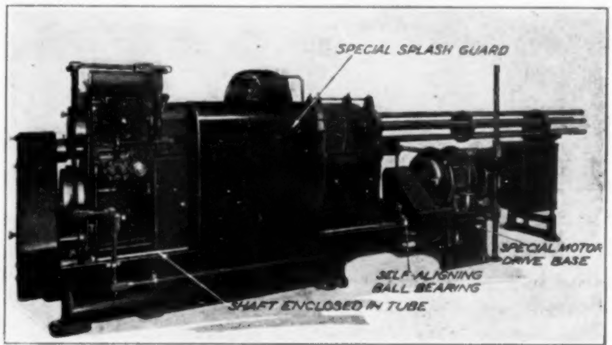

Fig. 4 Large Multiple-Spindle Screw Machine with Western Electric Co. Design of Motor Drive

attacked by locating the motors on brackets in the rear of the machines. This resulted in an increase in the floor space occupied, and indicated clearly that the future development of the milling machine would involve the incorporation of the motor in the base of the machine, totally enclosed, and properly ventilated. This idea was submitted to a few of the largest milling-machine builders, who, however, did not consider it advisable to change their line and offer it to the market in general, but expressed their willingness to build a certain minimum quantity. To do this it was necessary for the company to hold up purchases until a number of machines could be ordered sufficient to warrant the builder in changing the standard design. When these new machines with the built-in motors were finally installed the arrangement was found to be highly satisfactory, and the scheme has since been adopted by all the leading builders.

I am told that the demand for motor-driven machines of all types at the present time amounts to about 80 per cent of the total production.

### Screw-Machine Motor Drives

In addition to doing away with a forest of belts and overhead work, an endeavor has been made to limit the heights of the

machines, as it would obviously be inconsistent to go to the great trouble and expense involved in the motorization program and then to permit the machines themselves to obstruct the light.

Late-model multiple-spindle screw machines, for example, ordinarily furnished with the motor on top, are arranged with motor drives built in or on a special bracket so located that the height of the machine is not increased, and are a radical departure from standard equipment. The small machines have the drives built in the bases as shown in Fig. 3. In the case of some of the larger machines the motor is located at the stock end of the machine on a special base, Fig. 4. A chain connects the motor to the drive shaft which extends through the pan of the machine and drives the spindle at the other end by means of a second chain. The shaft is mounted on self-aligning ball bearings and is completely enclosed in a tube. With this construction not only has the height been reduced but the motor has been placed in a more accessible position, the floor load has been more evenly distributed, and the vibration appreciably reduced. Also a two-speed motor is used instead of the single-speed motor usually recommended, thus providing a wider range of speeds without changing chains or sprockets. The specifications for these machines included several other special features such as special stock reel, stock and control apparatus support, special attachments for threading in the second position, arrangement for revolving all tools at one time, and ball thrust bearings —altogether about twenty items, which, although adding to the cost of the machines, provided compact, well-arranged units which fill the operating requirements much better than the standard machines.

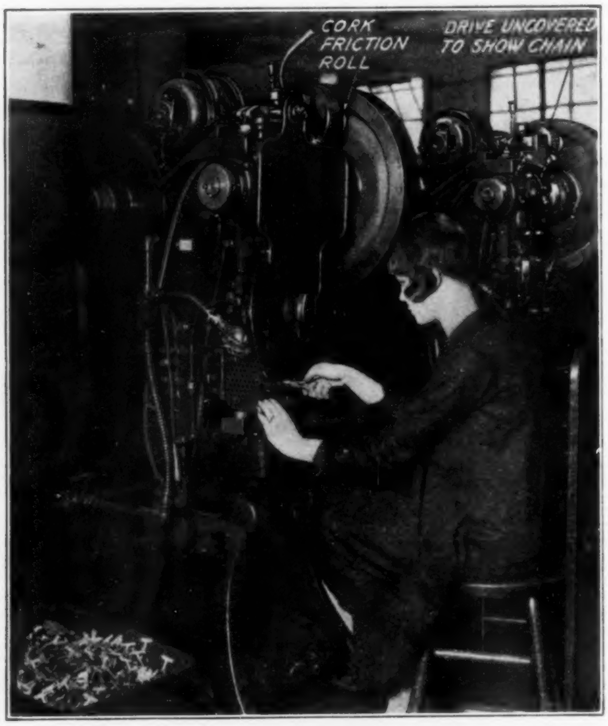

Fig. 5 Punch Press Embodying Several Western Electric Co. Design Features

One of the remaining groups of belt-driven machines which it is expected will soon be replaced consists of the one-inch and over-hand screw machines and turret lathes. A recent investigation of machines of this class reveals the fact that there is no motor-driven machine on the market with spindle speeds as high as are now being obtained on belt-driven machines. Some of those considered provide about half the speed now being used. Probably the reason for this is the difficulty of providing high speeds with geared heads. If this is the case other means should be taken by the builders to provide a range of speeds sufficient to handle economically parts such as those used in telephone apparatus.

## Punch Presses

There is probably no manufacturing machine that has undergone less change since the early designs than the punch press. Credit must be given to those who have had the vision and the courage to depart from conventional designs and to bring out low under-drive machines capable of high speeds. For blanking operations these presses are superior to gap-type presses because the ram is guided more satisfactorily and there is very little chance of misalignment of the tools. In the gap type the frame opens up slightly with each stroke of the press, and more expensive sub-press tools must be built to overcome this inherent fault. For second-operation work, however, the gap type is preferable, but in most cases the designs could be greatly improved.

In a plant using hundreds of medium-size presses and blanking and forming millions of parts per year, it is of the utmost importance, first, that these machines be safe to prevent injury, thus obviating lost time and a demoralized morale, and second, that they be constructed so that maintenance will be low in order that they may be kept constantly active. Western Electric Company punch presses are individually motor driven, having incorporated in their construction a special design of friction motor drive (Fig. 5); the bearings are bronze bushed throughout and the crankshaft bearings are split on an angle so that the upper bearings in the frame take all the upward pressure and the caps none (Fig. 6). The crankshaft is made of heat-

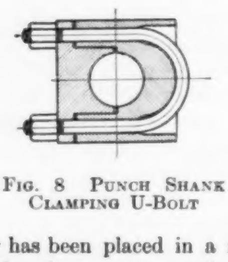

Fig. 6 Crankshaft Bearing, Punch Press

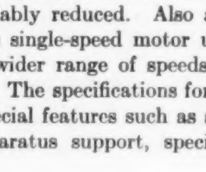

Fig. 8 Punch Shank Clamping U-Bolt

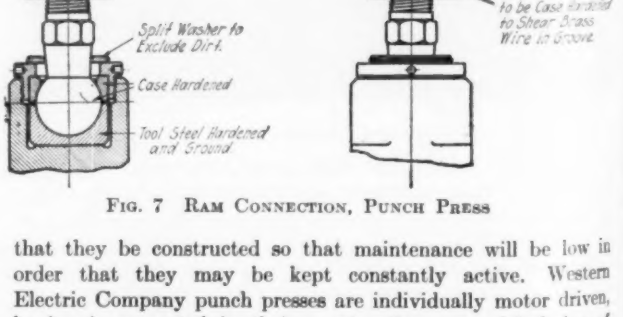

Fig. 7 Ram Connection, Punch Press

treated chrome-nickel steel as a matter of safety. The ram connection is provided with a shearing ring to protect the press from overload and the arrangement is such as to permit easy replacement of the ring whenever necessary. (Fig. 7.) A U-bolt is used for clamping the cap against the punch shank, as shown in Fig. 8. U-bolts are used here because they are easier to replace in case of breakage than the usual studs. The clutch is of the rocking-key type. The flywheel, which is mounted on ball bearings, is provided with several key-locking grooves to effect a minimum of clutching time. (Fig. 9.)

It is common knowledge that the punch press is one of the most difficult machines to guard efficiently without reducing output. These presses are completely guarded, including a balanced swinging gate operated by the foot treadle in such a manner that it is in place in front of the die space before the clutch is tripped (Fig. 5), and side gates to prevent the operator from reaching around the front guard. These are so arranged that when swung open the clutch rod is locked and the press cannot be operated.

The flywheels are webbed so that there is no chance of anything getting caught in them as is possible when spokes are used. Also the webbed wheels eliminate the usual flicker of light due to the rotation of a large number of spoked wheels. This has reduced fatigue and helped eliminate accidents. Punch-press accidents at Hawthorne are extremely low; in fact, the hazard has been practically eliminated.

To secure clean operating conditions a great deal of attention

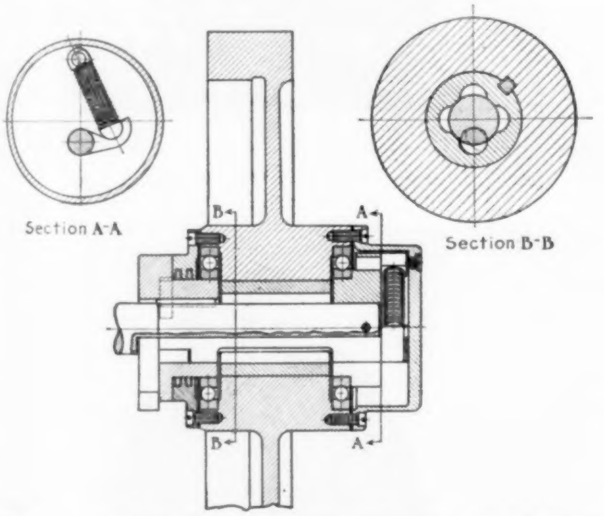

FIG. 9 SECTION THROUGH FLYWHEEL AND CLUTCH, PUNCH PRESS

has been given to preventing oil from leaking out of machines or being thrown off by revolving or reciprocating parts. Wipers and shields are required to obviate this. Punch presses, for example, are provided with shields (Fig. 5) to prevent oil from the crankshaft from being thrown on the operator.

### DRILLING MACHINES

Many well-designed high-production semi-automatic drilling machines are available for automobile parts and larger, but equipment for drilling small holes through comparatively thin material has undergone but little change in many years. The only important improvement that has been made is the increase in the spindle speed by the adoption of ball bearings. The aim seems to have been to provide machines for small work with relatively high drilling speeds with the idea of securing more nearly the same cutting speeds obtained with larger tools, though so far as the reduction in the cost of drilling small holes is concerned, this has never been an important factor. It could be shown very readily that the amount of time saved due to the higher drilling speeds is a very small percentage of the amount of time required for the complete operation of loading

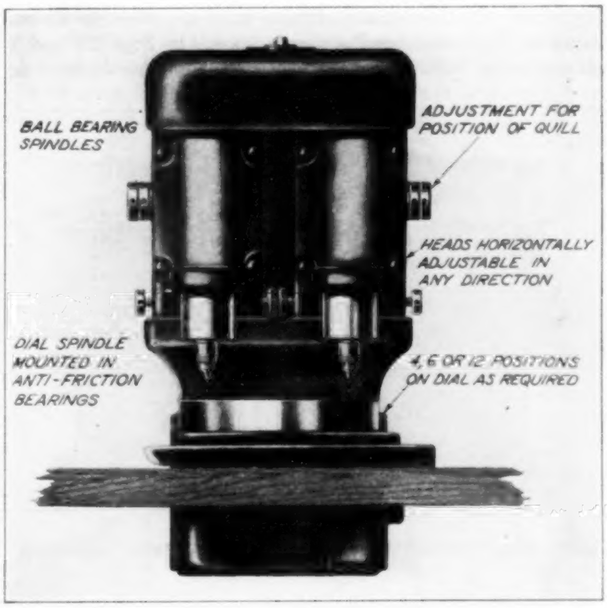

FIG. 10 TWO-SPINDLE AUTOMATIC DRILLING MACHINE, BENCH TYPE, DIAL FEED, FRONT VIEW

FIG. 11 TWO-SPINDLE AUTOMATIC DRILLING MACHINE, BENCH TYPE, DIAL FEED, SIDE VIEW

a jig, drilling, and unloading. It is true that automatic feeds have been developed, the principal advantages of which have been to reduce fatigue. They are a step in the right direction, however.

In the drilling of small holes at, say, 8000 r.p.m. through thin stock it often happens that, due to the nature of the work re-

quiring the loading and unloading of jigs and other handling, the drills are cutting metal only a small portion of the time; in fact, on some jobs less than ten per cent. So far as the author is aware, there is on the market no general-purpose machine suitable for small work in which the attempt has been made to cut down appreciably the time lost due to handling. For this reason the development engineers of the Western Electric Company have suggested a design shown in Figs. 10 and 11 which can be built with one or more spindles as desired, and

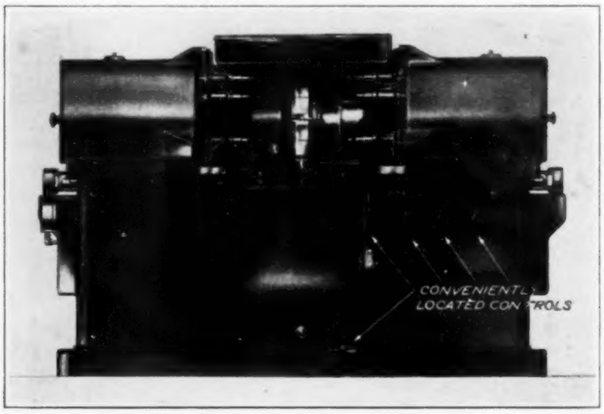

Fig. 12 Horizontal Duplex Semi-Automatic Drilling Machine, Front View

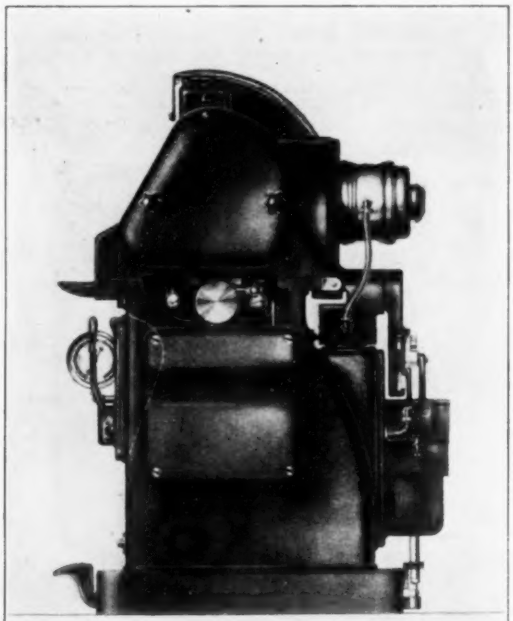

Fig. 13 Horizontal Duplex Semi-Automatic Drilling Machine, End View

which is provided with a dial for carrying the work to the drilling position by an intermittent motion, the drills being fed to the work by means of cams. The design shown in the illustration is that of a bench-type machine which is being developed at the present time. The driving and operating mechanism is entirely enclosed and adjustments are provided so that changes in speeds and feeds and the time of a drilling cycle may be varied as required. With this machine the operator will not be obliged to

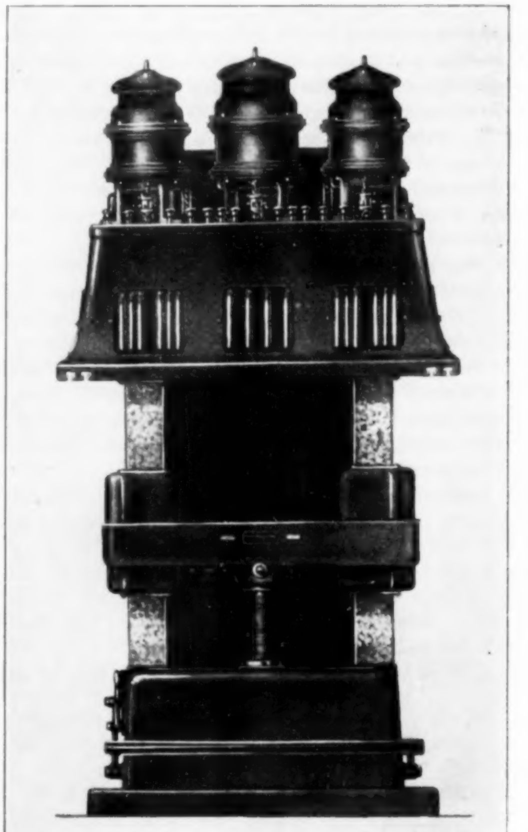

Fig. 14 Multiple-Spindle Drill, Front View

Fig. 15 Multiple-Spindle Drill, Side View

handle the jigs nor hand-feed the drilling spindle; her hands will be free for the sole purpose of loading and unloading. Even this labor may be eliminated on large production jobs by the use of automatic feeding and ejecting devices.

Another type of drilling machine which is being developed is shown in Figs. 12 and 13. This is a double-opposed machine with two heads, each carrying several spindles, which can be fed to the work from opposite sides. The work is held in a turret mounted on a horizontal axis in the center of the machine. The turret is hexagonal, each side of the hexagon carrying a fixture, and rotates intermittently, locating each fixture successively in line with the drill spindles in the opposite heads. The drilling heads are moved to and from the work hydraulically, arranged with rapid approach and correct drilling speed and quick return. It is expected that this machine can be used for drilling, burring, and tapping, and also for multiple drilling when required, simply by providing multiple drilling heads to be driven by the various machine spindles. The operator will sit in front of the machine and control it by means of a foot treadle. As long as the treadle is depressed the machine will continue to function, but as soon as the foot is removed from the treadle the machine will stop. The operator's task will be simply to load and unload the fixtures as they successively reach the position in front of her.

These drilling machines are shown, not because of their novelty, but principally to indicate the needs of a large manufacturer of small interchangeable parts in this machine-tool field.

A recent investigation of the available multiple-spindle vertical drilling machines with power feed, suitable for use on metal or wood, resulted in a decision that it would be necessary to design a machine in order that the desired operating conditions and maximum output might be obtained. Figs. 14 and 15 show the front and side elevation of this machine. Thirty-two spindles are provided, driven in groups by three vertical ball-bearing motors. The travel of the head to and from the work is accomplished hydraulically.

It is proposed to use cluster boxes having all spindles properly located for the job in hand so that the time of changing from one job to another will be a matter of a comparatively few minutes. For wood, higher-powered motors will be used as the drill spindles will rotate at speeds up to 8000 r.p.m. and the motors will be more heavily loaded. For this class of work it is highly important that no oil shall leak from the drilling-spindle bearings on to the wood parts. The ball-bearing spindles in the cluster boxes, therefore, will be provided with special oil retainers.

No user would prefer to design and build his own machine tools, and the Western Electric Company is no exception. The time spent on such work could be used to advantage on special-purpose machinery of which a large amount is required. It is found necessary to do so, however, on account of the relatively small number of different types of standard production machines available in the sizes used in the telephone-manufacturing business.

### Cost of Installation and Guards

The purchase price of machinery is never the entire cost. Often the cost of installation, including guards and electrical equipment, amounts to several hundred dollars. Much of this could be saved if the machine builder would build into his machines fuse boxes, switches, light brackets, and the necessary conduits, and would provide adequate and well-designed guards. This matter has been given more attention of recent years, but it is still found necessary to buy many machines on which these important features have not been provided.

Fig. 16 illustrates the electrical equipment and guards which had to be provided for a machine recently bought. In this case the additional equipment cost about ten per cent of the purchase price.

### Possibilities for Future Development

It is claimed that hydraulic feeds make possible higher cutting speeds and longer tool life; but whether or not this is true, there are advantages sufficient to justify the adoption of the hydraulic method of operation wherever possible. In the first place, the use of the hydraulic means for controlling, timing, and transmitting motion does away with the necessity of gears, cams, or screws, and the bearings and shafts on which they are mounted; consequently the maintenance by comparison would be extremely low. Another advantage is the exceptional flexibility of the system, it being possible to obtain very easily any speeds in either direction, or any variation in speed in either direction.

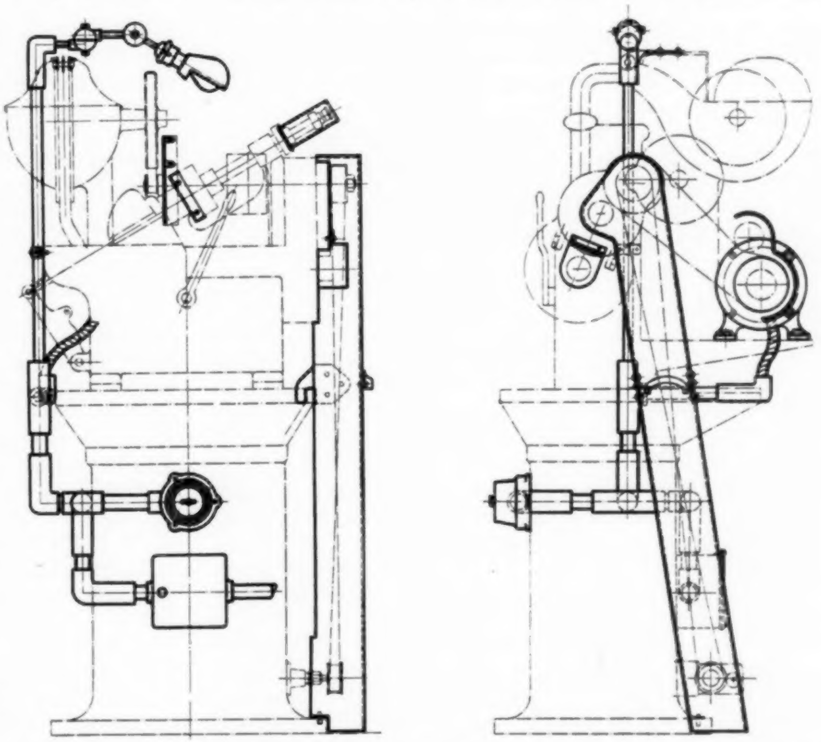

Fig. 16 Standard Machine with Electrical Equipment and Guards Installed by User

The advantage of the hydraulic system in the operation of punch presses would seem to be obvious; the length of stroke could be varied readily from a very short one, such as might be used in the high-speed blanking of small parts using an automatic feed, to a long stroke for forming or drawing operations. The speed of reciprocation could probably be as high as that usually obtainable with the crank style of press.

For small screw-machine work it would seem to be entirely practicable to design a vertical screw-machine unit which could be mounted singly or in multiple on a suitable frame and which

would take up much less space than the usual type. A unit of this type could be designed which would have a larger output than the present types of machines. There are some German and Swiss screw machines of small sizes on the market, but there is no machine built in the United States suitable for high production smaller than a No. 00 B. & S. automatic, which, including the stock rack, occupies about twenty square feet of floor space. This should be sufficient for about six units built vertically.

Furthermore, an attempt should be made to design screw machines capable of finishing each part completely instead of requiring additional work to be performed on them as is now necessary on a large percentage of screw-machine products.

### Conclusion

In conclusion, the author would like to emphasize the importance of giving special attention in the design of all new machine tools to the matter of maintenance, facility of operation and safety; and he would also emphasize the need of more semi-automatic production machinery.

*Maintenance.* By the use of anti-friction bearings and centralized oiling systems it is possible to increase speeds and to reduce the wear and tear on machinery to a point where the saving in the cost of production and by the elimination of losses incident to shutdowns for repairs will more than pay for these features.

A further means of reducing maintenance would be the reduction in the amount of mechanism by a liberal use of motors and by hydraulic operation, both reciprocatory and rotary.

*Facility of Operation.* A machine that is designed and constructed in such a manner that it is difficult to operate is no credit to the designer. There is little excuse for a machine of this kind. It is an indication of incomplete planning. Controls should require the minimum of physical effort, and the work of handling the product to and from the machine should be so easy as to result in as little fatigue as possible, even though these movements be repeated many times during the working day.

*Safety.* So much has been written on the guarding of machinery that the omission of guards by a builder would seem to indicate a disregard for the safety of the worker. It is probably due, however, to his hesitancy to increase the price of his machine sufficiently to cover the cost of the guards. The user should expect to pay for guards and should insist upon their being well constructed. It costs considerably less to have them built with the machine than to design and build them afterward.

*Semi-Automatic Production Machinery.* We would do well to encourage the design of more semi-automatic machinery for specific operations. There is an almost unlimited opportunity for the development engineer and the machine-tool designer in this production-machinery field, especially in the design of machines for the manufacture of small parts. Accomplishment in developments of this kind will be expedited if the machine-tool builder and the user will work more closely together, each assuming his share of the responsibility. This cooperative effort will result in benefit to both to a maximum degree.

## Discussion

L. D. Spence.[3] The work necessary for the manufacturing development department of the Western Electric Company at Hawthorne Station to perform in maintaining the machinery standards set forth by them, because of the nature of their work, places them in a position to view the machine-tool builders' products from a somewhat different angle from that of the average machine-tool user. The large production of small duplicate parts necessary in the manufacture of telephones and other electrical equipment enables certain features to be applied to machine tools that would assist in increasing the production of this class of work, and very often entirely special equipment is necessary to produce the maximum production possible for the operations to be performed.

Probably no class of manufacturers appreciates more fully than the machine-tool builders the call to cooperate fully with manufacturers who are engaged in mass production. In mass production there are, of course, some general lines of work that a machine could be designed to carry out, and such a machine would fit a large range of this work. In some respects it might not get the highest production for the specific job in hand; and the problem resolves itself into making a special machine, or into adapting the standard machine.

The past fifteen or twenty years have shown a cooperation between mass-production manufacturers and machine-tool builders that has brought forth wonderful results; and it is the writer's belief that as time goes on this cooperation will be strengthened, as each party to the arrangement will be urged on by this cooperative demand. More and more the manufacturer of standard machines realizes the necessities as just mentioned, and in order to fill more fully the requirements, efforts are constantly being made to build a standard or base machine to which attachments can be fitted that will fully meet the needs of the customers engaged in the various classes of work.

When the highest production is desired for the operation of a certain class of work, careful thought must be given to the loading and handling time. This time is often referred to as idle time. The machine-tool manufacturer has, during the last few years, given much thought to this in the design of machine tools, and at present we have the automatic milling machine, high-speed automatic screw machine, high-speed presses, and other machines suitable for more rapid production of interchangeable parts.

The machine-tool builder must, however, design his products so as to meet the requirements of various classes of work within the capacity of the machine. If machine tools are not carefully designed along this line, their use may be limited to firms which have only that class of work for which the machine is best adapted.

That portion of the paper referring to the progress made by the development department in connection with individual motor drive is very interesting. After a visit to a department of the Western Electric Company equipped with motor-driven machines, it is readily appreciated that the department is better arranged as far as light and working conditions are concerned, aside from the question of saving in maintenance cost of the overhead works and belting. Yet some classes of machine tools arranged in this manner are often more expensive than those designed for countershaft drive; and, as many machine-tool users are not ready to consider the individual motor drive, it makes it necessary for machine-tool manufacturers to build both types.

When reviewing the work performed by firms engaged in the manufacture of small parts in large-quantity production, it will be found that many special machines are used—machines designed for the operations necessary, such as drilling, etc. However, before the machine-tool builder can design new machinery to meet the requirements of this class of work efficiently, the extent of the field must be investigated in order to determine the extent of the usefulness of a machine of the design required.

Many special drilling, milling, tapping, and other machines have been designed by various machine-tool manufacturers; and, while they are very efficient on the class of work to be performed, their sales have been small as they cannot take care of the range or variety of work requiring the same operations.

A semi-automatic drilling machine having five horizontal spindles, each controlled by a cam, is efficient when producing work

[3] Brown & Sharpe Mfg. Co., Providence, R. I.

within its capacity. It is equipped with five drilling stations and its camshaft is so timed as to permit theun loading and reloading of one station while the remaining four spindles are drilling. A machine of the type referred to is suitable for the drilling of small parts of a shape that can be held in the holding fixtures.

Semi-automatic drilling and tapping machines having vertical spindles are also used to some degree. These machines have an automatic arrangement for indexing the circular table and, provided the shape of the work permits, a magazine can be arranged, thereby making the machine fully automatic.

Machine tools for other machine operations have been designed and offered to the user, and no doubt there is need for more high-production machine tools for this smaller work.

It would seem difficult for the machine-tool manufacturer to meet the requirements of the special equipment found necessary in the manufacture of watches and clocks and other lines in view of the efficiency of the special equipment now in use by firms performing this class of work.

The writer has in mind one firm engaged in the manufacture of a small article which required several milling and swaging operations. Because of the enormous quantities manufactured, special milling machines were designed and equipped with magazine loading and ejecting mechanisms. Seventy-six of these machines were used for four milling operations and required the attention of but four operators and two helpers.

The swaging machines were of standard design and each was equipped with a magazine. Thirty-two of these machines were operated by two operators and one helper. The average machine-tool user having work requiring swaging operations may not have a sufficient quantity of any one part to consider the feature of magazining blanks, as usually a change in a part necessitates a complete change in the magazining arrangement.

It would perhaps be difficult to find another manufacturer who would have a milling problem that can be worked out as efficiently as the work performed by the 76 milling machines in the plant referred to.

Our knowledge of the development of special equipment used in the mass production of these small parts should be of great assistance to the machine-tool builder in his endeavor to cooperate with such manufacturers in trying to arrange the standard types of machine tools so as more nearly to meet the requirements of all.

F. O. Hoagland.[4] In going through the Hawthorne plant of the Western Electric Co., it is quite evident that considerable ingenuity has been used in bringing about these developments that the author has described. I have personally seen several of them, and the job is well done.

The author comments upon the advisability of taking the motors off the tops of the machines. I have found it advantageous, however, on vertical-spindle machines to put the motor on top for the very reason that it gives a multiple-speed motor the advantage of having the highest speeds direct without any gear connections. I think in such a case it is not only justified but it is very desirable. On the other hand, when such conditions do not exist, I think the motor ought to be down in the base or as near to it as possible.

The author mentions obtaining higher speeds in belt-driven hand screw machines than in the motor-driven machines. Direct connection between the spindle and the motor for the higher speeds would make it possible to obtain almost any speed desired.

In regard to punch presses, I think the author's point about the web flywheel is very good. It eliminates the flicker he speaks about, and last, but not least, the chances of getting caught are less.

[4] Pratt & Whitney Co., Hartford, Conn. Mem. A.S.M.E.

The author does not see any particular advantage in high-speed small drills, and I think he is right as far as production is concerned, but it tends to eliminate breakage of the small drills.

The hydraulic-fed presses will undoubtedly come to the front. It is only a question of cost, or mainly so, but I do trust the day will come some day when the demand will outweigh the difference in cost.

In his conclusions the author refers to lubrication. As has been stated many times, 75 per cent of all breakdowns in machine tools are due to the lack of oil. The operator is not going to look around for hidden oil holes or oil cups but he will put the oil in a central place or have somebody else do it, and this will increase the life of the machine considerably. A wick oiling system must be given serious consideration because after the machine has been in the repair man's hands for the first time some of the wicks are apt to be missing, and it must be arranged so that the oil will move through at the proper place, wicking or no wicking.

A. L. DeLeeuw.[5] There are many cases in which a relatively small quantity of product can be produced on an automatic machine provided the tool equipment is not expensive and the set-up time not long, and as there are in existence at present many automatic machines in which both these requirements are met, every one should carefully consider whether one of the present types or perhaps a new type of machine would not be suitable for his work, notwithstanding the fact that he may not produce in large quantities.

Every shop man looks with a great deal of interest to see if a shaft or a gear or any part can be quickly removed in case repairs should be necessary. I do not wish to suggest that this is not an important consideration, but it is not all-important, and it is not as important as some other things. If designers can improve the mechanism but at the cost of some little delay in removing the part if necessary, they should not compromise. They should make the machine better and even let the man who has to do the repairing sweat a little bit. If the designer can make the machine so as to save one second on a minute's operation, then in the course of a year the total time saved is 40 hours, a long time to allow for the removal of a shaft and hence a considerable net saving.

In many cases a station machine might be used to good advantage, especially where quantities are fairly large though not necessarily extraordinarily large. Certain machines can be built so that it would be possible to take various heads off and put other heads on so as to make the machine capable of working on a variety of pieces. Such machines have been built, and many more could be built if again there were not that prejudice that seems to come up automatically in people's minds that enormously large quantities of pieces are required before such a machine becomes profitable. That, I find, is not the case. It is sometimes the case but not always. Again, here, careful consideration is necessary.

Our machines have been built from old practice, and old practice means a shop in which a machine had sometimes to drill a small piece, next a long piece, and then a wide piece, sometimes a high one and sometimes a low one. The machine was built so that it could take care of all these pieces, and in building a machine this way it became clumsy, expensive, and not very fit for any one of the operations. At the present time most of our manufacturing is not carried on that way. Most of it is done by single operations and machinery set for a certain operation. In 1900 and for a few years thereafter, everybody was impressed with the necessity of having a quick-change-gear arrangement on the lathe and milling machine. This is quite correct if a great variety of work must be done on a machine, but if a machine is at

[5] Consulting Engineer, New York, N. Y. Mem. A.S.M.E.

work for a few days and sometimes months and sometimes year after year on the same operation or the same kind of operation, there is no longer any benefit in having an expensive attachment to it for no other purpose than to save a few seconds in changing the feed or speed. In such cases the ordinary change gears or pick-up gears are all that is required. If a machine is at work three or four days at a stretch on one operation and it takes, let us say, three minutes to remove a pair of change gears and put another one on, the percentage of saving that can be made by a quick-change-gear arrangement does not pay.

S. Einstein.[6] The author mentions a number of improvements and suggestions which have been offered in the past to machine-tool builders, such as roller bearings, enclosed motors, and better lubrication. The experience of most machine-tool builders is that whenever improvements are made, it is hard to get users of the tools to accept them. When Mr. DeLeeuw introduced in 1908 milling cutters with teeth correctly spaced there was a considerable argument about the design tending to prove that these cutters were not desirable for a number of reasons. Today these cutters are standard. So it is with the improvements which the author mentions, even roller bearings and ball bearings. It takes an uphill fight all the way to make users of machine tools see their advantages.

Another point brought out by the author is that the needs of industries such as his for small machines are not being cared for. This, I think, is true only to a certain extent. Take, for example, the centerless grinder. When we started out with the centerless grinder considerable pressure was put on us to make it much smaller than the small size we are building now. It was argued that here was a machine, weighing 4000 to 5000 lb. and of correspondingly large proportions, designed for small pieces, say, $^1/_{16}$ or $^1/_{32}$ in diameter. If the requirements of such a machine are analyzed, it will be found that a heavy machine is essential.

Neatness of appearance is naturally very desirable, but here again many problems are put to the machine-tool builder. If all the mechanism is put inside the machine, certain dimensions will become larger and make the machine heavier.

P. E. Bliss.[7] If I understand the author rightly, he says that users of machine tools are paying for and should receive the benefits of more development work. It is a fair question whether they are paying for it, although they may think they are paying for it. Let me illustrate what I have in mind. Recently the National Machine Tool Builders Association made an investigation of some thirty of its larger members making a variety of products, none of whom did less than a million dollars' worth of business a year for five successive years. More than half of the business carried on by them was done at a profit of 10 per cent or less, and only a part of the remainder of the business was done at a profit that reached 14 per cent. That profit when related to the usable items of investment in their business, as to the first section I quoted, was less than 5 per cent return, and as to the other section, probably not in excess of 7 or $7^1/_2$ per cent return. The builders of machine tools are not satisfied with the amount of development work they have been able to carry on, but where the return is so meager the amount of money available for such purposes of necessity must be limited. I think it can be shown that in proportion to the volume of business which the industry does and the net return, the amount of development work carried on is in excess of the amount carried on by any similar national industry.

[6] Chief Designer, Cincinnati Milling Machine Co., Cincinnati, Ohio. Mem. A.S.M.E.

[7] President, Warner & Swasey Co., Cleveland, Ohio. Assoc. A.S.M.E.

O. W. Boston.[8] I wish to raise the question as to whether or not individual lighting arrangements, incorporated in the machine, are desirable in all cases. It seems to me that when individual lights are placed on machines the machinery becomes very complicated and the lights soon get out of order. I wonder if an adequate lighting system, lighting the room as a whole, is not more efficient in the long run.

The author takes up very seriously the question of guards. I am not at all conversant with the various state laws on guards, but it is my understanding that the machine-tool builders are up against a rather serious problem when they equip their machines with guards because a guard which is satisfactory to the laws of one state might not be satisfactory to the laws of another state. I am not sure that The American Society of Mechanical Engineers is doing anything by way of standardizing those practices. It might be desirable to instigate some action along that line.

L. D. Burlingame.[9] I was brought up in a factory where a standard type of machine was established. Because of carrying in stock, we could deliver it to the customer on receipt of a telegram or at a day's notice, and orders were refused which were not for that standard type. Soon the pressure became such that it was necessary to change the product to some extent to meet the needs of customers, and it gradually developed that the users impressed the manufacturer with the thought that the latter was better qualified to perform the service of equipping his machine with such modifications.

One such step is illustrated by the screw machines which were developed to be entirely automatic. Then came the turret forming and the threading machines; thus three kinds were developed. Each of these was built with or without motor, making six kinds, and then each of these was adapted for high and for regular speeds, making 12 kinds. Another variation makes 24, and another 48, until the whole thing becomes impossible. The solution has been partly found in the unit system, by which quick modifications can be made on machines carried in stock.

I believe there is closer and closer cooperation between the user and the manufacturer, but it is still somewhat of an open question as to where the cost should be borne. The cost of service is not one that it seems should be paid by the man who wants the standard equipment only. There are those who want special-purpose machines. The cost, I think, should be borne by the one receiving the service.

W. L. Millar.[10] In the early days it was recommended by the motor manufacturer that the motor be mounted so as to be up out of the dirt. On account of the fact that customers so many times specified that they must have a certain make of motor it was practically impossible for the manufacturer to incorporate the motor in the base of the machine. Therefore it seems necessary to allow the manufacturer greater leeway in selecting the make of the motor, or the principal dimensions of various makes of motors should be standardized.

E. F. DuBrul.[11] There is a growing demand among machine-tool users for standardization. Standardization of the things that affect the user are very properly, to my mind, the subject of the user's demand.

[10] Mechanical Engineer, Gisholt Machine Co., Madison, Wis. Mem. A.S.M.E.

[11] General Manager, National Machine Tool Builders' Association, Cincinnati, Ohio. Assoc. A.S.M.E.

This year the standardization of milling-machine arbors was a progressive step which will eventually show good results for manufacturers as well as the users. The principle can be extended to many different machine-tool elements.

The designer of any mechanism has to be infected, so to speak, with the production idea, if he is going to design production machinery such as the author has shown, and it seems to me that the machine-tool designer is not exposed to this infection at his own drawing board. If he is going to catch this infection, he must go where production is going on. The production atmosphere accounts for the development and the necessity of a staff of the size the author has mentioned, at the Western Electric Company. If it is a good thing for the machine-tool designer to get the production infection, I suggest that he be sent out where it is likely to attack him.

I have often thought as Mr. DeLeeuw has said, that we must be adding unnecessary complication to machine tools. I wonder why every lathe has to be built with a screw-cutting apparatus when most lathes probably are not used for cutting screws. I wonder if all the combinations of feeds and speeds are needed in radial drills—are really used in service. Perhaps the radial drill is enough of a general-purpose tool to require all of these combinations, but do the users of the radial drills see to it that the men operating their machines are using the facilities that are provided for them? The users like to have these things. The manufacturer who gives the most feeds and speeds has a marked advantage. It certainly adds to the cost of producing the regular line of machines to incorporate such complications, but do the users really use them after they have bought them?

Last September, Mr. Blanchard, of the Bullard Machine Tool Company, presented a paper before the Society of Automotive Engineers in which he discussed the method of "simultation." The machines I saw were a very fine example of simultation. They were for machining the carbon electrodes used in electric furnaces. An electrode is pushed into the machine at one side. Jaws on a big drum take hold of it at the bottom and carry it to the first station. Here the two ends of the electrode are drilled. The drills are withdrawn, and then the drum carries the electrode to the second station. As it moves around it passes between two disk grinders—stock machines furnished by another builder—mounted on the large machine, and by which the ends are faced. It stops at the second station at which two planetary milling machines furnished by a third builder are mounted bodily on the machine and by which internal threads are milled in the electrode. Then the drum carries the finished electrode to the bottom where the new one is pushed in, and pushes out the finished piece on the other.

It cost quite a bit of money to design and build this machine; it is the only one of its size and kind. Its existence is due to the ability of some designer to "simultate" these operations that makes it economical. This principle of simultation has been carried out in many station machines. But here is a case of "simultating" three different kinds of operations, two of them involving two complete machine-tool units that are simply attached as complete elements in this large construction.

The Author. There is no doubt, as stated by Mr. Spence, but that individual motor drives cost somewhat more than countershaft belt drives, but when the standardization of motors becomes a reality the difference in cost will greatly diminish. As I see the future, the smaller concerns who buy used machinery, as a great many of them do today, will eventually be buying the second-hand motor-driven machines, and in that way the entire manufacturing field will in time be supplied with the individual-motor-driven equipment. Then there will be no more need of discussing the relative merits of the two systems. The individual-motor drive is an element of progress and its universal adoption eventually is certain.

In regard to the placement of motors referred to by Mr. Hoagland, we prefer not to mount them on the tops of machines though we are not arbitrary about matters of this kind. We put the motor where it can be used to the best advantage.

Mr. DeLeeuw made a very good point when he said that accessibility is not the most important consideration. In buying or designing new machinery we expect the maximum of accessibility. I agree with Mr. DeLeeuw, however, that the importance of accessibility is sometimes overestimated.

In regard to the station type of machine, it is without question coming into more use. We have bought several and also are developing some of our own.

Mr. Einstein and Mr. Bliss spoke of the difficulties of machine-tool builders. We realize that they have their problems and that they are real problems. They are being met very capably by some of the builders. The outstanding builders who maintain efficient engineering and development organizations are not complaining much.

Relative to Professor Boston's question of the advantage of individual lighting, it is not our practice to put individual lights on machines regardless of the kind of a machine or the kind of operation; we use the general illuminating system as much as we can. We have very good lighting in our plant, but we recognize that there are many machines on which it is necessary to have individual lights so that the operators can see what they are doing without effort, and we do not hesitate to install them if it is necessary.

With regard to the laws of different states governing the guarding of machinery which conflict in many respects, these do not present any problem so far as we are concerned, for the reason that we endeavor to thoroughly protect our operators regardless of and often beyond the legal requirements. We have a plant in Illinois and another in New Jersey, and although the laws of the latter are more stringent than those of Illinois, our methods of guarding are the same in both plants and are more thorough in many cases than they need be if we followed the actual wording of the law instead of the spirit of it. We will not permit a machine to be used if it presents a noticeable hazard.

Mr. DuBrul has brought out the fact that machine-tool builders design their machines so that they are adjustable over a wide range. I have often heard salesmen use this as a sales argument. We do not care to pay an increased price for adjustments to cover a wide range of work when only a part of the range will ever be utilized.

I agree fully with Mr. DuBrul that machine designers should have an opportunity to study the economics of manufacturing. They know practically nothing about it. We solve the problem at the Western Electric Company by having two men on the job. One is an engineer who is capable of making a detailed economic study of the problem involved, and the other is a designer who has the engineering ability to lay out on paper the machine to meet the operating requirements, and the two work hand in hand. Designers should be encouraged to learn more about the economic factors involved in the designing and building of machinery.

# Symposium on Shop-Equipment Maintenance

*The first four papers composing the following Symposium describe the organization of the departments in whose charge this feature of the manufacturing problem is placed by four great American industrial concerns. The duties and responsibilities of the personnel of these departments are set forth, their relations with the production and other departments of the shops in question are described, the value of the records of maintenance expense is pointed out, and the methods of inspection to determine the need of repairs are explained in detail. The first paper deals with the methods used by the Westinghouse Electric & Mfg. Co., at East Pittsburgh, Pa., the second with those adopted by the General Electric Company at Schenectady, N. Y., the third, the organization at the National Cash Register Company's plant at Dayton, Ohio, and the fourth, the manner in which the problem is dealt with by the Hess-Bright Mfg. Co., at Philadelphia, Pa.*

*The fifth paper of the Symposium is more directly related to the fundamental economics of the question of plant maintenance. After defining plant maintenance as he understands it, the author lists twelve items which he later discusses in detail. He attacks the problem from the point of view of accounting practice in the distribution of maintenance expense and its effect upon invested capital, and after laying down some general principles, proceeds to apply the principles to the study of the twelve items previously enumerated, showing how the expense involved in each should be distributed. Leaving the economic aspects of the question, the author next sets up a personnel organization and physical layout to handle the problem of general plant maintenance. This is followed by some observations and warnings about the handling of repair orders. Finally, in a summary, the author returns to the economic phases of his subject and shows by an example how the proper accounting of expense will affect the return on the investment.*

## Plant Maintenance[1]

By GEO. H. ASHMAN,[2] SCHENECTADY, N. Y.

PLANT maintenance must be considered as a function distinct and separate from those pertaining to regular production work. It is supervised and carried out by an organization whose duties should have no connection with manufacturing. This department may be divided into three general branches; civil, mechanical, and electrical engineering. The first of these has charge of buildings; the second, of the machinery and tools; and the third, of power. While various plants will differ in regard to further subdivisions of this work, for purpose of discussion the following will be considered as best for keeping the executive in touch with the maintenance work in general, particularly in the matter of costs:

Buildings
Machinery
Electric apparatus
Ovens and furnaces
Dies
Patterns
Miscellaneous equipment
General plant facilities
Power, heat, and light
Safety devices.

### Buildings

The work of the buildings division should be divided into:

Care of buildings, including heating and ventilating
Sewers and underground conduits
Crane runways
Cranes; jib, traveling, gantry (exclusive of electrical equipment)
Elevators (exclusive of motors or control)
Roads and pavements.

A superintendent of grounds and buildings would be in charge of this work, and he would have on his staff a designing engineer, a civil engineer, a general foreman of construction, and foremen of carpenters, masons, structural-steel workers, and roofers.

The department is responsible for the safety and condition of walls, roofs, steelwork, stacks, stairways, and the safe load per square foot of all floors, for the cleaning of windows, and for all painting. Besides this a continuous inspection is made of crane runways and cranes, and of freight and passenger elevators.

### Machinery

The largest and most important division is that of machine tools and appliances, a number of interests centering here, such as the selection and purchase of new tools and their installation; the attaching of motors, control, and wiring; the repair, discarding, and scrapping of old machines; and the purchase of small tools and machine attachments.

The general superintendent of the plant has entire charge of this important phase of the work. The superintendent of a department asking for a new tool makes request on a special form giving a general description of the tool required; special features, if any; nature of work to be performed, with specific details; reasons for making request, whether new work, increased production, or replacement of a worn or obsolete machine. The saving expected in cost of production from this purchase is noted on this request.

Should the request be considered favorably by the general superintendent, bids are obtained by the purchasing department, through whose hands all correspondence passes, from manufacturers building the type of tool required. From these quotations and comments on them from the interested department, the general superintendent selects the machine. After the authorization to purchase has been obtained from the manufacturing committee, the machine is formally bought through the purchasing department.

Requisition for the necessary electrical equipment to operate tool is then made. This equipment is selected and designated by the electrical superintendent.

Foundations are built complete by the grounds and buildings department, and the machine is set in position by the millwrights—each a separate department having no connection with the organization of the shop in which the tool is installed.

The motor and control are next installed and the machine is wired by a special department controlled by the electrical superintendent. Before the machine may be operated for

---

[1] Presented before the Metropolitan Section, New York, N. Y., Mar. 28, 1927.

[2] General Electric Co.

Contributed by the Machine Shop Practice Division and presented at the Annual Meeting, New York, N. Y., Dec. 5 to 8, 1927, of The American Society of Mechanical Engineers.

production, it must be inspected and approved by a representative of the safety committee for gear guards and safety devices.

The machine is given a catalog number by which it is identified throughout its life; this number is not reissued when the tool is scrapped or otherwise disposed of, but remains as a perpetual record to identify it.

A separate account, kept in card-index form, is opened for each tool as it is received and installed. Besides accounting information there is given a general description, the capacity and purpose of the tool, feeds, speeds, maximum and minimum travel of essential working parts, and all special fixtures or attachments. The price of the bare machine appears as a separate item, all attachments, special fixtures, motors and control, etc. having their prices entered as extras. On the face of the card, besides the above information, is given the catalog number of the tool, date of purchase, name of manufacturer, and selling agent, if any, and its location in the plant. On the reverse side is noted all repairs or alterations made, giving date, nature of repairs, and cost. This information is of value in determining whether there is inherent weakness in the design of the machine, shown by the breaking of the same part several times. If the tool is not suitable for the work that it is performing, frequent repairs will be necessary. The second also indicates the extent of the abuse or the lack of proper care which the machine receives.

Every year a new depreciated value is entered on the record card, the rate of depreciation being governed by the class of tool (whether lathe, planer, drill press, punch, hydraulic press, etc.); by size (for example, small lathes are given a higher rate of depreciation than large ones); by location in the shop (toolroom lathes having a lower depreciation rate than production lathes, etc.); by obsolescence (change of methods of manufacture being more likely to affect certain classes of special tools than others).

The foreman of the department in which the machine is installed is responsible for its mechanical operation and upkeep, and for the instruction of the operator in its use. Particular attention is paid to lubrication; an automatic oiling system operating from a central tank on each tool is installed whereever possible, eliminating individual oil cups. Instructions are issued indicating the proper grade of lubricant to be used for each particular service, and attention is called to parts requiring grease lubrication under pressure.

The care of belting, renewal, proper tension, etc. is attended to by an expert gang in each department.

Repairs are undertaken at the direction of the foreman with the approval of the superintendent or general foreman of the department where the machine is located. Minor repairs or emergency breakdowns are taken care of by the tool-repair gang of the department. Major repairs are made by a separate department, equipped for this class of work. Repairs of this nature are only undertaken after a close estimate of the cost shows a good margin below the cost of a new tool. The depreciated value of the tool and obsolescence are factors in the decision for or against repairs.

Chucks, taper attachments, relieving attachments, collets, etc. and all replacements are handled by a central and separate small-tool department. Cold saws, milling cutters, grinding wheels, drills, reamers, arbors, etc. and all hand tools—hammers, wrenches, files—are also handled by this department. Data concerning their life and fitness are kept, and future requirements filled from those showing the best results.

All cutting tools for lathes, planers, millers, etc. are supplied by the small-tool department, which selects the proper tool steel, unless this is specifically designated on the requisition; it forges or constructs the cutters and grinds them for service, subsequent grinding or sharpening being done by the toolroom of the section operating the machine. The use of specially shaped cutting tools is discouraged. Facsimiles of standardized tools are exhibited in conspicuous places, each sample being uniformly numbered, and the operators make request for new tools in accordance with these numbers, no other shapes being furnished without very sufficient reasons.

All tools, lathe, planer, milling cutters, broaches, and drills are ground to exact contours by machine, in the various toolrooms, and other than rubbing up or dressing the cutting edges, workmen are cautioned against further grinding or shaping their tools by hand.

The small-tool department is also responsible for gages and measuring devices of all descriptions. This department not only furnishes the gage called for (being responsible for its accuracy), but also by weekly inspection checks each gage either by direct remeasurement or by comparison with master gages.

### Department of Power, Heat, and Light

Electrical apparatus, ovens, and furnaces come under the department of power, heat, and light. This department is divided into two sections, one electrical, the other mechanical, with the heads of these separate divisions reporting to one superintendent who is held responsible for the operation of both. The electrical division has charge of the selection, installation, and upkeep of all motors, generators, and controlling devices, and of all wiring, including transformers, throughout the plant. It will make all running and emergency repairs, replacing bearings, removing and replacing armatures and rotors, defective coils, contactors, fingers, and solenoids in controllers, brakes, etc. All lamps and fixtures, their installation and upkeep both in office buildings and shops, are under the care of this division.

The care and operation of the electrical features of the shop electric plant are under the direction of this division, and it is responsible for furnishing all current to the plant.

The steam engineer in charge of the mechanical features has direct control of all power plants (exclusive of electrical appliances).

The selection, location, and installation of boilers, stokers, feedwater heaters, pumps, blowers, exhausters, compressors, steam engines, and turbines and all coal-handling machinery and coal storage are directly under him. He is responsible for all alterations and repairs made to this equipment.

All piping throughout the plant—steam, water, air, and gas—is installed and kept up by him. He also is in charge of the design, installation, and repairs of furnaces, ovens, and fuel-oil systems. Heating systems are also under his jurisdiction.

### Die, Pattern, and Jig Work

One of the most important operations in a large plant, and one in which, next to machine tools, the greatest expenditure is made, is die, jig, and pattern work. Because of the nature of this branch of construction, it is centralized in separate departments, supervised by men who have specialized in this particular class of work and are familiar with the operation of dies for drawing, forming, and punching the various metals; molds suited to the several compounds molded; their proper proportioning and strength and the correct steel to use for the block, together with the best heat treatment to use. The storage of dies is an important consideration. A fireproof, heated building centrally located, is provided having crane facilities for handling the heaviest dies. All dies are inspected and put in first-class condition before being returned to this building.

### Transportation

Another department having a marked influence on cost of

plant maintenance is that of transportation: receiving material, movement of material and semi-finished parts from one department to another, movement of material within shop buildings, and shipping the finished product. Material is necessarily received and products shipped in broad-gage cars, therefore a system of standard-gage tracks is needed not only to the main receiving and shipping departments but to each shop, to save the labor of transfer of the bulkier and heavier material to the shop transportation lines.

For movement of material between shops a narrow-gage railroad seems to be the best solution of the problem, rather than a gas or electric tractor with trailers. Larger and heavier loads can be handled by one tractor and cars on a track, and cars be shunted into buildings, not pulled, conserving aisle space.

For transporting smaller loads of lighter material both between departments and from floor to floor in buildings, the electric truck, with and without lifting and tiering devices, and the tractor and trailer is the most mobile and also the cheapest unit.

### Safety Devices

Safety is handled by a separate department whose duty it is to see that the state industrial code is complied with in all cases, and that regular inspections are made of cranes, crane slings, elevators, elevator shafts, steam boilers, etc.

All new and relocated machine tools must be appraised by this department as to safety appliances before they are regularly operated. In each shop safety committees are appointed from among the employees, and their duty is to make suggestions to the safety department covering accident prevention and safety regulations and appliances.

Fire-protection apparatus and fire prevention are under the care of a fire department, which makes daily inspections throughout the plant, covering fire hydrants, hose, sprinkler systems, water buckets and extinguishers. It is responsible for the installation of all fire-protection apparatus and appliances.

# Plant Maintenance and Return on Capital Investment

By W. H. CHAPMAN,[1] HARRISON, N. J.

THIS paper is intended to serve as an expression of the author's opinions upon the subject of general plant maintenance viewed from the standpoint of obtaining the greatest possible return for expenditures which may be considered as chargeable to maintenance items.

Each plant must, of course, be considered according to conditions which exist due to the nature of product manufactured, plant layout, organization, and its financial structure. The management must become thoroughly acquainted with its maintenance problems through careful analysis of the various phases and establish certain policies pertaining to the accomplishment of the physical work, as well as the proper distribution of expenditures.

Efficient organization of personnel involved, with clean-cut placing of responsibility, is paramount. Equally important is a clear understanding of accounting problems. Without an accurate picture of the effect of maintenance upon his financial structure, a manager cannot hope for efficient maintenance control.

### Definition of Plant Maintenance

Plant maintenance, as treated in this paper, is defined as money expended over a given period of time for the sole purpose of maintaining a manufacturing physical structure at a point of operating efficiency that will permit the operating personnel to meet existing set standards of production performance.

This definition assumes that standardization of equipment and labor performance exists, consistent with expected rates of production and degrees of precision in manufacture, so that factory costs of manufactured articles have been accurately determined.

Any changes in equipment, instituted for the purpose of changing existing standards (whether due to changes in product design or methods of manufacture), are not classed as maintenance items. These are development items involving capital expenditures and are brought about for reasons of sales policy, quality of product, or an opportunity to increase return upon investment by cheaper methods of manufacture.

### General-Maintenance Items

General-maintenance items include the maintenance of

1 Buildings and grounds
2 Power-supply equipment
3 Machine-tool equipment
4 Processing equipment
5 Tools (perishable and permanent)
6 Materials-handling and storage equipment
7 Power transmission
8 Furniture and fixtures (office equipment)
9 Laboratory and experimental development equipment
10 Expense stores maintenance supplies
11 Heat-treating equipment
12 Fire-prevention and safety equipment.

Each plant has maintenance problems peculiar to itself, but for the average concern engaged in fabricating the more common engineering materials, the above classification is suggested.

### Accounting Practice in Distribution of Maintenance Expense and Effect upon Invested Capital

The gage of success of a business enterprise may be expressed in terms of percentage of net return upon invested capital. The amount of invested capital will fluctuate, and the most important problem faced by management is the control of the organization so as to obtain a satisfactory net return under the varying business conditions which may occur. Viewed broadly, it is important to regard expenditures from the standpoint of their effect upon this return on investment, in order that policies laid down to the responsible working personnel may be constructively interpreted and controlled.

It is important to recognize the effect of accounting distribution of maintenance items upon net return. In most lines of business there is a considerable variety of product in process in the factory at all times. It is usually true that parts which are being made in large quantities, and therefore permit the development of the cheapest manufacturing costs, are also subjected to the greatest competition and, therefore, show the smallest margin of profit, per piece, in a competitive market. Lines which are more or less special, or entail proportionately large manufacturing expenditures to produce, may in themselves create excessive maintenance burden. In the distribution of this burden against the various manufacturing departments, it may be readily seen that policy must be determined through the effect upon selling prices of various items, and the knowledge of the effect of these prices upon the profits of the business as a whole. Factory costs are usually the basis of arriving at selling prices. A very large percentage of the item of factory cost is made up of burden items, of which maintenance items

[1] Assoc-Mem. A.S.M.E.

are usually of considerable magnitude. In allocating burden centers for distributing expense items, it is important to consider not only the nature of equipment and operations involved, but also the variety of size and shape of product reflected in the relative amount of physical effort and expense required for each one of the various items. It may be desirable to create separate burden centers in the same manufacturing department, to enable differentiation between popular sizes and more or less special sizes and to prevent over-absorption of burden by the popular sizes which are subjected to the closest competition in the selling field.

It may also develop that certain sizes of product require special methods or equipment peculiar to themselves, which create costs not logically chargeable to the remainder of the product. Close study of such a situation will probably indicate the advisability of creating separate burden centers for the purpose of collecting created expense items and charging them against the product responsible; thereby insuring a more accurate basis for determining a logical selling price, and saving the more popular product items from burden inflation.

On the other hand, a concern may be fortunate enough to obtain a market for a large volume of sales involving an item which it can manufacture to extreme advantage, and which may then serve to absorb burden and permit reductions in selling prices on other items which otherwise would be handicapped in the competitive field. The successful manager will have his selling data and factory cost data well enough in hand to be able to set his policies for the guidance of his accounting department so that burden may be distributed logically to produce the desired effect.

### Buildings and Grounds

The expense of maintaining buildings and grounds includes such items as painting, roofing, repairs to masonry, floors, windows, fences, street pavements, curbing, sidewalks, lawns and gardens, trackage, platforms, etc. Lighting, plumbing, and heat equipment not involved in manufacturing processing, are also included from the accounting standpoint under buildings, to be distributed over the various burden centers.

The distribution of the above items should logically be upon the basis of floor space and the following method is suggested: Post all charges for the period covered (say, one month) and obtain the total maintenance expense represented by labor, supervision, material, etc. Obtain the percentage of floor space occupied by each burden center relative to the total floor space occupied by direct manufacturing activities. Multiply the total maintenance expense by each percentage and charge its proper proportion against each burden center. Each burden center is considered a tenant in the building which must be supported by the sum total of the producing burden centers, and expenses of building maintenance are equitably distributed upon the basis of space occupied. Non-productive departments are absorbed as a total, and distributed among the "paying tenants."

### Power-Supply Equipment

Power-supply equipment refers to power house and the general transmission of power not properly contained within any particular producing department, and comprises electrical, pipe-line, and power-generating equipment. It also includes materials-handling and storage equipment used for the purpose of fuel supply, ashes, etc. It is suggested that total maintenance charges of this class be distributed upon the basis of the percentage of total power used by each producing burden center. This is determined by electric, gas, steam, and water meters in each burden center.

### Machine-Tool Equipment

Maintenance of manufacturing machine-tool equipment accrues against the particular burden center involved, depending upon the amount of service expense required, and becomes a direct-expense charge for each burden center. Similar equipment located in service departments, such as tool rooms, machine shops, etc. is maintained as a part of the regular service expense, which is prorated over the producing burden centers in proportion to service work rendered. It may be considered as a part of the burden of service departments whose total expenses become absorbed through prorating among producing burden centers on the standard labor-hour basis.

### Processing Equipment

Processing equipment refers to cleaning, plating, painting, oiling, and similar equipment. Maintenance of these items should be handled, and expense distributed, in the same manner as outlined for machine-tool equipment. Each burden center is directly charged for service rendered, including repairs to accessory equipment, such as pipe lines, pyrometers, storage and pumping systems, etc. which have been definitely allocated to individual burden centers under the plant layout.

### Perishable and Permanent Tools

Perishable and permanent tools are chargeable directly to the burden centers in which they are consumed or used. Perishable tools are both repaired and replaced at frequent intervals and may be charged to maintenance accounts unless replaced due to changes in design or methods of manufacture. Permanent tools are maintained and charged directly, as repairs are made, to maintenance accounts, except when replaced due to obsolescence. These items usually represent heavy expenditures and require close supervision and control. The record of their performance as indicated by a system of detailed repair-order cards is of extreme importance in the appraisal of their value by interested executives, and also in forecasting probable requirements for the control of a large part of expense stores investment. The keeping of such records will be more fully discussed in a following paragraph.

### Materials-Handling and Storage Equipment

Railway equipment, automobiles, motor trucks, conveyors, cranes, inside trucks, "tote" pans and platforms, bins, scales, stock racks, etc. are included. Due to the interdepartmental transfer aspect of a great many of these items, direct-burden-center charges appear impracticable, and all repairs over a given period are lumped, and distributed upon the basis of the ratio of actual productive-labor man-hours occurring for the period in a particular burden center, to the total productive-labor man-hours for all of the producing burden centers during the same period.

### Power-Transmission Equipment

Power-transmission equipment refers to motors, electric lines, fuses, switches, starters, etc., pipe lines for water, gas, oil, steam; etc. leading from sources outside of the burden centers served, belts, pulleys, clutches, shafting, hangers and bearings, and similar miscellaneous equipment. All repairs or replacements of such equipment (except due to change of design or plant rearrangement) are chargeable directly to the burden center served. Maintenance of this nature is always a large item, and here again the value of accurate repair-order records will be found of great value to the organization. The determination of relative economy of performance of belts, hanger bearings,

clutches, motors, etc. will far more than repay the cost of obtaining the data.

### Furniture and Fixtures and Office Equipment

When located in a producing burden center, maintenance of furniture and fixtures is charged direct. For non-productive departments, total maintenance is lumped, and distributed against the burden centers on the standard labor man-hour basis. Office equipment refers only to that chargeable to manufacturing administration and does not include sales.

### Laboratory and Experimental-Development Equipment

Repairs of all kinds to laboratory and experimental-development equipment are lumped and distributed over producing burden centers as a part of the general plant overhead, upon the basis of labor man-hour percentage for each burden center.

### Expense Stores Maintenance Material

Certain items carried in expense stores are drawn out as needed and used in repair and maintenance work. When this occurs, the value of the material requisitioned and delivered is indicated upon the repair order and is thereby transferred from capital investment to works expense as explained in a following paragraph.

### Heat-Treating Equipment

It is suggested that these items be accounted for in the same manner as processing equipment.

### Fire-Prevention and Safety Equipment

Fire-prevention and safety-equipment expenses are distributed upon the floor space or "tenant" basis over the producing burden centers, as was suggested for "buildings and grounds" items. This refers only to repairs or replacements for the purpose of maintaining this equipment in first-class operating condition. Recharging of chemical extinguishers, etc. would fall under this class of maintenance.

The above indicates in a general way the suggestions offered for controlling the expense of handling maintenance work so that the costs involved may be readily studied and be properly posted by the accounting department in making up cost data for determining a proper basis for calculating selling prices. Where part of the product does not make use of certain of the burden centers, it is relieved of the proportionate burden which might otherwise accrue against it under other methods of cost distribution. A chance for flexibility in determination of factory costs of individual items presents itself without the danger of unknown or unexpected losses occurring due to unabsorbed burden created by maintenance items. The usual magnitude of these items makes for extreme importance in their intelligent control.

### Personnel Organization and Physical Layout to Handle General Plant Maintenance

The magnitude and ramifications of the personnel organization required to handle general maintenance work depend upon the size of the plant, the nature of the manufacturing processes, and the degree of precision to which machining operations are held. For large corporations having plants in several locations this organization may assume considerable proportions. For individual plants it is often remarkable how few people are required when properly organized and equipped to handle this sort of work. Maintenance work requires the services of skilled workers who are specialists in each of a variety of trades. Mechanics, tool makers, millwrights, riggers, electricians, plumbers, pipe fitters, tinsmiths, welders, blacksmiths, painters, carpenters, and laborers are all necessary. Many of these men are occupied at their trades within the plant on other than maintenance work for a great deal of the time, and for most plants a distinct maintenance department, fully manned, would not be economical. The handling of maintenance work under these circumstances is necessarily divided up among a number of departments which are not primarily created for maintenance work. The machine shop and tool rooms will have, however, a considerable part of their time taken up due to maintenance requirements in conjunction with the usual work done on new equipment, alterations, experimental tools, product development, etc.

Executives responsible for maintenance work in the average plant should be chosen so that their part of maintenance is logically in line with their other duties. The following layout is suggested as suitable in the average case.

1 Plant Engineer.

Maintenance duties cover the following items:

- Buildings and grounds
- Power-supply equipment
- Processing equipment
- Materials-handling and storage equipment
- Power-transmission equipment.

He will supervise:

- Safety engineering
- Watchmen
- Fire department
- Power house (electric, steam, gas, oil, and water)
- Electricians
- Plumbers and pipe fitters
- Millwrights, riggers, and belt men
- Outside transportation and storage systems
- Tinsmiths
- Masons
- General laborers.

When the services of mechanics, carpenters, welders, etc. are required in conjunction with the above, they are requisitioned from their respective departments, and their part of the job is supervised by their regular foremen to the satisfaction of the plant engineer, who assumes final responsibility.

2 Master Mechanic or Manufacturing-Equipment Engineer.

Maintenance duties cover the following items:

- Manufacturing machine-tool equipment
- Perishable and permanent tool equipment
- Furniture and fixtures
- Laboratory and experimental development equipment.

He will supervise:

- Machine shops and tool rooms
- Equipment-development work
- Machine and tool design
- Pattern and carpenter shop
- Standard methods and rate setting.

Each of the above individuals reports to the works manager and is responsible to him for proper maintenance service to all departments. Maintenance work is therefore handled without the creation of special executives for the purpose, but with responsibility clearly defined. Furthermore, no production executives are troubled with having to supervise maintenance but can look for assistance from those who are logically in a position to give them the best possible service in maintaining an efficient production layout.

It is felt that the above suggestions will prove of value to

management in the control of maintenance work for the following reasons:

1 Clear-cut responsibility for this work, assigned to permit minimum personnel requirements.

2 Accurate cost data available to serve as a guide to control expensive items of factory costs and permitting a flexibility of cost distribution to meet indicated sales resistance in a competitive field.

3 A clear indication of effects of factory costs upon return on investment, and data from which close forecasting of future costs is possible; in other words, a gage of the probable health of the business.

4 Maintenance experience is gained by those executives who also serve to determine manufacturing methods and equipment. This experience is therefore of utmost value in aiding arrival at the proper choice of these items and thereby obtaining the most suitable manufacturing layouts.

It is realized that in many plants peculiar conditions are present which will require a different treatment of maintenance problems. However, it is hoped that by bringing the foregoing ideas up for thought and discussion, some benefits may accrue to those interested in this phase of plant management, and that executives will realize that the importance of maintenance work is more far-reaching than is ordinarily appreciated.

### Handling of Repair Orders

It is important that the organization be thoroughly schooled in the proper classification of maintenance work to prevent inflation of maintenance expense. It is very common to find expenses charged to maintenance accounts which in reality are created by activities of a development nature (or else so-called "Government jobs") and which, from an accounting standpoint, should be set up as capital items and not as increases to works expense.

No system of authorizing and recording maintenance activities can be devised to overcome the misdeeds of persons who knowingly permit wrongful charging of time and materials. Only by intelligent appreciation of the detrimental effect of such practices can they be reduced to a minimum. Any responsible foreman must be as thoroughly alive to this fact as to the importance of the proper handling of his major production problems.

It is the author's opinion that the very foundation of successful maintenance-expense control lies in the success of the management in gaining full coöperation of production executives along these lines.

The control of repair orders in service departments must be handled with extreme care to prevent abuses and excesses of various sorts which are apt to be charged to orders for maintenance work. It is the author's opinion that it pays to expend sufficient clerical effort upon this class of orders to insure the keeping of accurate records of the nature and extent of each job; also to disseminate the data collected to interested executives as an important means of checking unnecessary expenditures, and to check the performances of both operators and equipment. Many sore spots in equipment or in methods of operation are clearly indicated by such records. They serve as valuable indexes when replacement of equipment is under consideration. Standing repair orders of a general nature, which fail to record accurate data regarding maintenance expenditures, frequently serve to cover up numerous activities which would not otherwise be authorized and are of questionable advantage to the concern.

When materials are requisitioned from expense stores for maintenance purposes they represent a transfer (from an accounting standpoint) from invested capital, indicated by their purchase price, to an expenditure chargeable to works expense. In other words, invested capital is reduced by an amount which is entered as a charge deductible from profits or net return upon invested capital. A close control of inventories represented by such materials is essential in order to keep down investment upon which a satisfactory return must be made. Here again the data obtained from specific repair orders can serve an extremely useful purpose. By the use of suitably printed cards which are punched in designated spaces, the necessary data may be quickly indicated and the cards later sorted by machine so as to keep such records without excessive clerical cost. This system is commonly used in a variety of ways, and involves very little outlay to be put into satisfactory operation.

### Summary

In the foregoing paragraphs the author has attempted to point out policies which apply to the average case without going into details. Details must of necessity apply to more or less individual plant layouts. It is felt that an organization which thoroughly appreciates the need for regarding the manufacturing plant as a financial institution attempting to earn the greatest possible return upon its invested capital, will be capable of working out necessary details along the lines of the general policies indicated. It is the lack of knowledge of such policies which handicaps many otherwise efficient engineers and production men, and causes the introduction of personal ideas that are often sincerely believed to be helpful, but which may be detrimental to the main object of the plant as a whole.

Because of the custom of gaging the success of business enterprise in terms of percentage return per annum on invested capital, and regarding capital as money borrowed at a rate of 6 per cent per annum, the following example may be of some value in stressing the need for proper understanding in handling maintenance expense items.

Assume that a concern at the close of a year's business is capitalized at $1,000,000. Operating expenses have been $2,000,000, and net profits from sales have been $300,000. The year's business has then shown a 30 per cent return on the investment, or a 24 per cent return after deducting 6 per cent interest on the capital investment. If, during the year there have been alterations to machines which have improved operating conditions, and, say, $100,000 has been spent to accomplish this but charged against repair orders, then this $100,000 has been charged to works expense rather than to new capital, and net profits have suffered by this amount while invested capital has not increased.

If the expense had been properly accounted for, the firm would have borrowed working capital of an additional $100,000, making the following showing:

| | |
|---|---|
| Invested capital | $1,100,000 |
| Operating expenses | 1,900,000 |
| Net profits | 400,000 |

Return on investment, 36.36 per cent, or 30.36 per cent after deducting 6 per cent for interest on invested capital.

The above figures are not intended to be accurate but to serve only to indicate the nature of the problem which must be kept in mind by all concerned, so that the best possible showing may be obtained.

It is not intended to give the impression that it pays to inflate capital investment, as this should be kept to a minimum, especially through controlling inventories, but it will serve to show the care necessary so that the annual balance sheet may reflect the best possible condition from a financial standpoint and thereby best serve the interests of the stockholders.

# Maintenance of Shop Equipment

By J. R. Weaver,[4] East Pittsburgh, Pa.

At the main works of the Westinghouse Electric & Mfg. Co. at East Pittsburgh, Pa., there is a large amount of equipment which must be properly maintained. To do this arrangements have been made to keep it in working condition at all times instead of waiting until a machine breaks down or requires a complete overhauling. In this way manufacturing is carried on with very little interference and without the necessity of having duplicate equipment to take care of shutdowns due to repairs. The organization which is charged with equipment maintenance is described in this paper.

## Checking Up on the Machine Tool

Each department has a tool supervisor who reports directly to the superintendent of that department and indirectly to the superintendent of the equipment department. The tool supervisor is the mechanical man in the department in which he is located and is responsible in all respects for the tools and equipment over which he has jurisdiction. He must see to it that he obtains the right machine tools for the job and that the machines are properly tooled. He must see that the machine tools and fixtures are properly maintained. We have about fifteen tool supervisors in the East Pittsburgh works.

In addition to the tool supervisors we have a force of machine-tool demonstrators. There are about fifteen demonstrators in the East Pittsburgh works and they report to the superintendent of equipment. These men are specialists in that each is trained to cover just one kind of machine tool; one man is trained on grinders, another on milling machines, etc. These men are responsible for proper selection, maintenance, and operating conditions for their particular kind of machine tool throughout the entire shop. Twice a month the demonstrators inspect machine tools throughout the shop for cleanliness and need for repair. In this way it is possible, to a very great extent, to locate machines that are in need of repairs and to correct them before a serious breakdown occurs.

The foremen and assistant foremen of the various departments are naturally interested in keeping their machines in good repair at all times, and they also help to keep the tool supervisors and demonstrators informed as to the condition of the machine tools in their departments.

## A Special Repair Department

The methods of locating machine tools that are in need of repair have been pointed out. To make these repairs there is a repair department thoroughly equipped for repairing all kinds and sizes of machines that are used in the shop. This department is in charge of a superintendent who reports directly to the works manager. It is divided into several sections in order to facilitate the work that is to be done in it.

A machining section is provided in this repair department to take care of any machining that it may be necessary to do. A variety of machine tools makes this department largely self-sufficient, and only in case the work is very large is it necessary to send it out of this department. In such cases the work is done in the large-machining aisle.

The assembling section of the repair department is equipped so that, if necessary, a machine tool can be completely rebuilt. In this department special machine tools which cannot be bought in the open market are also built.

The field section is composed of a number of men scattered throughout the various production departments in the shop, who make minor repairs and attend to any trouble jobs that may develop. This has helped to a great extent in keeping the machine tools in operating condition, and only in cases of serious breakdown is it necessary for the field section to send the machine tool to the repair department.

## Cost Records

An accurate record is kept of the cost of repairs. This is done through a system which compels the repair man to report the time spent on the repair job. All machine tools are numbered, and the repair cost is recorded against the machine-tool number. A permanent record is kept of the cost of repairs to the machine tools. At the end of each month a report is sent to each superintendent in the shop giving him the cost of repairs to his equipment during the preceding month. This report shows whether the repair was made necessary by excessive wear, accident, or negligence. The superintendent can then investigate and correct whatever may have been responsible for the breakdown. By the use of this permanent record it is also easier to decide when a machine tool should be replaced due to the excessive cost of upkeep.

## Safety Devices

A safety-application department is also maintained by the repair department for the purpose of properly guarding all machine tools. Up to the present time this department has very thoroughly canvassed the shop and has applied guards to prevent accidents. All new equipment, as it is received, is checked by this department, and if it is not properly guarded the manufacturer is notified and a proper guard is applied before the machine is actually put into operation.

Through the efforts of this department in conjunction with the safety department it has been possible to reduce lost-time accidents from 140 per month in the year 1924 to 54 per month in the year 1926. In fact it is found that most accidents at the present time are not due to machine tools but to the carelessness of the workman in handling material. There are more accidents due to the accidental dropping of material than to improperly guarded machine tools.

There are very few breakdowns due to the dropping of a wrench or other material into the working mechanism of a machine tool. This has been prevented by proper guarding.

## Replacement

Every three months a survey is made of the shop for the purpose of replacing equipment that is worn beyond repair. The tool supervisors request each replacement on a form called "request for equipment." On this request is given the reason for replacing the old machine tool, the repair-department records being used to show the cost of maintenance. At this same time, of course, there is also requested new equipment that is necessary because of improvements in the design of machine tools which make replacement advisable.

## Value of Records to Machine-Tool Builders

The complete and accurate records which have been kept at the Westinghouse works have been of great advantage to machine-tool manufacturers. In several cases where trouble has developed shortly after the machine tools were received the manufacturer has been notified and given a detailed report as to just what trouble was experienced and what was thought to be the probable cause and the cost. In this way the machine-tool manufacturer has been able to correct his design, if necessary, and avoid this trouble in other shops.

---

[4] Assistant Superintendent, Equipment Department, Westinghouse Electric & Mfg. Co. Assoc-Mem. A.S.M.E.

### Weekly Inspection

As mentioned before, a semi-monthly inspection is made of all machine tools for cleanliness, proper oiling, and the need of repair. This inspection is made primarily for cleanliness and is usually held on Saturday afternoon after the shop has closed down for the week. All machine tools which are not properly cleaned or which are untidy in any respect are reported to the superintendent of that department and to the works manager.

By keeping the machine tools clean, we have reduced our maintenance cost and have added greatly to the appearance of the various departments. The weekly inspections have also instilled the idea of cleanliness throughout the entire shop and have resulted in proper cleaning and painting of the departments and also the proper arranging of material. The results of the maintenance system have been lower maintenance costs, less interference with production, and fewer accidents.

# Maintenance of Machine Equipment at the National Cash Register Company's Plant

By WM. HARTMAN,[a] DAYTON, OHIO

MAINTENANCE work at the plant of National Cash Register Company is divided into three classes:

1 General factory maintenance
2 Tool maintenance
3 Machine-equipment maintenance.

This paper takes up briefly the third class, machine maintenance work.

Following the company's general practice of specialization, this work is divided between four departments, each handling their own particular branch of work.

1 The general machine department repairs and rebuilds all machines, and takes care of all general machine-shop jobbing work.

2 The electrical department inspects and repairs all motors, wiring connections, and other electrical devices.

3 The millwright department inspects, installs, and repairs overhead work (countershafts, lineshafts, main drives, etc.) and belting. This department also moves all machinery.

4 The purchasing department coöperates with the above departments in securing the necessary replacement parts and furnishing up-to-date prices on new equipment when there is a question of whether to repair or replace.

There is no one department responsible for the condition of machinery in this plant. Each production foreman is held strictly accountable for keeping his machinery in first-class shape. All orders for repair work on machinery originate in the production departments and bear the foreman's signature. In order to keep a responsible check on this work these orders are approved by the division supervisor and general superintendent. Each order bears an order number, and costs are kept on this work by the comptroller's department through time cards turned in by the mechanics.

There is no budgeting of repairs in this plant because, due to the closeness of the work, machinery must be kept in perfect condition and it is felt that a budget would tend to keep a machine in use longer than its mechanical condition might warrant, resulting in bad work and dangerous conditions for the operators.

The necessity of repairs is determined by the foreman and his assistants in two ways: (1) A regular inspection of certain types of machinery, deemed particularly important or dangerous, and (2) by continual daily inspection and observation on the part of the foreman, job foreman, job setter, and operator on all types of general manufacturing equipment.

[a] National Cash Register Company.

### Machine Inspection and Repair

The machines covered by regular monthly inspection include punch presses, commissary equipment, scales, and certain types of special machinery. These machines require the attention of experts to keep them in working order and in some cases would cause a serious accident or tie-up in the production schedule in case of unwarned-of breakage. Where possible, a machine of this type needing repairs is run overtime. The increase in production thus gained allows the machine to be shut down for the necessary repairs. Where this is not possible, as in power-house equipment, the repair work is done during overtime.

The monthly inspection of punch presses, because of their dangerous nature, consists of a general inspection of the machines and a detailed inspection of all wearing parts which might cause an accident, such as clutch blocks, trips, clutch plungers, and springs. Any unusual noise or sluggish movement of parts is immediately reported to the foreman and the machine is shut down. A mechanic, who is a member of the general machine department, is stationed in this department and is always available for running repairs on this type of machinery. If the condition of the machine warrants it, the machine is taken out of commission and either sent to the general machine department or, in the case of a very large machine, is repaired on its own foundation.

Machinery covered by the second class of inspection consists of screw machines, mills, drill presses, lathes, etc. which are constantly being watched by every one who comes in contact with them and are repaired whenever they require it. Their work is transferred to other machines of the same type while they are out of service.

Because of the large number of screw machines in use in this plant and the complicated nature of such machines, a comparatively large assortment of replacement parts is carried in stock. The particular parts and quantities carried have been determined by past experiences. Extra spindles of Brown & Sharpe machines are always on hand, and as soon as one requires attention it is sent to the general machine department for repairs, an extra spindle is substituted, and the machine is put into service again at once. Standard sizes have been established for reground spindles, and bronze bearings are carried for each size so that when substituting a repaired spindle the proper size of bearing is always available. This same idea is carried out wherever the nature of the machinery requires it.

When machines are sent to the general machine department for repairs due to wear, they are inspected for the cause of wear and the weakness is remedied and the errors due to wear corrected. If this is not done experience has shown that the same machine may be back for repairs in a short time. It is sometimes necessary to substitute a different kind of bearing such as bronze instead of babbitt or even a ball bearing at times. A bearing may wear too much on one side. Replacement may get the machine into service again, but the way to keep it in service may be to provide a better support for the bearing or to make it longer. The aim is always to make the repaired machines as strong as possible in the known weak places. Where parts cannot be strengthened by better design, due to the conditions in the machine, an effort is made to produce the part in a stronger material. For instance, cast-iron dog carriers used on a certain type of machine are replaced by cast-steel parts whenever one is sent in broken. They last much longer and save their cost

many times over in production time. Repair parts which do not show marked weakness in design are purchased whenever it is cheaper to buy them than to make them.

When, in his survey, either the production foreman or the general-machine-department foreman find that the cost of repairs is excessive, they recommend to their supervisor that the machine be abandoned and a new one purchased to take its place.

This plant has an annual two weeks' vacation, during which period the entire production is shut down. This period is utilized to give all machines which run continuously a thorough inspection by the general-machine-department mechanics, and all parts which show signs of wear are replaced. Some time before vacation a survey is made of all departments, and machines which are known to need repairs are listed. This enables the machinists to do considerable preliminary work in advance. A great deal of power-house repair work is done during this period.

### Lubrication

One of the least expensive things that can be used in a machine shop is oil. It is very important that all machines be oiled regularly. Each operator is responsible for the oiling of his own machine. If he is a new man or an old man being placed on a new machine, he is first given thorough instruction in oiling and his machine is inspected by his job foreman for a few weeks, to see that it is taken care of properly. Extra-large oil cups are provided and, where practical, automatic oilers are installed. With the grade of operators employed by the company, experience has shown that in place of neglecting to oil, there is a tendency to use too much oil. However, it is better to have this condition than not enough.

This method of oiling machines is in use in most departments where an operator is on one machine only. His responsibility is easily fixed. In a few departments where different machines may be used by many men in the course of a year and where work is of a very accurate nature, such as for instance the toolmaking department, it has been found best to have an experienced man devote his entire time to the oiling of machines.

All overhead work is oiled by regular men from the millwright department. Except in special cases, countershafts are oiled twice a week while lineshafts, due to roller bearings, are oiled once every two weeks. At one time electric motors were oiled by a man from the electrical department, but at present the regular oiler takes care of this work. If there is too much or not enough oil used the man who inspects each motor daily calls this to the oiler's attention.

### Electrical Department

The electrical department repairs all motors and electrical work and specifies all new equipment, thereby maintaining equipment standard and lessening the amount of maintenance work in the future. Emergency repairmen have stations in different places throughout the plant to take care of small repair work.

There are approximately fifteen hundred motors in use, and an average of one hundred are rewound each year. Motor equipment is held down to as few sizes and types as possible, and in most cases there is a spare motor in stock for each ten to fifteen motors in operation. Should a motor break down there is on hand one to take its place. Where a special motor is necessary on some important equipment which might tie up a production unit, there is a spare motor for each one in active use. Repairs are promptly made so that a re-occurrence of the breakdown can be quickly taken care of. Each motor is inspected once every day, and a thorough examination and efficiency test made once each month.

### Millwright Department

The millwright department installs and maintains all countershafts, lineshafts, and belting, and furnishes oiling service and emergency belt-repair service. A telephone call brings an expert belt man on a small electric truck, equipped with a supply of belting and repair tools. All machine work on countershafting is done by the general machine department.

The entire maintenance program of this plant is planned to strengthen the weak places before a breakdown occurs and when a breakdown is encountered, the cause as well as the damage is corrected.

# Maintenance of Shop Equipment

By C. S. GOTWALS,[6] PHILADELPHIA, PA.

MODERN industry demands that shop equipment be kept in good condition for operation, and keen competition requires that new equipment be purchased as soon as it will pay for itself in a reasonable length of time.

For the greater number of productive machine tools a conservative estimate of the rate of wear can be made so that repairs can be attended to when they cause the least amount of confusion in the shop. In the Hess-Bright shops repair expenses are budgeted and repairs are made when convenient, emergencies excepted.

The departmental foreman and the accountant confer for the purpose of making this budget. The foreman knows approximately the amount of money needed for repairs, while the accountant translates this figure into a percentage of the productive labor in that department. Thus the amount of money allowable for repairs as per the budget will depend upon how much productive labor is in the department. Realizing that a repair has to be made, the production manager and the chief of the repair gang confer, so that a definite understanding is made concerning the exact nature of the repair and the approximate date when the machine will be back in production.

The departmental foreman knows when the machines need repairs, mainly because of the inspection given them by the repair chief. The inspection of the machine tools takes place periodically, their condition being reported to the foreman. Thus repairs are predetermined and intelligently made.

Whenever it is necessary to make repairs, the machine is taken down by the repair gang. The parts which have to be replaced are sketched by the drafting department, so that a permanent record is kept on file of that particular part. Many times when a machine has been taken down it is found that a slight alteration in the design of the part will increase its life. Other times a better grade of material is used in making the new part, thus tending to keep the machine in production longer. It has been found that it is desirable to replace worn cast-iron gears with steel gears, to replace plain bearings with ball bearings, to use hardened steel instead of soft steel, etc. Quite frequently upon analyzing the cause of a repair it is found that the part in question was not properly lubricated. This part is then redesigned to give better service.

### Lubrication

It has been found desirable in the case of large machine tools to put the lubrication of them under the supervision of the maintenance engineer. There are therefore men in the shop whose duty it is to see that the machines under their care are properly lubricated at all times. In this manner some cases have been discovered in which it was necessary to change the

[6] Time Study Dept., Hess-Bright Mfg. Co. Mem. A.S.M.E.

nature of the lubricant, while in others it was necessary to change the construction of the lubricating system. In the case of the smaller machine tools, the individual operators are expected to oil each machine whenever it is started. The precaution has been taken of preventing dirt from getting into the bearing surfaces along with the oil wherever possible. This is usually accomplished by filtering the oil at the point of its entrance into the bearing surface. It is quite true that a great quantity of dirt can be found in the ordinary shop oil can, which is constantly being used wherever production machinery is kept in motion. By preventing this dirt from reaching those parts of the machine where it would do considerable damage, a substantial reduction in the repair bill has been made.

### Division of Repair Work

Wherever possible, repair work is subdivided into groups so that one repair man or group of repair men will work on the same or similar equipment constantly. Thus for large machine tools one man is directly responsible for their proper repair when they have to be taken down. In this manner he learns to know the weak parts of the machine and is thereby enabled to make suggestions for the strengthening of these parts. There are also chief repair men in several departments, who, working under the supervision of the general foremen, are responsible for the proper repair of the machines in their respective departments.

The repair of grinding-wheel spindles has been specialized. That is, the spindle repair man works on nothing but spindles. There was a time not so long ago when each grinding machine was equipped with one plain-bearing spindle. Then, whenever it became necessary to "take up" the spindle the operator lost considerable time and a loss of production occurred. If this plain bearing had to be scraped, it of course took considerably longer. At the present time, however, these same grinders are equipped with ball-bearing spindles, and when it becomes necessary to adjust them, the spindle repair man immediately takes out the spindle that needs adjustment and replaces it at once with another spindle which has been adjusted in the spindle department. The spindle needing adjustment is then taken to the spindle department, where it is put into condition for operation. There are always enough spare spindles on hand, so that a machine operator loses a minimum amount of time and production when his spindle goes bad.

There are also repair men who specialize on the repair of punch-press dies, and others who do nothing but repair forging-machine dies. These men keep a record of the total number of pieces produced from each die as well as the number produced after each repair. In this manner a record is kept of various makes of materials used in the manufacture of the dies, whereby it is possible to find the desirability of changing from one kind of material to another.

### Replacement Policy

All of the foregoing concerning the repairs quite naturally leads to the question, When is it more economical to purchase new equipment than to repair the old? When the cost of repairs to any machine per year approaches 20 per cent of the cost of a new machine, new equipment is looked over. Or it may be found that the new machine, due to its improved design, will produce more or better work than the old, thus making a saving in labor. If the saving in labor plus the saving in the repair expense will pay for the new equipment in two years, it is considered a sound investment. Before purchasing any new equipment, however, it is ascertained that the old machine cannot be improved nor altered to make it worth while to continue to operate economically. Sometimes in this manner it is found that the possibilities of the old equipment have not been fully developed, and new equipment should not be purchased.

## Discussion

J. E. Webster.[7] The question of what should be done and what should not be done in a maintenance line is a very important point to decide. The quantity of the work to be done and the quality of the work to be done, are subject to great variations in judgment. A building will house an activity if the roof is in rather bad shape as long as it does not leak, and if the windows rattle, and if it is not painted, and if the floors are bumpy. Whenever officials of a company go through a plant the thing that impresses them as favorable or unfavorable toward the operating officials is the appearance of the plant, the cleanliness and the general neatness and quality of the maintenance work and how well the floors and stairways look.

The best way to handle maintenance is to have each type of work, such as painting and repairs to floors, repairs to roofs, maintenance of cranes, etc. budgeted for the year, and all work charged to an account number so that the man in charge or the plant manager can at the end of each month see what has been spent on that line of work. The man in charge of maintenance must "sell" the budget to the executive so that it will not be necessary to get approval for each item. If he can persuade the executive that he must spend so many dollars a month on each one of these items during the year to keep the plant up, then he can be made responsible for the selection of the various items to be done.

A. L. DeLeeuw.[8] Mr. Chapman speaks of the necessity of considering whether a machine should be disposed of or repaired again. This point is well taken. It takes more than a mere view of the machine itself to determine what to do. A look must be made into the future on the matter of obsolescence, which is so closely connected with the matter of repair that the one should never be considered without the other.

K. D. Hamilton.[9] It is indeed gratifying to see that the subject of maintenance has been brought up from a professional point of view. Maintenance has become today an engineering profession. Years ago it used to be that a Jack-of-all-trades fixed belts, stopped leaks in pipes, repaired boilers, and started up engines. Today, in the large plants, a man has charge of the entire organization, and the managers of the plants today should be convinced that the maintenance department can pay for itself. It should be run as a business. It should be able to compete with outside contractors. It should show a profit and can be proved to show a profit. Business methods should be organized throughout the entire department.

There should be a budget, a system of records of costs, and of prorating those costs among the various departments. The maintenance engineer, or the plant engineer as we should call him, should be an executive equal in standing with the superintendent, directly responsible to the management. He should sell his services as a high-grade executive. He should have charge of heat, light and power, buildings, plant, maintenance of machinery, new construction, and purchase of equipment in cooperation with the purchasing department. He should be able to function as a man who can handle labor, and above all he should prove to his management that he can make a dollar instead of spending it.

If accurate costs are kept of all phases of maintenance, each

[7] Westinghouse Electric & Mfg. Co., East Pittsburgh, Pa.

[8] Consulting Engineer, New York, N. Y. Mem. A.S.M.E.

[9] Mechanical Engineer, Geo. E. Keith Co., Brockton, Mass. Mem. A.S.M.E.

job assigned to each particular number, maintenance men need not fear the point of view which is so readily taken by most managers, that the maintenance department is an unnecessary evil.

M. Sklovsky.[10] The problem of maintenance is so varied in its application—from buildings to the grinding of tools—that the same rules do not apply to all kinds of maintenance. I desire, therefore, to confine my remarks to machine-tool maintenance.

In more recent years the use of machine tools for production purposes has increased so radically that more machines today are used for production purposes than for maintenance purposes. A machine tool originally was a maintenance tool. We have made estimates in recent years and have found that on the basis of metal removed, the amount removed by a production machine was over fifty times that removed by a maintenance machine, so that on the old basis of putting in a new machine and having it last for 25 years it would result in a new machine's lasting only 6 months on heavy production work. It is obvious, therefore, that machines wear out much faster than they did years ago when they were used for lighter work and for maintenance work.

The cessation of production on account of shutdown of machinery is too serious a matter and need not be discussed. It is obvious. The user's problem is to acquire machinery that will stay conditioned the longest possible time and can be maintained in the readiest manner.

Two factors which have been referred to by the persons presenting the papers are very essential. One of them is lubrication. Lubrication—the proper kind of lubrication—assures the longer life of the machine. The haphazard way in which many plants provide rules for lubrication is such that in many cases lubrication is not applied in the proper amount nor with regularity, and for this reason machine-tool builders should definitely provide for the lubrication of all essential wearing parts.

The next point which machine-tool builders will be forced to take into account is the proper kind of bearings, and also, of course, the right kind of driving parts such as gears, etc. Bearings, however, are the most important as we see it. We specify, almost exclusively, roller bearings or ball bearings as the case may be, not from the standpoint, as is usually assumed, of saving power; that is an insignificant point and does not cover the extra fixed charges on added investment, but because roller bearings, for example, can be held in proper location and can be tightened up, and because instead of repairing such parts we prefer to replace them. Replacement of parts can be done readily, sometimes in a half-hour or at most a half-day. The overhauling of a machine with the old type of bearings may take anywhere from three days to three weeks, and during that period the machine is out of commission. We have, therefore, in purchasing equipment stressed the item of bearings that are to go with these machines, and we have found it advisable to pay an added sum for machines so equipped.

As to the organization back of maintenance, we find that the foremen of departments are too overloaded with production problems to be depended upon for the follow-up of maintenance. We leave that entirely to a separate department which has the responsibility for the condition of the machinery. The department foreman may report needed repairs, but he is not held responsible for the condition of a machine.

J. S. Packard.[11] Speaking from a designer's point of view, I should like to hear from some maintenance men who are confronted with the problem of keeping the machines going all the time, what are the faults with machines. Just where do they break down? What are the causes of breakdown?

The subject should be brought right back to where the troubles may start, and that is on the designing board. The man who designs the machines often does not know or cannot conceive the conditions under which those machines are going to be used, and I think I speak for most designers when I say that they personally would be glad to know of the things which cause breakage so that in the future designs they can have them in mind.

Then there is the question of guards. There is really no reason why a designer cannot guard all the moving parts properly unless he wants to close his eyes to the problem or wants to design a machine too cheaply. It is just a question of the viewpoint which the designer has.

There is the factor of gears. A man may design cast-iron gears or steel gears without any consideration of the actual work the machine has to do, nor can he conceive of some of the possibilities of hardship that they may have to endure where a little extra-carbon steel or chrome-nickel steel would make the life of that machine longer.

E. F. DuBrul.[12] I was in an automobile plant some time ago and saw many automatic lubricators attached to machine tools. They had been put on by the automobile company at great expense. They had been installed so that the operator would not have to look after the details of lubrication. Two and three hundred dollars per machine were quite common figures for the cost of installation of these lubricating systems. However, I have been told that the automobile manufacturer was not particularly favorable to the idea of paying two or three hundred dollars extra for the machine tool with the lubricator built in to save him the trouble of putting it on.

One speaker has just remarked that in the matter of removing metal the production tool of today removes fifty times as much metal in a given life as was removed by the maintenance tools of some years ago. I am reasonably certain that none of you are paying fifty times as much for those tools. I am sure that no machine-tool builders are getting fifty times as much for the tools that they are selling today compared to those of early days. But there is the performance.

The more automatic, the more complex the machine gets, the more trouble is built into the machine. I don't suppose it can be helped. Even a large plant having a very well-organized maintenance department will have difficulty, I think, in keeping expert service men capable of knowing all the kicks and quips of all the different kind of complex machines that they are getting in their factory.

Now, who is going to pay for the added expense of service made necessary by the complexity of these machines? Eventually the user has to pay for it. If the builder today does not charge for it he will not be building machine tools after a while. The builder of the future will charge for it, because the builder that does not charge for it today will be out of business after a bit.

Is it fair to put that service charge into the price of the machine, to spread it into the overhead? I don't think so. While that might be an easy way to cover it up, I don't think it is fair to users who are more competent, more careful of their machines, and who do not call for service. Why penalize the user who is efficient and make him pay more for a machine to cover up this sort of factory service by concealing it in the price? The fair thing all around is to charge the man who gets the service, and not to charge directly or indirectly the man who doesn't call for it.

[11] Philadelphia Machine Tool and Sizing Co., Philadelphia, Pa.

[12] General Manager, National Machine Tool Builders Association, Cincinnati, Ohio. Assoc-Mem. A.S.M.E.

A. A. Richardson.[13] Service, generally speaking, is worth paying for. Equipment ought to have service when necessary, and then it is usually asked for. This plan appears much better than to believe it hidden in the price of the machine and paid for whether needed or not. Our plant, however, is more or less independent of the manufacturers' service because of the character of our organization. In many transactions it appears that service is neither more nor less than a good piece of sales argument. Some manufacturers do not regard it so, because we have service men who come to assist in our maintenance work voluntarily. We, of course, have to assume that the cost of it goes in on an annual overhead basis in that company's accounting.

In the National Carbide and Carbon Corporation maintenance is budgeted. In some plants it has been brought to a fine point where it is figured down to the individual machine, and we take that individual-machine maintenance cost over the year as representative of its next year's cost. We analyze that cost, of course, to determine both improvement and obsolescence, one or the other determining the disposition of a machine which is costly to maintain.

In maintenance work, I have been confronted by the problem of encouraging a maintenance force to reduce the cost of maintenance. As a rule the mechanics in the maintenance department are men who are more or less independent of your employment, because nearly all industrial plants have a maintenance crew to take care of the machines and the opportunity for another similar job is good. They also almost always possess a fairly good set of tools, and so can move from one plant to another without much loss. Some of them are expert mechanicians. But they are all paid on an hourly basis. I have inquired to find if time study and management have been applied in maintenance departments to assist in reducing maintenance costs and improving the earnings of the personnel. I have not found it yet. If the incentive of the piece-work rate can be applied to maintenance production, I am sure it will be profitable to all maintenance engineers as a means of reducing costs and improving the quality of the work.

D. R. Long.[14] Our maintenance problem is slightly different from that of the manufacturer of machine-tool equipment, for it consists of maintenance of tools we have designed and built. For that reason about eight years ago we started to chart repairs according to the cause. The cause of a given repair was ascribed by the men who made the repair and their foremen. It was surprising to learn the great number of repairs which could be ascribed to lack of proper lubrication. We found that from 3 to 40 per cent of the repairs charted each month could be attributed to lack of proper lubrication. Over five years it averaged about 30 per cent. Our repairs at that time were running about $400,000 a year, so you see there was a very appreciable amount of money spent for faulty lubrication.

We took the second step, then, to overcome some of the troubles. We organized a lubricating force. We withdrew from all the production foremen and all the machine operators the duty of lubricating the bearings on the machines. Since we organized that force four years ago there has not been a drop of oil kept in a storeroom in any production department. Lubricating men, eleven of them, under the direction of a competent foreman, trained as junior lubricating engineers, have charge of that work. They not only apply the oils and greases to the oiling devices, but select the kind of oil to be used on the particular bearing, and select the type of oiling device which is to be used.

[13] Works Engineer, Niagara Works, National Carbon Co., Inc., Niagara Falls, N. Y. Mem. A.S.M.E.

[14] Chief Engineer, Armstrong Cork Co., Lancaster, Pa. Mem. A.S.M.E.

The third step we took was the selection of a high-grade manufacturer of first-class lubricating oils, and we purchase all our oils from that particular manufacturer. We came to the conclusion that while we might be able to select one lubricant from one manufacturer and another from another and so on all over the country, it would be better to stick to the one manufacturer. We found we could get better prices on account of the volume. We selected a company competent to furnish a satisfactory lubricant for all the bearings and surfaces that we had to lubricate.

The results were threefold: First, as we originally intended, we reduced maintenance appreciably—several times the cost of the wages paid to these men. Second, we increased production through reduction of shutdown time due to repairs, and third, we have been able to work with the engineering department through these lubricating men to get better design. The machines now are designed with some of the lubricating devices and oiling channels that are necessary to apply the lubricant. I think that the feature of maintenance is sometimes overlooked, but it has a very important bearing on reduction of cost, and certainly no maintenance engineer has performed his function unless he has tried to reduce the cost of repairs.

E. J. Kearney.[15] During the last 25 years there has been a revolution in production methods and a revolution in the design and building of machine tools. In the earlier period very simple machine tools were operated by very competent men. Now we have very complex machine tools operated by operators more or less competent. Naturally trouble arises in such a situation.

During this period of machine-tool evolution changes have come about very rapidly. If machine tools could be designed and manufactured without change for a period of years the question of supplying repair parts would be just as simple as it would be supplying repairs for the Model T, but it is not so. The pressure of competition means that almost every lot of machine tools embodies changes, and it is exceedingly difficult for the machine-tool builder to maintain complete records and complete sets of repair parts so that when the maintenance departments of these various plants make requisitions for them he can supply immediately the necessary repair parts.

This question of maintenance will become more and more important. In railway service it has been reduced strictly to a science. The railways classify maintenance strictly on the basis of the performance, and performance is an entirely different thing from what it was 25 years ago.

In all fairness to the user, machine-tool builders themselves through their association should formulate some scientific plan whereby the user, by applying that formula, can tell whether he ought to buy a new machine or repair his old one. There are so many variables entering into this question that it is quite impossible for a machine-tool salesman coming in offhand to answer it. Large factories, at any rate, have no excuse for not approaching the question from a scientific basis. A machine tool may produce three times as much as the one in use and do it better and still not be economical to buy, principally on account of the fact that the old machine may be used only one month out of the year.

There is one phase of maintenance which is often neglected, and that is noise. I was in a factory in one of the New England states just a few days ago, and saw some old machines running that were designed and built in the particular factory where they were used. Apparently they were functioning properly, but a pair of gears that transmitted the power from the pulley

[15] Secretary-Treasurer, Kearney & Trecker Corp., West Allis, Wis. Mem. A.S.M.E.

to the machine was so noisy that it must certainly have put the operators in no great length of time into a state of physcial and mental decline.

Geo. H. Ashman. For the last 23 years the General Electric Company has used the budget system successfully. Every year, revised each six months, the department manager prepares a budget of expense covering repairs and relocation of tools and machinery. He also submits an investment budget of the new tools, buildings, and appliances he may need in the coming year. He prepares this latter from a production estimate given him. Very seldom has this budget been exceeded.

In the last inventory we have 13,000 catalogued tools. At intervals an analysis is made of the repairs that may be necessary to keep them in running order, their fitness for the work they may be doing where located in the plant, and their obsolescence. Records of cost of repairs for each machine are kept. With these data, each superintendent, with his productive-hour capacity as a basis, prepares his budgets of expense and investment. They are subject to revision by the general superintendent.

There is a tool department in each section under the supervision of a tool expert and competent mechanics. A foreman reports to the general foreman that certain machine-tool repairs are necessary; if of a minor nature, this man inspects them and makes the repairs, if in his judgment it is advisable. The question of replacing an old tool with a new one is made by the superintendent of the section on a special request form to the general superintendent of the plant, who bases his decision to purchase largely on the data submitted, showing the productive or working value of the tool as a percentage of the price of the new tool.

W. H. Chapman. I should like to say a word about budgeting and also about the design of equipment. I know of a plant that is successfully budgeting what is termed direct expenses. This is forecast on the basis of the sales forecast broken down into a production schedule and then broken down into direct-labor standard hours which are estimated on a piecework basis to require a definite machine-hour production per month. The forecast is made under a three months' period but is definitely forecast for one month; by that I mean there are forecasts for two months ahead of the month under consideration. The method of arriving at the budgeting takes into consideration the machine-hours, as well as the direct-labor hours, for they are pretty much tied together, and the method used is to merge all of the direct expenditures for each particular operation. The expense forecast is based on the standard-hour forecast and specifies the amount of money to be spent on various accounts during the month.

Of course it will be realized that there must be a very intelligent interpretation on the part of the men who are creating this budget. They must not only be good men from the accounting standpoint, but they also must be familiar with the plant conditions, department conditions, and any special conditions which may arise which are largely a matter of past experience. That is, they must be able to tell what is coming due to performance in the past. In this particular instance the budget last ran between 90 and 100 per cent efficient over a period of months in meeting the forecast. Usually it runs slightly below the actual expenditures.

On the question of design of equipment I should like to stress two points: One is the application of the power drive to the machine, the other, the selection of bearings by the designer. We have more trouble with bearing failure and drive failure than with anything else. I think in all probability most machine tools in the past have not been designed to stress the cutting tool to its efficient limit. In other words, there is an economical rate at which a cutting tool may be employed in the operation, and the machine most certainly should be provided with a drive and bearings which will permit the cutting tool to be used to its utmost capacity, assuming, of course, reasonable wear of the cutting tool. I have in mind particularly grinding machines, which only recently have been developed so that the fullest capacity may be obtained and at the same time satisfactory performance life of the machine without breakdowns.

From the standpoint of lubrication I am an advocate of anti-friction bearings because they use a slight amount of oil and if they are properly installed the oil reservoirs are designed to keep the bearings properly lubricated, and also because of the fact that they can easily be taken out and other bearings put in. Why any operator should have to send to the machine-tool builder to replace a bearing is beyond my comprehension, for the average man should be able to make the normal adjustment without having to call on experts from the machine-tool builder. I should say in cases where this is done that the maintenance men are either behind the times in understanding modern methods, or are thoroughly incompetent from a mechanical standpoint, for there is nothing tricky or incomprehensible about any of the well-known types of anti-friction bearings.

J. R. Weaver. In regard to service, we get wonderful service from the machine-tool manufacturers on machine tools. At times we call their men on certain jobs, but we try to take care of any troubles as far as is possible ourselves. But it seems to me that there is something else necessary in the machine-tool business, and that is probably a closer inspection or a running of the machine tool before it is sent out. In quite a number of cases a machine tool has come into our shop with the gears meshed too tightly or with clutches that will not run at a certain speed. This shows that the machine was asembled and shipped without a proper operating test.

In regard to lubrication, we do not have a central department for lubrication, but we have a corps of men, demonstrators, who are specialists. Each man covers a certain kind of tool and he is responsible for that kind of machine tool throughout the shop. His duty is to train the operator to take the proper care of it. This idea of taking too much responsibility away from the operator is wrong, for he will not take the proper care of it. Teach him that that machine has to do a certain task, that it must be treated in a certain way, and that it must have oil in certain places, and he will be there to do it in case something goes wrong.

In regard to replacement, we keep what we call an open shop. We say that if a machine-tool manufacturer comes in and can justify the expense of new equipment on any job we will buy it. When you say "justify" that may mean several things. Ordinarily we say that if in two, three, or four years it will pay for itself we will replace it. It depends on conditions. The product may change in design and it would not pay to buy a special machine for that job if the design is going to change. If the product is of a stable design we will replace with modern machine tools, even though it may take five years or more to justify the expenditure.

We do not budget repairs solely, but we do budget expense. In other words, budgeting by production each superintendent is allowed a budget of so much to cover jigs, fixtures, small tools, rearrangement, etc. He is required to keep within that budget if it is possible. It is not always possible, but when it is not, he is questioned.

Although we have had no time study on repairs we are anticipating it. We have gone into time study on repairs of small

tools and it is working out satisfactorily. In our tool room we have to a great extent adopted the time-study plan. We are making a study of the repair department to adopt the same thing. It is going to be difficult. It will be divided into certain phases. One set-up will take down the machine, another will assemble it, and another will keep it in repairs. We hope to be able to take care of it in the future.

C. S. Gotwals. We find that it is quite desirable to filter the oil. Oil is often fed to the bearings by the ordinary drop system by the operators, and we find that by placing a wick directly below the reservoir the wick will feed the oil to the bearing as needed. This prevents dirt from getting into the bearing itself. It is also true in other types of machine tools where an industrial filter can be applied.

# Symposium on Hydraulic Feeds for Machine Tools[1]

## Characteristics of Hydraulic Feed and Drive for Cutting Tools

By WALTER FERRIS,[2] MILWAUKEE, WIS.

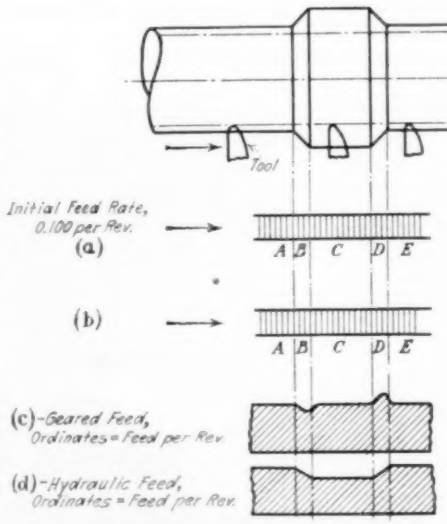
*In this paper the author attempts to show that the application of hydraulic feed and drive for cutting tools has been made possible by the return to the principles of the hydraulic method as it existed before the introduction of the accumulator, and through the introduction of the multiple-plunger pump. The general principles of hydraulic devices used for driving or feeding apparatus for machine tools are presented, particular attention being given to speed control and adaptability to control of inertia forces. The hydraulic drive may be applied either as a straight-line device or as a rotary device. Actual experience during the past five years has developed some peculiarities in the application of hydraulic feeding as compared with geared units, and these are described and discussed by the author. These peculiarities affect more the design of the tools than their field of application. In this connection the author describes the regulating devices and the various types of the application of hydraulic drive, in particular, variable-delivery pumps with closed hydraulic circuits vs. constant-delivery pumps with bypass circuits. He considers flexibility to be the most obvious peculiarity of hydraulic feeds, and illustrates by examples its value.*

IN CONVERSATION with machine-tool builders and users at the exposition in Cleveland this fall, it was apparent that many men who are interested in the evidently increasing use of hydraulic feeds are not yet thinking of the hydraulic method on its own merits. They are still comparing its results with the familiar performance of mechanical devices, and assuming the mechanical method as a standard with which oil-pressure devices are to be compared. There is now no reason why mechanical feeds and drives should be assumed to be superior to oil-pressure feeds and drives, and the two methods should be compared with the idea of visualizing more accurately the exact nature of the hydraulic devices, rather than with the idea of judging these hydraulic devices by comparing their results with the results obtained from mechanical devices.

Five years ago it was assumed that a broach should be pulled by a screw, and a hydraulic broach drive which showed a distinct jump as the broach teeth pulled through the work was immediately condemned for lack of steadiness. Obviously the performance of the screw was assumed as a standard to which the hydraulic performance should be compared. Today it is fully proved that for one reason or another the hydraulic machine is capable of pulling a broach from three to five times as fast as the screw machine, and that the broach will last longer. When hydraulic feeds were first introduced they were similarly compared with mechanical feeds, with the tacit assumption that mechanical feeds leave nothing to be desired. The large number of machines operating with oil-pressure feeds at the Cleveland show is sufficient evidence that there was something wrong with this assumption. Yet the most striking recent innovation—the oil-pressure feed on large milling machines—was strongly criticized because the feed was not perfectly steady and rigid in its advance. It showed elastic follow-up characteristics similar to those which experience has proved to be associated with especially successful operation in broaching machines, drilling machines, and boring machines.

These observations suggest the desirability of carefully analyzing the inherent properties of oil under pressure, taken from a multiple-plunger pump as a driving means. Such an analysis will lead us to examine and think of hydraulic feeds and drives on their own merits in view of the work to be done.

To understand the revival of hydraulic methods in power transmission during the past few years, it is necessary to consider the characteristics of the old hydraulic plants using accumulators,



APPROXIMATE FEED RATES

| | A | B | C | D | E |
|---|---|---|---|---|---|
| GEARED | 0.100 | 0.100 Reducing to 0.080 | 0.080 Increasing to 0.100 | 0.100 Increasing to 0.120 then Reducing to 0.100 | 0.100 |
| HYDRAULIC | 0.100 | Reducing to 0.075 | 0.075 | Increasing to 0.100 | 0.100 |

FIG. 1 GEARED AND HYDRAULIC MACHINE-TOOL FEEDS: EFFECT OF VARIATIONS IN DEPTH OF CUT ON RATE OF FEED

[1] A series of four papers contributed by the Machine Shop Practice Division and presented at the Annual Meeting, New York, December 5 to 8, 1927, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

[2] Vice-President and Chief Engineer, The Oilgear Company, Mem. A.S.M.E.

and to note that practically all the new applications discard the accumulator and substitute a high-speed multiple-plunger pump.

The accumulator method had become thoroughly discredited among engineers due to the uncertainty of control, the shocks and damage to the system from the operation of the accumulator and the throttle valve, and the extravagant consumption of power. Hydraulic machinery was rarely used when any other method was possible. The possibility of dispensing with the accumulator and going back to the first hydraulic principles was opened by the development of the high-speed variable-displacement pump, which would deliver large quantities of

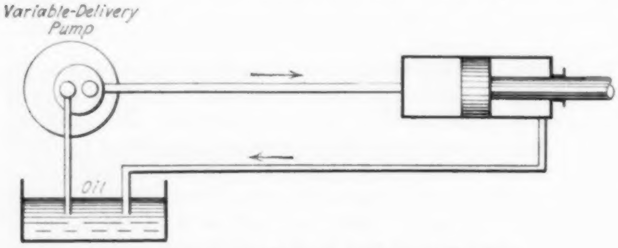


Fig. 2 Hydraulic Feed with Closed Circuit

fluid at high pressures when required, and would graduate the amount delivered exactly in proportion to the position of a control lever, and without regard to the pressure against which the pump operated at the instant. Probably because of the disfavor with which hydraulic methods have come to be regarded, engineers have been slow to realize that those methods are radically changing, and that the hydraulic method is now the only appropriate one for many an operation where it would not have been considered a few years ago. The perfect speed control where there was formerly no reliable speed control, the very high power economy where formerly hydraulic transmission was the most wasteful of all, and the great durability of the working parts running in high-grade lubricating oil and without heat, combine to make the hydraulic method more suitable than either mechanical or electrical methods of power transmission through a great range of applications. The above outlined facts underlie the increase in hydraulic applications, which has led to the assignment of the present session of the Annual Meeting exclusively to the hydraulic operation of machine tools.

The first hydraulic press was driven by a volumetric pump. At every stroke of the plunger the ram advanced a definite

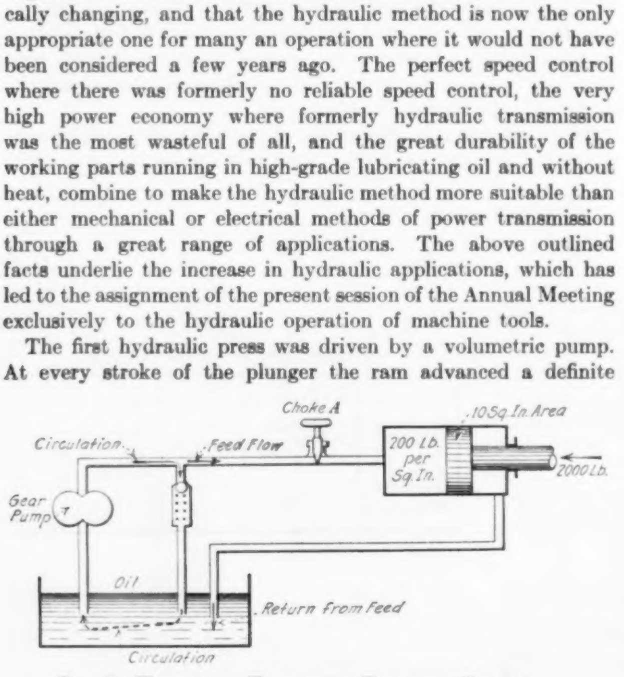

Fig. 3 Hydraulic Feed with Bypassed Circuit

amount. Also if there was no work in the press the pump operated easily, as it was only necessary to overcome the packing friction to advance the ram. If the press was used for baling cotton, the ram would at first move very easily, and as the cotton was compressed, the pressure would gradually rise to the maximum. Thus the original hydraulic press had a speed completely responsive to the rate at which the operator worked the pump, and the work required to drive the pump corresponded exactly to the work actually done in compressing the cotton bale plus friction. At that time, however, the available pumps delivered only very small volumes, and the accumulator was invented to enable this small pump to work continuously and store up its delivered volume. In this way the press could make a stroke in a much shorter time.

But with this change to accumulator operation, the original response of the ram to the pump and the economical performance of the work to be done were both lost. From that time every such hydraulic plant has used the maximum of energy for each stroke, whether the work required it or not. Also the speed at which the ram advanced became uncertain, depending on the opening of the throttle valve and the resistance encountered. The throttle valve introduced intense jet action, causing the minute quantities of abrasive in the liquid to rapidly cut the working parts. The wasted energy was also developed into heat as it passed through the throttle valve, resulting in further damage.

During the past five years considerable progress has been made in the application of hydraulic methods to machine-tool operation. Most of this progress is directly due to a return to the principles embodied in the original hydraulic press, before the accumulator was invented. The new hydraulic devices are driven by definite volumes of liquid delivered from each pump to its operating cylinder. The pressure is low if the piston encounters no resistance, and the distance moved by the piston corresponds to the discharge of the pump, whether the resistance be low or high.

## General Properties of Hydraulic Devices

In considering hydraulic driving or feeding devices for machine tools, the following list of general properties of these mechanisms may be helpful in determining their practicability, and assisting the designer to select the proper hydraulic apparatus.

Some of these characteristics are as follows:

(*a*) *High Efficiency.* This is illustrated by the efficiency of the hydraulic broaching machine, which is from three to four times as great as that of the screw machine. This might have

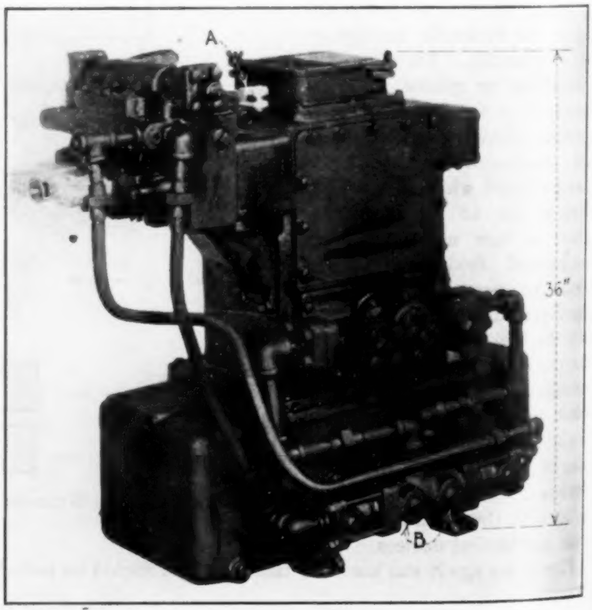

Fig. 4 Automatic Variable-Delivery Pump—Type WM

(*A*, 7-position control-valve stem, operated by cam plate on carriage; *B*, pipe connections to ends of 8-in. feeding cylinder. Pump provides two feeding speeds and rapid traverse in either direction. Capacity, 3060 cu. in. oil per min. at 1000 lb. per sq. in. pressure.)

been easily predicted, but the possibility led to no practical advance in the art for many years.

(b) *Speed Control.* This also has been much discussed, yet its importance in the future development of machine tools is not realized. As applied to feeds it permits the operator, without stopping the machine, to select at any moment the maximum feed which the work and tools will stand. At the Cleveland show the author saw one milling machine demonstrating the maximum application of power to cutting. In one case the feed was a little more than the machine could take. The motor was stalled and the demonstration stopped. With oil-pressure feed the operator would have gradually increased the feed by watching the ammeter for maximum power input. This was clearly illustrated on another machine at the same show. When applied to driving the spindles of lathes or boring mills, a complete hydraulic design will embody a minimum amount of gearing, and automatic hydraulic-gear shafting, so that the operator need only place a pointer on a dial at the figures indicating diameter of cut and cutting speed desired. The operation of such a headstock is explained later in Par. (h).

(c) *Lower Cutting Force.* It has been experimentally proved that a broaching tool working in a given material and at a given speed requires fewer pounds of force to pull it through the work in a hydraulic broaching machine than in a screw broaching machine. The power saving is of no importance commercially, but the fact may be of great significance in investigating the action of cutting tools.

(d) *Adaptability to Control of Inertia Forces.* The gradual change of speed due to the progressive stroke changes in the driving pump is of great advantage in handling heavy masses such as large grinder tables, which must be frequently reversed. This principle had many illustrations at the Cleveland show as applied to grinding machines and honing machines. Some employed closed circuits (see Fig. 2), in which the kinetic energy of reversal is transmitted through the pump to the driving motor. Such circuits may be either high-pressure or low-pressure, and both were represented at the show. Another method is to use constant-displacement, low-pressure pumps and motors, absorbing the energy of reversal by expelling part of the oil in the circuit through regulated orifices (see Fig. 3). The applications so far made would indicate this method for very rapidly reciprocating tables of comparatively small weight such as internal grinders. As yet there is little experience with the closed circuit on such work.

(e) *Flexibility of Design Conditions.* When designing hydraulic feeds it is not necessary to accurately specify the rate of feed required, which can be determined experimentally when the machine is operating. This greatly reduces the losses due to inability to foresee conditions, reduces the time and cost of the design, and increases the output obtained from the machine by facilitating experiment during production.

(f) *Standard Units.* Nearly all hydraulic feeding schemes

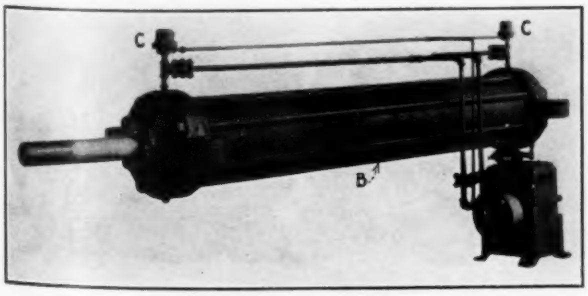

Fig. 5 Hand-Controlled Feed Pump and Cylinder

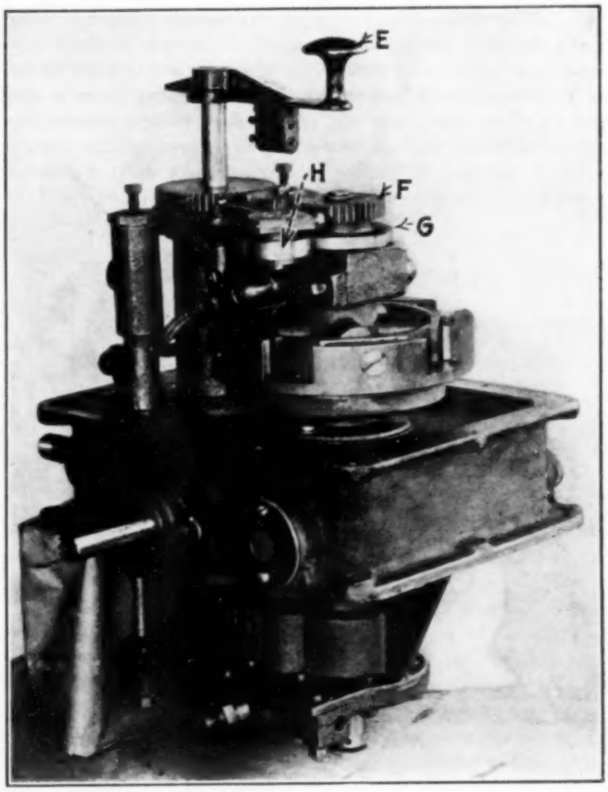

Fig. 6 Pump Removed from Its Oilpot and with Cover Off

can be carried out by using one or another of a series of standardized pumps with the appropriate standardized cylinder or rotary motor. The technic involves a knowledge of many different oil circuits, which are worked out and diagrammed in a manner suggestive of electric circuits.

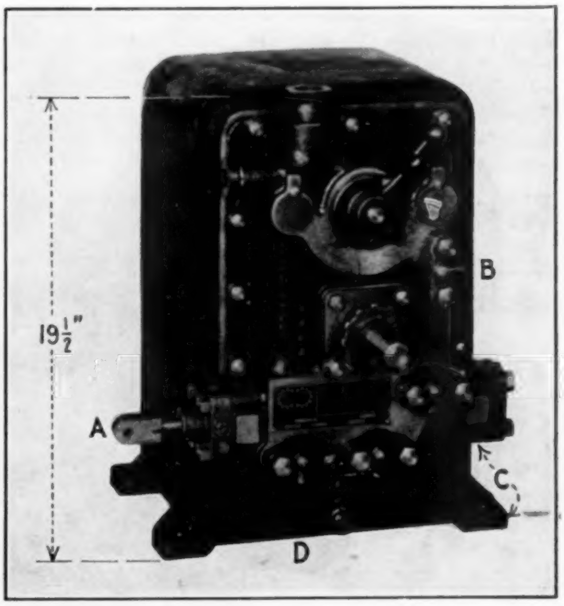

Fig. 7 Automatic Variable-Delivery Pump—Type QS

**(*B*, auxiliary circuit from gear pump to operate fixtures, etc.; *C*, main discharge and return connections; *D*, return from auxiliary circuit. Capacity, 550 cu. in. per min.; maximum working pressure, 1000 lb. per sq. in.; speed of drive shaft, 860 r.p.m.)**

(*g*) *Adaptability for Operating Auxiliary Devices.* Many of the standard feeding pumps available include in their construction a low-pressure gear pump which is used to supercharge the variable-delivery feeding pump, and in many cases is also used to effect rapid traverse. With such pumps connections may be taken out from the gear-pump circuit and used to operate auxiliary clamping devices for holding work, for shifting clutches or gears, or for any other desired function (see Fig. 8).

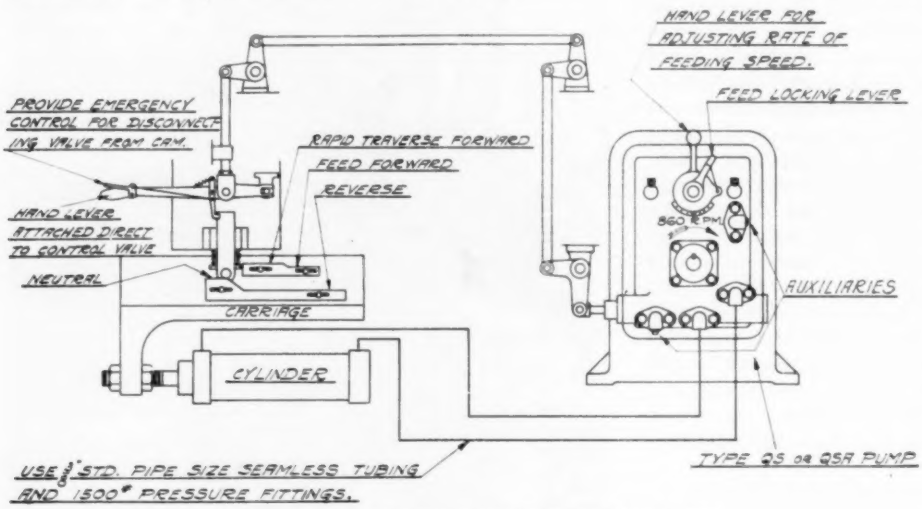

Fig. 8 Method of Operation of Control-Valve Stem

(*h*) *Straight-Line or Rotary Applications of Power.* Every hydraulic transmission consists of a driving pump and a driven motor. The motor may be a reciprocating cylinder, illustrated by honing machines, and in most of the feeds on cylinder feeding and boring machines. Or it may be a rotary motor, illustrated by the large face-grinding machines at the Cleveland show and by rotary-table milling machines where the motion is continuous. The rotary motor comprises the same running parts as are used in the corresponding pump, usually omitting the variable stroke. In the general case of spindle drives, however, variable-stroke motors will become almost as essential as variable-stroke pumps, because spindle drives characteristically require a constant horsepower input which can only be obtained when the pump is running at its full capacity. The speed variation will then be obtained by gradually reducing the motor stroke, causing the motor to speed up as the diameter of the cut is reduced. When the minimum practicable motor stroke is reached (about $^1/_2$ or $^4/_{10}$ stroke) the back gears may be automatically changed to the next faster ratio. The motor will be simultaneously returned to full stroke and the cycle repeated. On facing cuts the r.p.m. changes with the radius of the cut so as to automatically maintain a constant cutting speed. Such a lathe head has not yet been made, but is now only awaiting a machine-tool builder with the vision to appreciate its advantages when compared with the present typical lathe or boring mill. A 20-in. lathe with three sets of back gears may be carried through a range from 14 r.p.m. to 800 r.p.m. at practically uniform cutting speed and horsepower. The spindle would have to be mounted on ball or roller bearings to permit the high spindle speeds. These high speeds made available for small diameters of cut on a turret lathe will in themselves effect a material saving in production time.

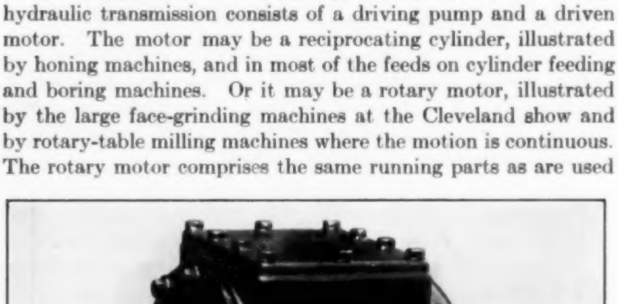

Fig. 9 Constant-Displacement Motor—Type RC

(*Standard:* Displacement, 4.6 cu. in. per rev.; max. torque, 690 in-lb. at 1000 lb. per sq. in.; max. speed, 860 r.p.m.; output at max. speed and torque, 9.4 hp. *Special:* Displacement, 6.08 cu. in. per rev.; max. torque, 920 in-lb. at 1000 lb. per sq. in.; max. speed, 725 r.p.m.; output at max. speed and torque, 10.6 hp.)

(*i*) *Operating a Plurality of Feed Motors.* To have complete individual speed control of two or more hydraulic motors, each motor must be driven by its own pump and the entire flow from the pump must go through that motor. If the flow is divided between two or more motors in parallel, the motor encountering the least resistance may take the entire flow of the pump until that motor has finished its stroke or is stopped by closing a valve in the circuit. Thereafter the motor next easiest to drive will go through its stroke, and so on. The total time required to put all the motors through their cycles will be the same as though they operated simultaneously.

Such an arrangement is indicated in Figs. 11 and 12. In this case the pump stroke may be changed to give any desired speeds while cylinder *B* is operating, and again adjusted for other speeds while cylinder *E* is operating. This is possible

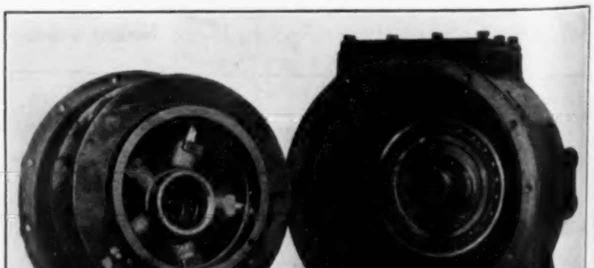

Fig. 10 Interior View of Motor Shown in Fig. 9

because the spring-resistance valves $C$ and $D$ really separate the parallel circuit from the pump through the two cylinders into a pair of individual circuits. The circuit leading to the clamping cylinder $B$ operates below the pressure at which the spring-resistance valves are set, while the circuit leading to the main press cylinder $E$ is operated only by forcing oil through these spring-resistance valves.

(j) *Cylinders in Series.* If the speed control required on two cylinders is simultaneous and proportional, the two cylinders may be placed in series in a closed circuit with a single pump. Such a circuit with three cylinders in series is indicated in Fig. 13. This circuit is applicable to a way drill with three drilling heads. Such heads are usually coordinated mechanically by racks and pinions or by linkage, but the hydraulic method is more flexible, safer against breakage, and in some cases may be cheaper. The three cylinders must be graduated to the speed requirements of the heads. If one head is to move twice as fast as another head, its cylinder must have one-half of the volume. Also, each cylinder must be so designed that the volume displaced in its piston-rod end is equal to the volume displaced in the head end of the next succeeding cylinder. This is evident from the diagram, as the oil supplied to the head end of each cylinder after the first one comes from the rod end of the preceding cylinder.

In order to keep such a set of pistons operating in coordination with each other, they must be arranged to run against the cylinder heads at the termination of each cycle, so that they always start the next cycle in the same relation. Hence the relief valves indicated in the diagram, permitting oil to pass around any piston which has stalled against its cylinder head during the back stroke, thus bringing all of the pistons successively back against their cylinder heads.

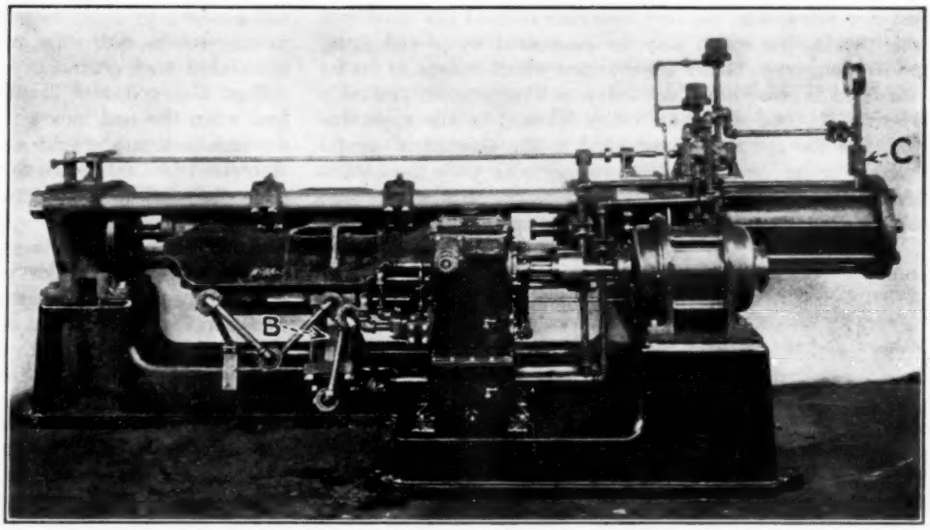

Fig. 12 Rear View of Press Shown in Fig. 11

(k) *Use of Multiple Transmitter.* The series circuit of Par. (j) divides the total working pressure into as many parts as there are cylinders. This reduces the maximum working pressure available in each cylinder, and tends toward large cylinder diameters. For this and other reasons it is sometimes better to use a multiple transmitter consisting of one double-acting cylinder reciprocated by the pump and operating several cylinders whose piston rods are attached to a single crosshead. Each of these secondary cylinders acts as a pump or impeller for its own individual driven or feeding cylinder. This system establishes several separate closed hydraulic circuits, each of which operates its feeding cylinder at definite speeds, the pressure in each separate circuit depending on the resistance against the piston rods of the respective feeding cylinders and on the corresponding piston areas. The strokes of all the impelling cylinders are the same, but their diameters and the diameters of the feeding cylinders may be varied to give any desired feeding forces and strokes to the respective feeding cylinders, provided the totals are within the power capacity of the pump. All speed variations and distances traveled by the pistons of the respective feeding cylinders are proportional to the speeds and distances traveled by the piston of the main cylinder connected to the pump.

In this case also it is necessary to provide means similar to those shown in Fig. 13 to bring each of the feeding cylinders against this cylinder head at the end of every cycle to keep the pistons in coordination. A system of this kind is indicated in Fig. 14, only the principal circuits being shown. In practice, the circuits of both Figs. 13 and 14 require low-pressure make-up lines from pump to each circuit, and other details which are omitted for the sake of clearness.

(Clamping and pressing are accomplished with one movement of a single lever.)

### Inherent Characteristics of Hydraulic Feed

Actual experience during the

past five years with the new hydraulic method has developed some peculiarities which may be considered as proved facts, and has suggested others by evidence which cannot as yet be considered as proof, but which indicates directions for profitable experiment. Still others are really inherent in the apparatus used, but are apt to be overlooked in the absence of careful analysis, or to be clouded by comparisons with mechanical devices.

In the application of hydraulic feeding as compared with

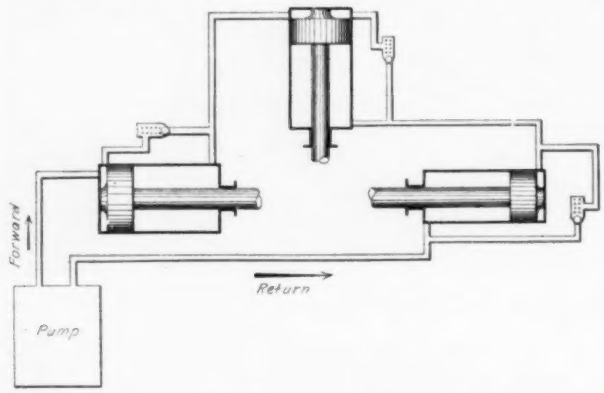

FIG. 13 DIAGRAM OF SEVERAL CYLINDERS IN SERIES

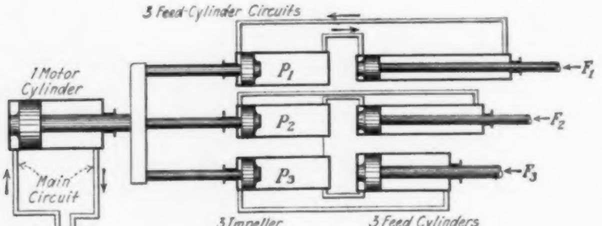

FIG. 14 DIAGRAM OF MULTIPLE-IMPELLER SYSTEM

(Rod speeds vary inversely as the respective piston areas. Pressures $P_1$, $P_2$, and $P_3$ vary with resistances $F_1$, $F_2$, and $F_3$, and inversely as piston areas.)

geared feeds, there are several essential peculiarities which should be taken in account.

(*a*) *Slip.* A tool holder fed by an oil-pressure piston and a volumetric pump cannot be used to chase a thread; and of course its rate of feed is not absolutely constant. There is always a certain amount of leakage (across the bridges and through the plunger fits) in the pump, and this leakage is greater as the cut gets heavier and the oil pressure rises. If the feed is small in inches per minute, this leakage may be a considerable percentage of the pump delivery. This is the "slip." In our early exhibits of hydraulic feed, visitors uniformly assumed that it was a defect. Geared feeds do not slip. The tool must cut the given thickness of chip whether the material is hard or soft, the cut deep or shallow. If the tool manages to back off slightly due to wind-up in the rods and gearing, the lost travel must be made up, and the average thickness of chip throughout the cut must be equal to the geared feed rate.

If the tool is fed by oil from a volumetric pump, it will never move faster than the nominal feed rate, but higher pressures will cause the feed to slow up more or less. The travel lost by this increased slippage is never made up. Hence the tool is not damaged by being forced to maintain the given feed rate, as may be the case when overload causes winding up of the mechanical feed gear.

Figs. 1(*a*) and 1(*c*) illustrate the action of a mechanical feed when the tool moves from a light cut through a heavy cut and back into a light cut. A temporary reduction in the theoretical feed rate when the tool strikes the heavy cut represents the wind-up in feed rods and other elastic parts. This wind-up progresses until it develops a sufficient increase in feeding force to compel the tool to resume its theoretical rate in the heavy cut. If the cut proves to be so heavy that the feeding mechanism is not strong enough, a breakage will occur unless some slipping clutch is provided. When the tool runs out from the heavy cut into the light cut, there is a temporary increase in the rate of feed above the theoretical rate, due to the unwinding of the feed rods, etc. It is thus evident that through the entire range from light to heavy and back again into the light cut the theoretical feed rate is maintained irrespective of the resistance encountered by the tool.

Figs. 1(*b*) and 1(*d*) show the radically different action of a cutting tool driven by a column of oil under pressure from a multiple-plunger pump. The pump has a fixed theoretical displacement which determines a maximum steady flow of oil into the feeding cylinder. This is the maximum rate of flow which the pump would deliver if there were no resistance to the feed. But in practice there is a certain amount of slip or leakage of oil past the pistons or other running fits of the pump, and past the piston in the cylinder. The rate of this leakage depends upon the pressure, and the pressure is directly caused by the resistance encountered by the tool. Consequently the flow of oil actually delivered by the pump into the feeding cylinder is less as the resistance increases. In actual practice this reduction of feed with increasing pressure may be a very significant fraction of the theoretical feed rate, especially with heavy cuts at slow feeds. For instance, a standard $3^7/_8$-in.-diameter feed cylinder has a piston area of 11.8 sq. in., and can deliver a net feeding force of 11,800 lb. to a cutting tool. When working at this maximum pressure of 1000 lb. per sq. in., the slip of the entire apparatus would quite likely amount to 15 cu. in. of oil per min. In ordinary cuts such a feeding cylinder usually operates at pressures of 250 lb. or 300 lb. per sq. in., and the slip is perhaps 5 cu. in. per min. Therefore, if the feed were ad-

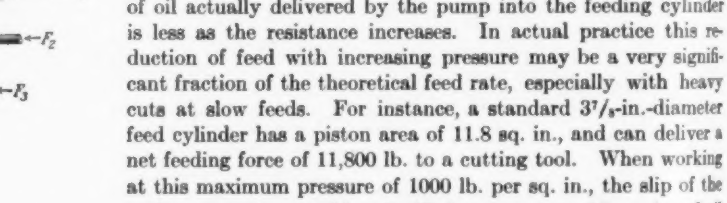

FIG. 15 SPRING-RESISTANCE VALVE

justed to give 4 in. per min. under 250 lb. pressure, the additional slip of 10 cu. in. of oil as the pressure rises to nearly 1000 lb. would reduce the rate of feed by nearly $^7/_8$ in. per min., leaving a net feed of about $3^1/_8$ in. per min. during the excessively heavy cut. This amounts to a 20 per cent reduction in the 4-in.-per-min. rate of feed. If the feed rate were set at 16 in. per min., the reduction would be 5 per cent, as the amount of slip is practically constant for given pressures.

The above figures of amount of slip are based on a type of pump having relatively large leakage through a distributing valve. Other types would show about one-half of the maximum slip.

Fig. 1(*b*) shows that this reduction in rate of feed continues during the entire period of the heavy cut. Also, when the tool runs out again into the light cut the slip of the pump reduces to the former figure, and the rate of feed merely returns to the original 4 in. per min.

(*b*) The foregoing examples show rather extreme variations in rate of feed for the sake of clear illustration. In ordinary cuts there is little change in the rate of feed during the cut. On the other hand, in heavy shaving cuts with a wide tool a still larger proportion of the pump delivery may be represented by slip, and such a cut may very likely end by stalling the carriage against a stop and delivering the entire flow of the pump through the relief valve for a few revolutions until the surface is finished and the tool withdrawn.

(*c*) *Follow-Up.* This is caused by the elasticity of the oil column and the cylinders and conduits which contain it. It would seem to be closely analogous to wind-up in the feed rods and other parts of a geared feed. But in the case of the oil column the amplitude is small and the action is practically frictionless. The effect seems to be to soften or cushion the peaks of feeding force applied to the tool. The author merely suggests the term for use in formulating convenient hypotheses to account for observed greater durability of tools under oil-pressure feed.

(*d*) *Vibration or Resonance in the Column of Pressure Liquid* which receives a rapid succession of impulses from the pump plungers. These impulses have a frequency of from 100 to 200 cycles per second, depending upon the number of plungers and the speed of revolution. Although the rate of flow from the pump is almost uniform, these pressure impulses are very evident at high pressures on an unprotected pressure gage. In high-pressure broaching cuts, the shape and appearance of the chips are also distinctly different when the tool is actuated by oil pressure. The author has reflected on the fact that a man's hand can push a chipping hammer through a cut which, in the absence of the little hammer blows, would require a planer. Possibly there is something analogous in the effect of the tool carriage impelled by the elastic oil column, with the pump imparting impulses to the other end of the column.

(*e*) The intensity of these impulses varies with the pressure, and for such work as grinding, the working pressures must be kept low enough to avoid perceptible vibration which may mark the work. This condition tends to favor the gear pump for reciprocating small grinder tables, as the gear pump is normally a low-pressure unit. However, the gear pump itself has a strong tendency to transmit vibrations, which are probably somewhat damped out by bypassing a part of the discharge through an orifice. The disadvantages of the gear pump are already leading some grinder manufacturers to experiment with low-pressure pumps of variable capacity, to get a definite series of table speeds. This entire phase of the hydraulic-feed art is rapidly developing. It seems likely to the author that grinders of the heavier types will tend to be driven by pumps of definite displacement, with closed hydraulic circuits.

(*f*) *Stalling.* The ability to stall against an obstruction protects the parts against breakage and at the same time provides an ideal method of locating shoulders, facing to length, etc. The relief valve on the pump may be set to limit the stalling force to any desired amount.

(*g*) *Pressure Readings and Regulating Devices.* The pressure gage on either a feeding or driving circuit gives important control over the operations. Dulling of tools is clearly indicated before breakdown of the cutting edge. This is particularly valuable where expensive milling cutters and broaching tools are being used. The habit of watching the pressure gage is now bringing results in controlling the use of tools which will have a strong influence in extending the field for the hydraulic drive.

Various protective and governing devices may be operated by the pressure in the circuit. Broaching machines are equipped with an overload circuit breaker, which may be set to open and bypass the pump discharge when the pull on the broach exceeds any desired limit. Feed pumps are available which will automatically reduce their stroke as the pressure rises. These may be employed to give a gradually reducing feed when cuts become excessive, as in the large fillets in castings and forgings.

Other regulating devices include a time-limit relay in the form of a dashpot attached to the valve gear of an automatic pump. This delays the actual carriage reversal after the feed reverse has tripped, and gives an adjustable time for completion of a facing cut.

### Variable-Delivery Pumps with Closed Hydraulic Circuits vs. Constant-Delivery Pumps with Bypassed Circuits

All of the preceding remarks on the characteristics of hydraulic feed are based on the use of a variable-delivery pump having an adjustable stroke, so that it is set to deliver only the exact amount of oil required for the given rate of feed, plus unavoidable leakage. Fig. 2 illustrates the oil circuit in such a case. For the sake of simplicity the figure shows the pump pushing the piston outward, and omits a valve which must be used to interchange the discharge and return pipes on the in-stroke. It is obvious that this arrangement gives a definite rate of feed proportional to the metered discharge of the pump, less leakage from the closed pressure side of the circuit through the pump pistons and the feed piston. It will also be clear that the rate at which the piston moves will never exceed the rate corresponding to the fixed discharge of the pump, and that greater or less resistance to the movement of the piston will only raise or lower the pressure in the cylinder and connecting pipe to the pump, without materially changing the speed at which the piston moves.

Another type of circuit is extensively and successfully used for reciprocating grinder tables, etc. as mentioned earlier. Such a circuit is illustrated in Fig. 3, showing a gear pump pushing a piston at a rate corresponding to only a fraction of the displacement of the gear pump. The excess displacement escapes through a relief valve into the oilpot and is again taken up by the gear-pump suction pipe and continuously circulated. The pressure in the pipe leading to the cylinder is set at 300 lb. per sq. in. by the relief valve as indicated. As the oil flows through the choke $A$ (which may be an adjustable needle valve) it falls to whatever pressure is required against the piston to overcome the mechanical resistance. As shown in Fig. 3, this pressure is 200 lb. per sq. in. on a piston of 10 sq. in. area to give a feeding force of 2000 lb. Under these conditions, the flow through choke $A$ corresponds to 100 lb. net pressure, determining the rate of flow which will furnish 200 lb. pressure against the piston at the rate of feed for which choke $A$ is adjusted. When the drills break through, or the mechanical resistance is otherwise removed, the pressure in head end of cylinder drops from 200 lb. to 0, and the flow through choke $A$ immediately changes to the rate corresponding to 300 lb. net pressure instead of 100 lb.

If the load to be driven by the piston of Fig. 3 consists of a grinder table weighing 500 or 600 lb. and carrying a grinding wheel whose total feeding resistance against the work is perhaps 10 lb., the load is principally due to inertia and is almost constant, and this type of circuit is distinctly applicable and its advantages are properly weighed by the designer against the advantages of the closed circuit of Fig. 2.

As the bypassed circuit with an inexpensive gear pump is

extensively used for reciprocating tables, it is natural to infer its applicability to hydraulic feeds for drill presses and boring machines. As a matter of fact, drill-press feeds generally require closed hydraulic circuits and variable-displacement pumps.

If these conditions are not met, the results will usually be unsatisfactory. If a constant-displacement pump is used with a choked bypass to reduce the flow into the feeding cylinder to a required feed rate, the following troubles are encountered:

(*a*) A large drill will feed slower than a small one. Several drills will feed slower than one drill. Still more important, after the drills are dull they will feed very much slower than when sharp, at which time the feed rate was adjusted.

Hence the choke valve must be reset for every change in condition. When tried in practice, this is usually unsatisfactory except for very light drilling, or possibly in some cases for drilling wood.

(*b*) *Overheating.* The oil bypassed under pressure during the feed is continually circulated by the gear pump against the full pressure of the relief valve as indicated in the figure. As the gear pump is usually made very large to provide displacement for a rapid traverse movement many times as fast as the feeding movement, almost the entire energy of this large gear pump is continuously converted into heat during the feeding operation. This overheats the oil, generates gas, and makes the feed irregular. In some cases use of the highest possible grade of lubricating oil will reduce these ill effects.

(*c*) Rate of feed cannot even be approximated except by trial.

(*d*) Drills jump ahead excessively when breaking through.

### Flexibility, Extreme Feeding Force, and Durability of Hydraulic Feeds

The most obvious peculiarity of hydraulic feeds as now available is their flexibility. Any rate of feed may be selected and the effect proved on the work. Designers of single-purpose machines do not have to assume feed rates in advance. The feeds given on production tickets may be tried under shop conditions, and increased or decreased to get the best results. Experience shows that the effects of hydraulic feed cannot be predicted by records from mechanical feeds. The essential peculiarities pointed out in the paragraphs on Inherent Characteristics suggest that hydraulic feeding is an art in itself, and should be so treated. Some users report that a given gang of drills may be pushed twice as fast with the oil feed as with mechanical feed. The records of feeds and speeds made with geared machines are not reliable guides for oil-driven machines. The most conspicuous example of the error of relying on traditional practice is the increase during the past few years in broaching speeds from 4 to 5 ft. per min. up to 12 to 30 ft. per min. This performance has been well known in the trade for four years, and during that time many special milling machines have been equipped with Oilgear feed. Yet most makers of standard milling machines doubted whether anything of importance was to be gained by hydraulic feed, until one prominent builder showed a machine doing a heavy form-milling job with a feed of 10 in. per min., when the same builder's best geared feed had only been able to feed the same job at $2^{1}/_{2}$ in. per min. In an example like this the increase is probably due in part to other factors than the hydraulic feed. But the builders of the machine referred to know of no way to get such a high feed rate except by hydraulic pressure. And they state that their cutters stand up better when fed by oil pressure.

*Extreme Feeding Forces.* A car-wheel boring machine has recently been built using four variable-delivery pumps each having a capacity of 3060 cu. in. per min. at 1000 lb. per sq. in. pressure. Two pumps are used for chucking the car wheels, and two for feeding two boring heads. The feed cylinders are 9 in. bore, giving an available feeding force up to 60,000 lb. on each carriage. The usual force is about 20,000 lb. These feeding pumps are shown in Fig. 4. The maximum rapid-traverse speed is about 100 in. per min.

Another example showing the adaptability to very high feeding forces is a machine for facing the ends of built-up structural columns. The cut is not fed across the end of the column, but a faceplate carries radially placed cutting blades, which are fed against the end of the column. The machines already equipped have one 9-in. feeding cylinder, driven by a hand-controlled pump. The minimum feed required is 0.05 in. per min. The feeding force specified was only 20,000 lb. and the 9-in. cylinder was used to make possible the extremely slow rate of feed (see earlier paragraph on slip).

After reporting very satisfactory results, the makers are now specifying a machine to be fed by two 9 in. cylinders in parallel with a single pump, to give a total feeding force of 100,000 lb.

The design in this case is simple in the extreme. Two simple cylinders with abutments to support them on the baseplate, and with piston rods attached to the carriage, a standard pump costing about $400, and a few pipes complete the outfit.

*Durability.* A most significant advantage of hydraulic over mechanical feeds is their indifference to heavy work. A hydraulic outfit will deliver its maximum feeding force day after day for long periods without strain or perceptible wear. Breakage is almost unknown.

### Hydraulic Feeding Units and Oil Circuits

(*a*) Fig. 5 shows a hand-controlled feeding pump *A* with its two pipe connections leading to the two ends of the feed cylinder or press cylinder *B*. At the high points of the pipe lines are automatic air drains *C* with drain pipe back to oilpot of pump.

Fig. 6 shows the pump removed from its oilpot, and with cover off. Control handle *E* operates stroke-changing cam *G* through a train of gears *F*. Cam *G* rolls against a fixed roller *H*, and is held against roller by a light spring and a small hydraulic plunger not shown.

This is the simplest feed-control system, and the automatic pump and circuits shown below are developed around it. This unit comprises two separate pumps; a variable-delivery pump on the upper side of the baseplate, and a large gear pump on the lower side. The latter pump is employed to furnish a large flow of oil for rapid traverse movements.

(*b*) Fig. 7 shows the simplest valve-controlled pump arranged for automatic control. The unit comprises a variable-delivery pump with a slightly larger gear pump to supercharge it. But the flow from the gear pump is not used for rapid traverse, as in Par. (*a*) above.

It has one rapid traverse movement and one adjustable feed in either direction. The control-valve stem *A* has five positions, and is operated from cam plates attached to the table or tool head, as indicated in Fig. 8. This valve operates to control the flow from the variable pump to the feed cylinder, and also controls the admission of pressure from the gear-pump circuit to change the stroke of the variable pump from full stroke for rapid traverse to the preadjusted full stroke.

When very long table strokes are required as in some grinders, or when the table movement is rotary as in some milling machines, it is desirable to use a rotary motor in place of the feed cylinder. Such a motor is shown in Figs. 9 and 10. Its case is about 13 in. diameter. Its capacity in horsepower and in torque is given in the caption of Fig. 9.

The working parts of such a motor are identical with those of the corresponding pump.

Figs. 11 and 12 show respectively the front and rear views of a semi-automatic press for pressing the brake spiders on the ends of a rear-axle housing. The housing is accurately located and held by expanding jaws *A*, Fig. 11, which are operated by the cylinder *B*, Fig. 12. This cylinder must operate through its full clamping stroke before the main pressing cylinder *E* begins its stroke; a requirement which is met by the spring resistance valves *C* and *D* in the pipe leading from the pump to the two ends of the main cylinder. The branch pipes leading to the clamping cylinder have no resistance valves, and hence the clamping cylinder operates first in both forward and return strokes.

The spring-resistance valves referred to are shown in Fig. 15. These valves oppose a definite resistance to the passage of the oil in one direction, and permit free passage in the opposite direction. The valves may be either adjustable or non-adjustable.

### Conclusion

In this paper the author has only aimed to make an outline sketch showing the trend and progress to date of this development. The changes in machine-tool design which have actually come about in the past five years seem sufficient to suggest that every machine-tool designer should now be studying the new hydraulic engineering, as he has learned in the past to study electrical engineering. When a large number of designers in the machine-tool field are actively considering the possibilities of the hydraulic solution of every problem as compared with the possibilities of the electrical and of the mechanical solutions, the true field of the hydraulic method will be rapidly defined, to the great benefit of all builders and users of machine tools.

# Hydraulics and Modern Machine-Tool Design

By WALDO J. GUILD,[1] WORCESTER, MASS.

*After showing that incompressible fluids have advantages over air for machine-tool drive and operation, the author shows how the pressure and volume of the pumping unit are determined by the energy required of the device in a unit time, and passes on to a study of the control devices for regulating the volume of fluid delivered to the driven unit by the throttle valve and bypass valve. Applications of hydraulics to several types of machine tools are then described, with brief comments on the valves employed and on air accumulation in the oil lines.*

HYDRAULIC pressure has been in use for many years in the mechanical trades to obtain movement in its various forms, as can be readily seen in hydraulic presses, testing machines, saw tables in the lumber industry, etc.

Compressed air has also been used to a large extent in the operation of chucking devices, drills, hammers, in the movement of slides from one position to another against stops, etc.; and this development is a very logical one, owing to the extreme flexibility of the application of air for the remote control of distant or moving parts, to its automatic adjustment of pressures at whatever position the mechanism is stopped, and to the ease of employment of high pressures with the minimum of manual labor, all of which make this development a logical parallel to the use of hydraulic pressure.

However, the compressibility of the air itself has defeated all attempts to obtain uniform movement of slides by air. This condition is caused by the necessity of building up pressure to overcome the static friction at the start of the movement, thereby creating an uneven or jerky motion which causes the slide to jump forward until the pressure equals the friction plus the load on the slide.

This uneven motion has caused engineers to turn to incompressible mediums such as water, mercury, or oil, particularly to oil on account of its lubricating qualities, and it has been proved that as long as air is kept out of the system, it is a very efficient means of transmitting a steady flow of power.

### How Hydraulic Power May Be Applied to Machines

First, let us consider how this power may be applied. Any mechanical movement, reciprocative or rotative, that is to be obtained hydraulically can be figured to require a certain maximum amount of energy in a given interval of time, as, for example, inch-pounds per minute. Hydraulically this means pressure per square inch times the area in square inches of the surface on which this pressure is impressed, times the travel of the said surface in inches per minute.

This reduces, of course, to pressure per square inch times the displacement in cubic inches per minute, a direct indication of the capacity of the pumping unit required, subject to correction for losses by friction in pipe lines, by leakage, etc.

Having determined the pressure and volume required in our pumping unit to satisfy the maximum requirements of our mechanisms, let us see how we may control this mechanism from rest to its maximum speed; for, aside from its simplicity of application as a transmitter of power, the most outstanding advantage of this hydraulic transmission of power is in its sensitive and easy control of the speed of the driven mechanism.

If we pass the entire output of our pumping unit through our driven unit, the speed of this driven unit may be regulated by controlling the volume delivered by the pumping unit by varying either the latter's speed or its displacement. This constitutes a very efficient means of control, limited only by the mechanism involved to accomplish the result.

Speed control may also be obtained by means of a throttling connection between the two units. If this throttle is closed, the flow of fluid will not pass to the driven unit, and therefore the driven unit will remain at rest or stop if it is in motion. The output of the pumping unit in excess of momentary requirements must be taken care of by a bypassing relief valve set to open at slightly above the maximum pressure needed for maximum requirements. In other words, the pumping unit becomes a nominally constant-pressure unit as well as a constant-volume unit. Truly, it imposes a constant load on the factory power system, but matched against this is its simplicity and general utility. The pumping unit becomes a common source of supply from which a number of various mechanisms may be operated, governed by their individual controls, up to the limit of its own capacity. The relief valve takes care of the excess volume and maintains full pressure on all of the lines at all times.

### Examples of Application of Hydraulic Pressure in Machine Tools

The following outline of several different applications of hydraulic engineering to machine tools will give a brief idea of what is being accomplished in this field.

[1] Chief Engineer, The Heald Machine Company.

Internal-grinding-machine tables are being reciprocated at high speeds with practically no shock at reversals. This is accomplished by using a double-acting-cylinder unit, to drive the table in either direction, controlled for reversing by a four-way valve which connects one end of cylinder to the pressure line and the other end to the exhaust line in one position of the valve, and reverses these connections in its other position. Various types of valves are used, some of the piston type, some of the disk type, and still others of the taper or stop-cock type. This reversing valve is operated by dogs on the table, adjustable for various lengths of stroke and relative position of the stroke to other units. Reversal of the valve by the dogs at each end of the stroke may be wholly by mechanical actuation, or may be accomplished through the actuation of a supplementary valve or valves which in turn actuate the main valve hydraulically. To obtain reversals at high speed, oil dashpots are generally employed in the reversing mechanism to impede its action. However, the use of a relief valve on the main oil supply automatically prevents the rapidly moving table from being at any time imposed against an incompressible body of oil in a closed chamber.

As stated, previously, air must be kept out of the oil system to insure smooth motion. This means tight joints in the pipe lines, especially on the suction side of the pumping unit. At best, however, some air will be picked up by the oil, and must be allowed to escape. This may be done by the occasional opening of pet cocks at the highest points in the system, or will be done automatically if provision is made to keep the oil in motion at the highest point, thereby carrying the air with the oil back to the reservoir tank. Sharp turns in the pipe lines should be avoided, if possible, to reduce friction. Eddy pockets should be avoided as these tend to separate the air which the oil may be carrying in solution.

These grinding machines also gain in speed control by the use of oil transmission of power. By the use of suitable throttle valves and bypass valves, four changes of table speeds are employed during the grinding of one work piece: a rough-grinding speed, a wheel-dressing speed, a finish-grinding speed, and a fast speed for separation of wheel and work to allow room for chucking. The three first named are all adjustable independently.

Oil pressure is also made use of on machines of this type, for the operation of chucking devices, for the opening and closing of chuck guards, for the actuation of diamond dressing tools, etc.

On other types of grinding machines, oil pressure is used to obtain feed of the wheel to the work, either by increments or continuously, during the grinding operation. Wheels are rapidly advanced to and withdrawn from grinding position, as in the grinding of crankshafts. These crankshafts are now being clamped by hydraulic pressure with the mechanism interlocked so as to prevent any grinding being started before the clamps are in proper position.

Wheels are being carried across the work surface at slow speed in one direction and retracted in the opposite direction at high speed, by interposing a valve which will throttle the oil supply when passing through in one direction and which will open as the direction of oil is reversed—a modified check valve. This valve of course is placed between the main reversing valve and one end of the cylinder.

Indexing mechanisms are being operated and locked by hydraulic pressure on various types of machine tools.

Broaches are being pulled through by hydraulic-cylinder units.

Drills and cutters are being held into their cut at a uniform pressure by hydraulic means, with an automatic withdrawal at the completion of the operation.

It will thus be seen that the use of hydraulic pressure on different machine tools and also for different movements in any one machine tool is of great value in eliminating complicated mechanisms with their attendant strains and bearing friction.

Hydraulic pressure is rapidly being applied to all types of machine tools and fixtures, and its uses are practically unlimited as it remains only necessary to solve the problem of the proper method or system of application.

# Hydraulic Feeding Mechanism for Milling Machines

By SOL. EINSTEIN[1] AND HANS ERNST,[2] CINCINNATI, OHIO

*After giving a brief history of the development of power-driven feeding mechanisms for milling machines generally, the authors describe a hydraulic system which they believe meets the conflicting requirements which a power-driven feeding device on milling machines should satisfy. The operating characteristics of a hydraulic feeding device are stated and the various circuits such as the feeding, rapid traverse, etc., are described. The purpose of the differential pressure-control valve is stated, and the device illustrated and described. By lowering the idle pressure as compared with that required by the simple relief-valve system and by holding the pressure at all times to the level required for the cut taken, this device increases the cutting capacity of the machine and its mechanical efficiency. At the same time it reduces the variation in back pressure under intermittent cutting, and consequently produces a smoother table movement.*

THE development of power-driven feeding mechanisms on milling machines has proceeded along lines similar to the development of other machine tools.

The first milling machines built some hundred or more years ago had no power-driven feeding mechanism at all. About the middle of the last century the so-called Lincoln-type milling machines were introduced, and on these the table-feeding mechanism was driven by means of a belt and multiple-step cone pulleys, thus providing a variable feeding rate. Structural limitations of pulley diameters and belt widths resulted in their restriction to relatively light cuts and correspondingly slow feed rates. The rate of table traverse was a function of the number of revolutions per minute of the spindle, since one cone pulley was placed on the spindle itself and the other upon the feed driving shaft.

Toward the end of the last century and the early part of the present century milling machines with positively driven feed-change mechanism began to make their appearance, and with this construction faster feed and heavier cuts became possible. The disadvantage of the construction then used, however, was that the feed transmission was still driven from the spindle. Thus when the spindle rotated at slow speed the rate of feed in inches per minute was slow even when the fastest feed of the mechanism was used, while when the spindle was running fast an exceedingly high table travel resulted. This was frequently too high for practical use, even when the slowest feed rate was employed.

[1] Chief Engineer, Cincinnati Milling Machine Company.
[2] Research Engineer, Cincinnati Milling Machine Co.

To overcome this difficulty a drive of the feed mechanism entirely independent of the rotation of the spindle was developed, thus providing feed rates in inches per minute.

With this construction the spindle and feed mechanism were driven from the same source by independent belts, and whenever the spindle-driving belt slipped, an accident resulted.

With the advent of the single-pulley milling machine with self-contained speed-change mechanism the feed transmission was driven directly from the pulley shaft. Feed rates in inches per minute and independent of the spindle speed were

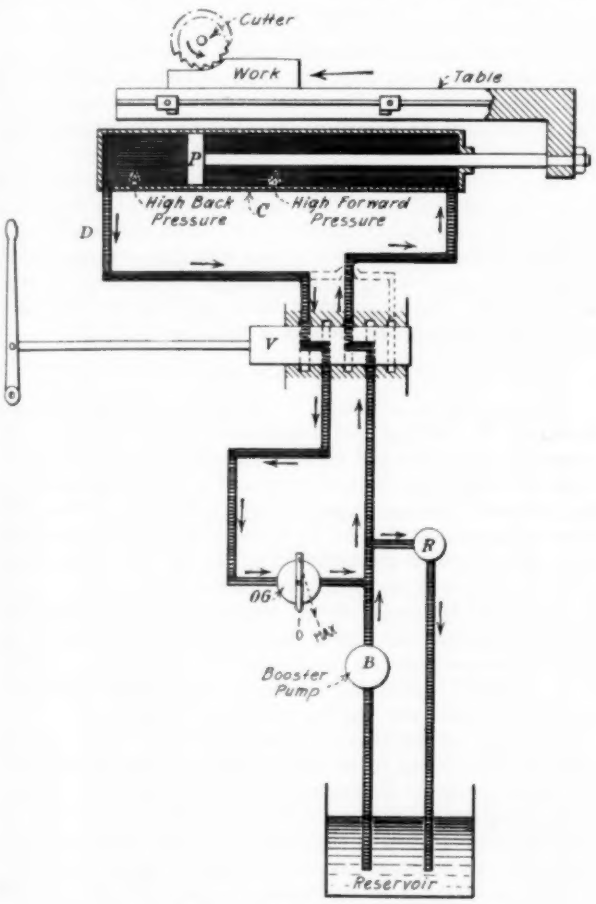

Fig. 1 Feeding Circuit

provided, and at the same time the possibility of a wreck as indicated above was avoided.

At the present time the rates of traverse provided on milling-machine tables vary through a wide range. This is due not only to the great variety of materials milled but also to the great variety of diameters and types of cutters used. Consequently we find many milling machines with a feed range of from $^1/_2$ in. to 30 in. per min. (i.e., a ratio of 60 to 1).

To cover such a large range with a mechanical feed-change mechanism naturally requires a large number of gears, as in order that the most economical feed rate may be used for each individual job it is essential that the gaps between successive rates be not too great. As usually arranged, the mechanism provides a feed rate advancing in a geometric progression, and even an increment of 20 or 25 per cent might not give the most economical feed rate.

It is therefore desirable to have as large a number of feed changes and as close a spacing as can possibly be provided.

Frequently the amount of metal to be removed on various sections of the piece varies considerably. The amount to be removed at one place may be 10 cu. in. per min. and at another place only 3 cu. in. per min. For production work it is impracticable to manually change the rate of feed during the cutting operation in order to utilize as nearly as possible the maximum capacity of the machine. It is, however, very desirable that such an automatic change of feed rate shall be obtained for maximum production.

In other classes of work it is desirable that when the cutter enters the work the feed rate shall be slow, so that the work will not be lifted out of the fixture or vise. Later the feed rate may be materially increased, and thus the cutting time of the piece reduced.

On work where feeding against a shoulder or into solid metal is required, automatic decrease of the feed rate is very desirable, thus increasing the production and at the same time raising the grade of finish.

These are some of the problems which up to this time have not been satisfactorily solved in production milling.

Frictional feed devices of course provide just the conditions desired but lack positiveness and durability. Mechanical devices give positive feed but lack flexibility.

The hydraulic system described below as embodied in the Cincinnati Milling Machine Company's "Giant Hydromatic" fully meets these conflicting requirements.

## General Characteristics

In the application of hydraulics to the reciprocation of a milling-machine table the following operating characteristics must be provided:

1 Reciprocation in either direction at normal feeding rates
2 Reciprocation in either direction at rapid traverse rates
3 Positive control of feeding movement regardless of the direction or amount of the resultant cutting force
4 A locked condition of the table when in the stopped position, thus rendering it incapable of movement under the action of the cutter
5 The ability for accurate reversal of the table under any cutting condition
6 A readily controlled acceleration or deceleration of the feed rate during a cut
7 Economical operation.

Items 3, 4, and 5 are particularly necessary whenever the resultant cutting force may lie in the same general direction as the normal feeding movement. This condition frequently occurs in face milling when the arrangement of the work surface is such that it engages with the cutter on the lower portion only. It also occurs in certain classes of slab-milling and slot-milling work, where a downward movement of the cutter upon the work has been found to possess marked operating advantages.

The above operating characteristics have been obtained in the present instance by the use of a special combination of pumps and auxiliary devices arranged to provide a locked control system; this system being the outcome of a great deal of experimental work with a considerable variety of circuits.

## The Feeding Circuit

Fig. 1 shows in simple diagrammatic form the arrangement of the elements involved in the feeding circuit only. $C$ is a cylinder securely bolted to the bed and carrying a sliding piston $P$ connected to the table by a substantial piston rod. $V$ is a reversing valve; $OG$ an Oilgear variable-displacement pump, and $B$ a small high-pressure booster pump coöperating with the latter to produce a continued forward pressure upon the piston $P$,

the amount of this pressure being determined by the setting of the relief valve *R*.

The space within the cylinder on both sides of the piston is at all times completely filled with oil, consequently, in order that the piston may actually be moved in a given direction by means of the forward pressure, it is necessary that the oil on the other side may be able to escape.

If no escape is permitted there will be no movement of the piston; if some escape is permitted then the piston will advance just as fast as the escaping oil will allow it, and with a positively controlled escapement the rate of advance is virtually independent of the amount of forward pressure applied.

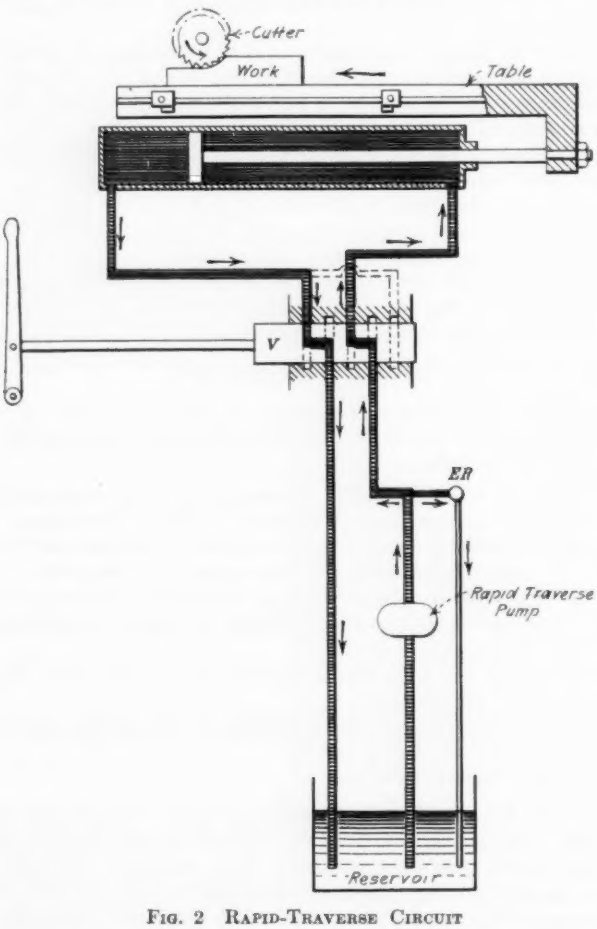

Fig. 2 Rapid-Traverse Circuit

From Fig. 1 it is evident that the only avenue of escape for the oil from the rear end of the cylinder is by way of the pipe *D* through the reversing valve and thence through the Oilgear pump. Consequently, the quantity of oil permitted to escape from the cylinder is definitely fixed by the displacement of the Oilgear pump. As the displacement of this pump may be varied at will from zero to maximum, it is obvious that in this way the forward rate of the table may likewise be readily varied from zero to maximum. Furthermore, in contradistinction to ordinary practice the feed rate is determined not by the amount of oil fed to the cylinder, but by the amount permitted to escape from the discharge end. In this way a high back pressure is built up to resist the movement of the piston, thus providing a constantly receding restraint.

The amount of this back pressure is not constant but varies with the direction and amount of the resultant cutting force. In the case of an upward cut (i.e., *against* the direction of the feed) the back pressure is approximately equal to the forward hydraulic pressure minus the horizontal component of the cutting force, whereas in the case of a downward cut (i.e., *with* the direction of the feed) the back pressure is approximately equal to the forward hydraulic pressure plus the horizontal component of the cutting force. The exact figure in each case is dependent also upon the amount of the frictional resistance encountered by the table, and upon the ratio of the effective areas of the two sides of the piston.

### Rapid Traverse

The circuit described above pertains to a movement of the table at feeding rates only. In order to provide in addition a high table speed for rapid approach to the work and rapid return, use is made of an auxiliary, large-volume, low-pressure gear pump.

Fig. 2 shows in diagrammatic form the arrangement of the rapid-traverse circuit, and from this it is evident that operation of the reversing valve to right or left causes an alternate connection of the opposite ends of the cylinder to pump and to reservoir, thus providing a rapid traverse of the table in either direction. An emergency relief valve *ER* is provided to safeguard the system in the event of a table jam.

### Combined Circuit

For the sake of simplicity in the foregoing paragraphs and sketches, the feeding and rapid-traverse circuits have been separately described and shown. In actual practice both circuits are interconnected and operated by a common control or selector valve arranged to provide both a reversal of table movement and a change of speed from feed rate to rapid traverse, or vice versa. This is accomplished by the use of a valve having both reciprocatory and oscillatory motion.

The entire hydraulic circuit, together with the effects produced by successively placing the selector valve in each of its four operating positions, is shown diagrammatically in Figs. 3, 4, 5, and 6. An auxiliary valve to start and stop the table movement under any condition is shown at *S*.

Inspection of the above diagrams will show that when the selector valve is set to provide a rapid traverse movement of the table the entire feeding system is short-circuited, and similarly, when set to provide a feeding movement of the table the rapid-traverse system is short-circuited; thus either system is independently available at will for table reciprocation.

A check valve *H* in the rapid-traverse-pump discharge line provides a means for preventing a reversal of flow in this line, and thus permits a rapid return movement of the table even when in the middle of a heavy downward cut. Without this valve the horizontal force imparted by the cutter to the table in the direction of its feeding movement would be sufficient to overcome the relatively low rapid-return pressure, thus reversing the flow in this line and opening the emergency valve *ER*. Such an action would permit a rapid escape of the back-pressure oil, with a consequent jamming of the work under the cutter.

By the provision of the check valve *H*, this reversal of flow is prevented and the cutter is permitted to properly clear itself before the initiation of the return movement.

### Differential Pressure-Control Valve

In the foregoing description of the feeding circuit the forward pressure has been assumed to be maintained at a constant value by the relief valve *R*. In actual practice, however, this is not the case.

In order to obtain economical operation and also to maintain a steady table movement, it is desirable that the forward pressure

be not constant but be automatically adjusted to meet the various operating conditions. This is accomplished by the use of a special differential control valve (D.C.V.—Fig. 4) which takes the place of the plain relief valve shown at *R* in Fig. 1.

As previously described, the back pressure on the piston under all conditions is a function both of the forward hydraulic pressure and of the horizontal component of the cutting force. For the simple circuit shown in Fig. 1 (where the forward pressure is maintained at a constant value) the variation in back pressure due to changes in direction and amount of the cutting force is approximately as shown in Fig. 7.

With a downward cut the back pressure rises; with an upward cut the back pressure falls. Thus, from the curves shown, it is evident that with a constant forward pressure of 600 lb. per

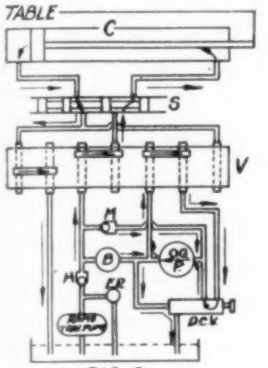

FIG. 3

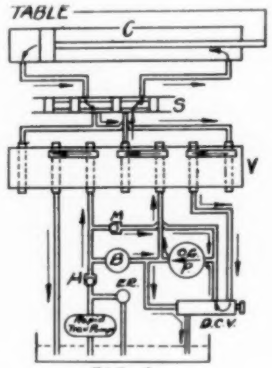

FIG 4

Fig. 3 Rapid Traverse to Left

Fig. 4 Feed to Left

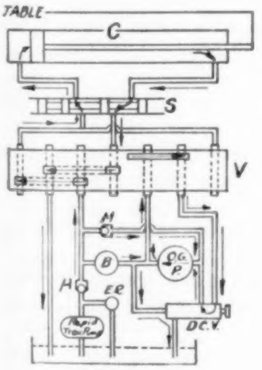

FIG. 5

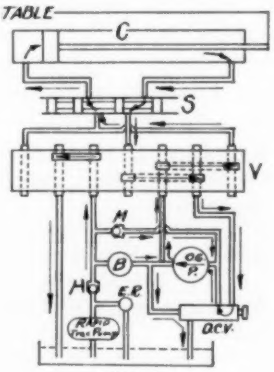

FIG. 6

Fig. 5 Rapid Traverse to Right

Fig. 6 Feed to Right

sq. in. and a cylinder of $4^1/_2$ in. bore the limit of upward cutting is reached with a horizontal cutter load of approximately 8000 lb.; the back pressure under these conditions being reduced to zero. With a downward cut the increase in back pressure is directly proportional to the resultant horizontal force imparted by the cutter to the table, and it will be noted that when this force has a value of 7500 lb. the back pressure (feeding to right) has already reached a value of 1200 lb. per sq. in.

Furthermore, with such a rapid change in back pressure relative to the cutting force, the effect of momentary changes in this force (as caused, for example, by the successive impacts of the cutter teeth, and by the eccentricity of the cutter itself) may become unduly great. It may readily be shown mathematically that owing to the compressibility of the oil these changes in back pressure, with the resulting volumetric variation in the oil itself, may cause an objectionable degree of table movement. This is overcome, as stated above, by the use of the differential valve.

Fig. 8 shows the general arrangement of this differential valve. The end *A* is connected to the forward pressure line, and the plunger end *B* acts in an exactly similar manner to that of the simple relief valve shown in Fig. 7(*a*) to permit the escape of the excess oil supplied by the booster pump. The back-pressure oil returning from the cylinder enters this valve through the inlet port *C* and passes out through the outlet port *D* on its way to the variable-displacement pump. In passing through this valve the back pressure also acts by way of the radial and axial holes *E*, *F*, and *G* upon the enlarged plunger head *H*, thus assisting the forward pressure in its work of moving the plunger against the compression of the spring *J*.

Thus it is obvious that if the back pressure be reduced, the forward pressure must carry a greater proportion of the spring load and thus will be correspondingly increased; whereas, if the back pressure be increased, the forward pressure will correspondingly decrease.

The effective area under the head *H* upon which the back pressure acts is, in the present instance, three times the area of the end *B* acted on by the forward pressure. Thus, for a given change in back pressure, the corresponding change in forward pressure is three times as great.

The relation between forward and back pressures for any resultant force under these conditions is shown in Fig. 9. It will be noted that by the use of the differential valve the capacity of the machine has been tremendously increased. In upward cutting the back pressure does not fall to zero until a cutting force of approximately 15,000 lb. has been reached, yet at this time the forward pressure has not exceeded a satisfactory figure. With a downward cut of 6000 lb. the back pressure is only 400 lb. per sq. in., the forward pressure at this time being reduced to about 50 lb. per sq. in.

Under these conditions the forward pressure has reached the limit set by the natural throttling of the oil through the small orifice *K*, thus no further reduction can take place, and consequently for increased cutter loads in this direction the back pressure will increase at a faster rate. This accounts for the sharp upward break in the back-pressure curve at this point.

In order to safeguard the machine against excessively heavy downward cuts, the upper portion of the differential-valve plunger is provided with a tapering shoulder *L*, which acts under a predetermined limit of pressure to shut off the flow of the back-pressure oil to the variable-displacement pump, in this way tending to reduce or entirely stop the table feed.

In upward cutting, a limit is automatically provided when the back pressure falls to a low value. Under such circumstances a check valve *M*, Figs. 3 to 6, opens to admit a flow of oil from the rapid-traverse-pump discharge line to the variable-displacement-pump intake. This tends to keep the entire system filled with oil under pressure at all times and permits an uninterrupted normal operation of the variable-displacement pump under all operating conditions.

By the use of the differential valve, the idling pressure has been lowered to 300 lb. per sq. in., as compared with at least 600 lb. per sq. in. required by the simple relief-valve system, and at all times the pressure is advanced only to the degree required for the cut taken. Thus the cutting capacity of the machine and its mechanical efficiency have been greatly increased; and furthermore, by virtue of the compensating action provided, the variation in back pressure (and consequent irregularity of table movement) have been reduced to a satisfactory condition. Surging of the valve is prevented by the choking

action of the restricted passage space between the plunger portion *H* and the valve-body bore.

### Practical Application

In the development of this hydraulic feeding system a considerable variety of circuits and devices were experimented with

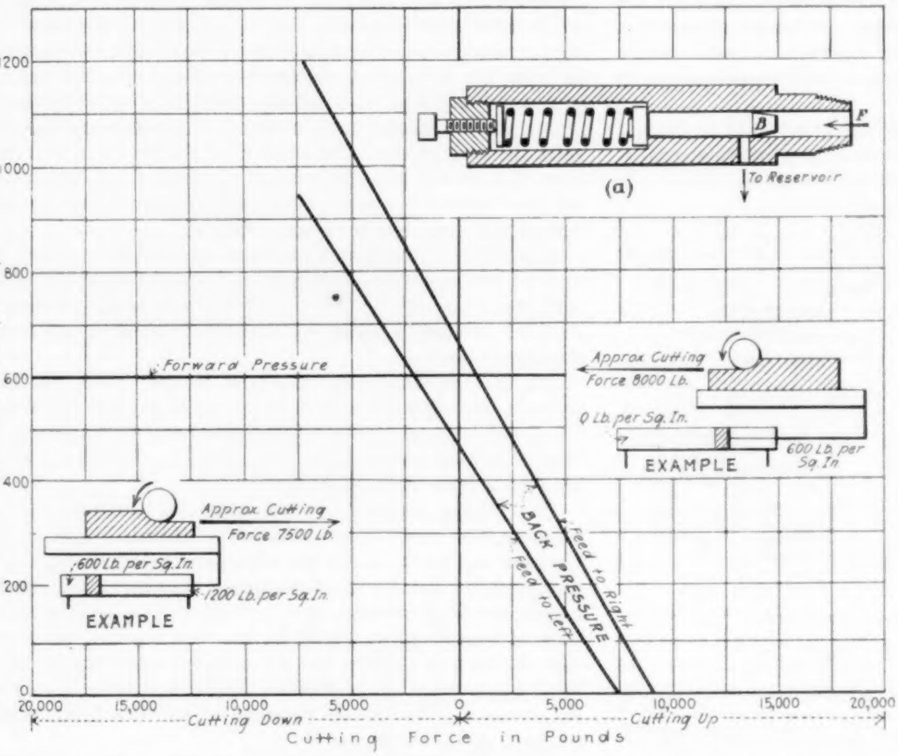

Fig. 7 Approximate Relation Between Forward Pressure, Back Pressure, and Cutter Load with Simple Relief-Valve System

to determine their ability to fully meet production milling conditions.

For this purpose the various experimental elements were arranged as shown in Fig. 10, the pumps being independently driven, and connected with the cylinder and valve members by means of piping. In this way any desired circuit could be arranged and tested under actual milling conditions. The final circuit as described above is the result of this investigation.

In its practical application the system has been reduced to a few relatively simple parts so grouped as to form a compact yet readily accessible hydraulic unit. As shown in Figs. 11 and 12, the elements used comprise the rotor and pendulum of a standard Oilgear pump, a small booster pump of extremely simple construction, a high-grade gear pump, and the necessary control valves. External piping has been practically eliminated, the various interconnections being chiefly made by drilled holes through the various parts. This insures a correct and dependable arrangement of the circuit, and adds greatly to the neatness and reliability of the entire system.

From Figs. 11 and 12 it will be seen that all three pumps together with the control valve and auxiliary mechanisms are compactly arranged in a single casing, an extended lower portion of which forms the oil reservoir. As shown in Fig. 13, this unit is attached to and forms the closing member for the rear portion of the main bed structure of the Cincinnati "Giant Hydromatic" miller, two pipe unions only forming the connection from the unit itself to and from the table cylinder.

This construction renders the entire unit readily removable and furthermore any slight leakage from pumps, valves, etc. is directly returned to reservoir.

### Elimination of Air from System

In any hydraulic system used in the operation of machine tools it is essential that special care be taken to eliminate air from the entire circuit. This is successfully accomplished in the present instance by the provision of an air-drain coil in each cylinder head.

These air drains each consist of a tightly wound coil of about 36 ft. of 0.045-in.-bore copper tubing, one end of which communicates directly with the inside of the cylinder at a point close to the top, and the other end with a pipe leading to reservoir.

As the resistance to the flow of air through these tubes is so much less than that encountered by the oil, a ready escape is provided for any air which may enter the cylinder, while the leakage of oil through the same tubes is an insignificant amount.

### Advantages Gained by the Use of Hydraulic Feed

1 *Flexibility of Feed Control.* The advantages gained by the use of hydraulic feed are as follows:

*a* Any desired feed rate from zero to maximum. As previously stated, this is accomplished merely by the setting of the pendulum of the variable-displacement pump from zero to maximum.

*b* Automatic change of feed rate during cut (if desired), thus providing maximum metal removal.

*c* Any desired cycle of feed and quick traverse in either direction, together with automatic stop or feed change at any point.

*d* Possibility of milling in a given direction until the table encounters a positive stop, then dwelling to allow cutter to clear itself, and after a predetermined short interval of time automatically returning the table at a rapid traverse rate.

*e* Accuracy of trip. Owing to the fact that no clutches or other mechanical devices are employed which may carry varying loads depending on the size of the cut taken, the tripping from feed rate to rapid traverse or vice versa is very accurate. This is assisted by the particular design of valve used, which provides a balanced condition at all times.

Item *b* is particularly valuable in production milling wherever the width of piece to be milled is not uniform throughout its length. Under existing practice it is necessary to limit the feed rate for the entire piece by the proper rate for the widest part, whereas with the hydraulic system a simple cam may be arranged as shown in Fig. 13 to automatically adjust the feed rate to the amount desired for each successive table position.

Figs. 14 and 15 show the benefit derived by the use of this feature on a typical face-milling job. The curves shown were

described by a graphic wattmeter and thus indicate both the instantaneous power required and the length of time taken for the entire piece. With a constant feed rate as in Fig. 14 the maximum power was required for a relatively short space of

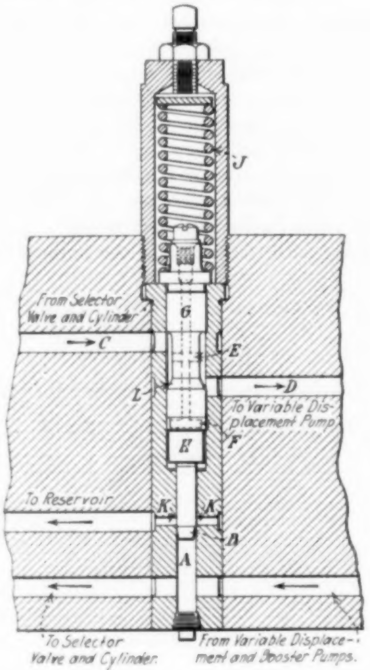

FIG. 8 GENERAL ARRANGEMENT OF DIFFERENTIAL CONTROL VALVE

time, the entire cut taking 137 seconds. On the other hand, with the cam-adjusted feed rate as shown in Fig. 15, this time was reduced to 100 seconds, the maximum power being approximately constant throughout the entire cut.

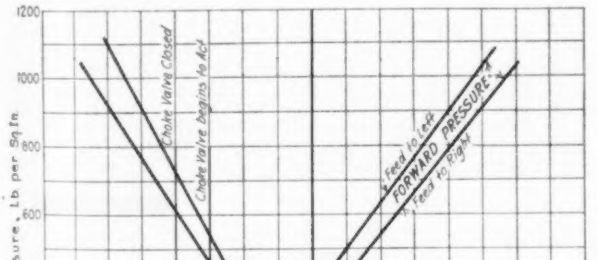

FIG. 9 APPROXIMATE RELATION BETWEEN FORWARD PRESSURE, BACK PRESSURE AND CUTTER LOAD
(With differential valve; ratio 3:1.)

By the use of an auxiliary hydraulic attachment a similar automatic adjustment of feed rate to suit the work can in certain cases be provided, thus eliminating the need for a special cam.

2 *Longer Cutter Life.* In the application of hydraulics to broaches, drilling machines, and other machine tools one of the most outstanding characteristics noticed has been an exceptional

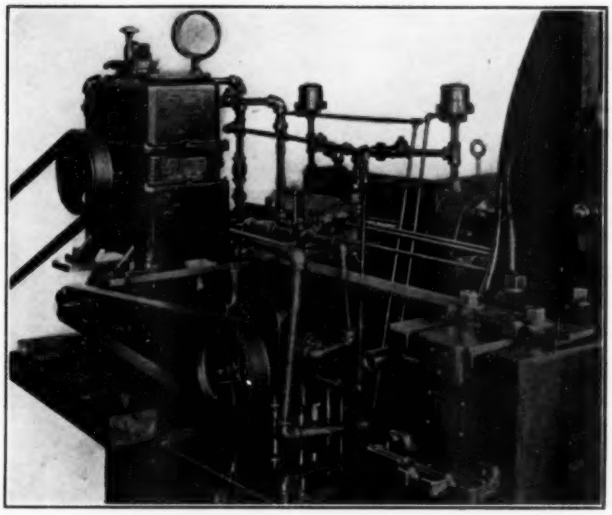

FIG. 10 EXPERIMENTAL HYDRAULIC-FEED UNIT

increase in the life of the tool, and the same effect has been found to exist in the case of the hydraulic-feed milling machine.

For a proper understanding of this phenomenon we must consider in detail the action of a cutting tool during the process of chip formation.

It has been repeatedly shown that the formation of a chip by the action of a tool in its passage through the metal is by no means a continuous or uniform process involving a constant pressure upon the tool. Even when the chip removed is of uniform cross-section, the force normal to the cutting edge varies in a definite cycle with the formation of each successive chip element. It appears, in fact, that with a chip of any practical thickness we have a continued succession of plastic deformation—with a consequent crystal elongation and work hardening—and subsequent shear.

Under practical cutting conditions these load variations occur at exceedingly high rates (probably in the neighborhood of 1000 per second), consequently the actual instantaneous force variations on the cutting tool will be greatly influenced by the character of the mechanism sustaining the work in opposition to the cutter. Where this mechanism is of a mechanical nature, relatively little yield can occur, and consequently the peak loads may rise to a high value. Furthermore, to the extent that any of these members may yield, the energy stored by such yielding is fully returned to the system during the periods of diminishing load. With a hydraulic feed mechanism, on the other hand, owing to the far greater compressibility of the oil, greater yielding can

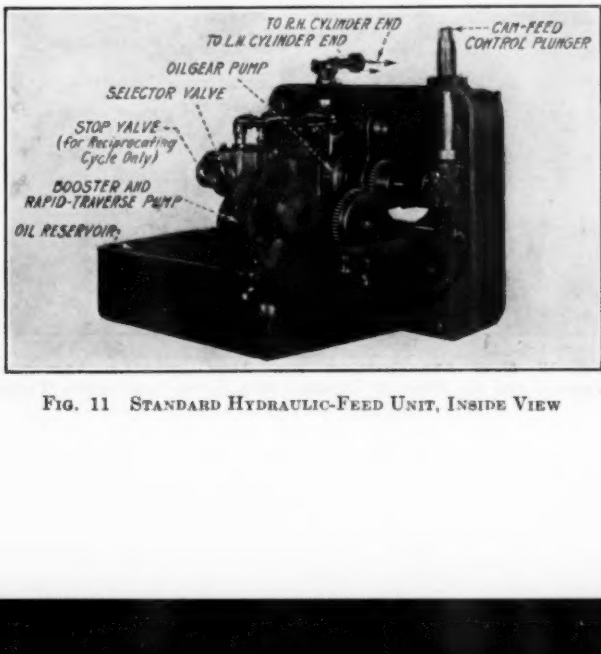

FIG. 11 STANDARD HYDRAULIC-FEED UNIT, INSIDE VIEW

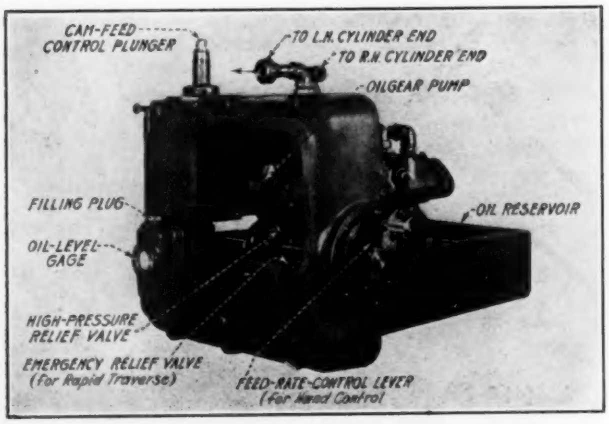

FIG. 12 STANDARD HYDRAULIC-FEED UNIT, OUTSIDE VIEW

take place; consequently the peak loads cannot rise to so high a value. Furthermore, due to the fact that the slight leakage constantly occurring throughout the system is a function of the instantaneous pressure, it is obvious that such momentary increases of pressure as do occur tend to momentarily increase the leakage. Thus in this case there is never a complete return to the system of the energy stored in the yielding members.

The exact effect of the hydraulic feed upon the character of the instantaneous-pressure curve has not yet been definitely determined, but it is apparent that some such action as above described must inevitably take place. An investigation is now under way to obtain exact information in regard to this action, and to the effect of the various factors involved; the instantaneous force variations being analyzed by the use of piezoelectric pressure gages.

In the case of milling we have in addition to these high-frequency force variations a further cyclic variation due to the successive impacts of the cutter teeth upon the work. Even in the case of spiral or helical mills where several teeth are in contact with the work at the same time, the summation of their individual loads cannot be constant. Furthermore a milling cutter is never absolutely concentric, and thus we have an additional cyclic variation of the load per revolution of the cutter. The last two variations, namely, those caused by the tooth

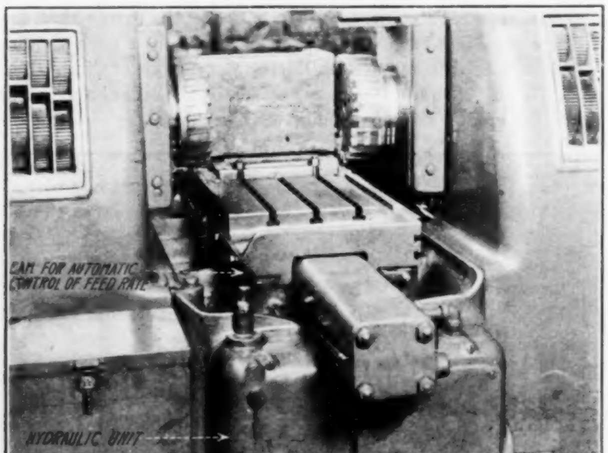

FIG. 13 CAM ARRANGEMENT FOR AUTOMATICALLY ADJUSTING FEED RATE TO AMOUNT DESIRED FOR EACH SUCCESSIVE TABLE POSITION

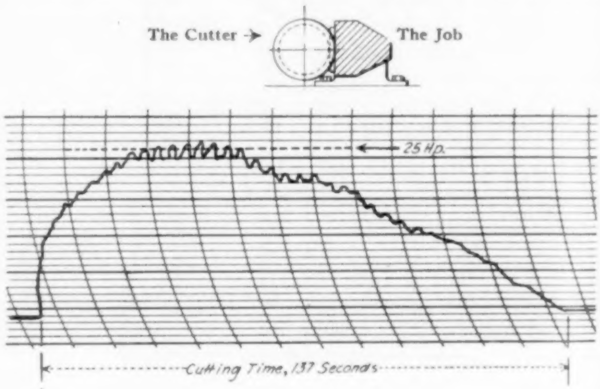
impacts and by the eccentricity of the cutter, can readily be investigated by the use of a graphic wattmeter.

Fig. 16 is a graphic-wattmeter record expanded to such a degree that both of these variations are clearly visible. Figs. 17 and 18 are wattmeter records of identical cuts taken on machines similar in every respect with the exception that one was arranged with a mechanical feed while the other was arranged with hydraulic feed. The same cutter was used and all precautions were taken to produce identical conditions on both machines. From an inspection of these curves it will readily be seen that the power variation due to cutter eccentricity was very much less in the case of the hydraulic feed. Owing to the depth of the cut taken in this case, and the scale of the chart, the individual tooth impacts are not visible.

Simultaneously with the taking of the power records, records



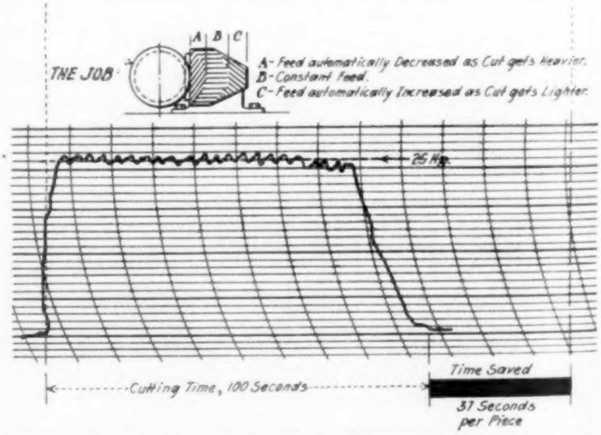


FIG. 14 (ABOVE) POWER CHART FOR CUTTING BY USUAL METHOD WITH CONSTANT FEED RATE

FIG. 15 (BELOW) POWER CHART FOR CUTTING BY NEW METHOD WHERE A CAM-CONTROLLED VARIABLE FEED GIVES CONSTANT METAL REMOVAL FOR ENTIRE JOB

were also made of the actual movement of the milling-machine tables; the curves made by the mechanical and hydraulic machines being respectively shown in Figs. 19 and 20. Close inspection of these curves will show that the mechanically driven table moved at a practically constant rate, while the hydraulically moved table did not move at a constant rate but definitely yielded a measurable amount under each successive tooth impact and for each revolution of the cutter. These curves definitely associate the yielding of the table with the reduction in power variation per revolution of the cutter, and consequently tend to bear out the theory that the increase in cutter life with a hydraulic feed mechanism is directly due to the fact that it does provide a yielding drive in place of the

absolutely constant drive furnished by a mechanical feed.

3 *Efficiency of Metal Removal.* Practical tests covering a wide variety of work have indicated substantially higher efficiency of metal removal per hp. by the use of the hydraulic feed.

The result of this investigation together with detailed data obtained by the investigation on cutter life and chip formation,

(Cutter diam., $6^3/_4$ in.; cutter speed, 32 r.p.m.; depth of slot $1^3/_4$ in.; width of slot, $^{23}/_{32}$ in.; feed rate, $3^1/_2$ in. per min.)

(when feeding both with and against the cutter), will be made the subject of a subsequent paper.

4 *Safety.* As previously described, the entire feeding transmission is automatically safeguarded against overloading by the action of the various relief and control valves, consequently at no time can a wreck occur.

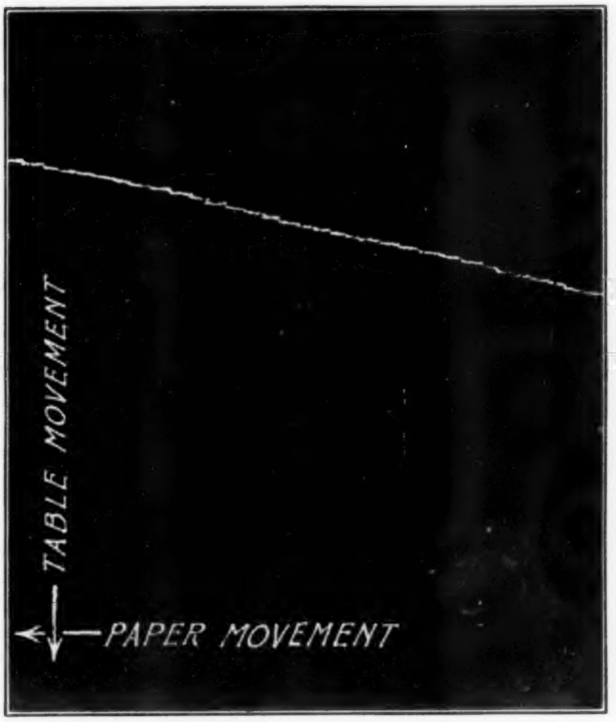

FIG. 19 RECORD OF TABLE MOVEMENT UNDER INTERMITTENT CUT ON MECHANICAL-FEED MILLING MACHINE

During the experimental work which was carried on it frequently happened that the machines and cutters were overloaded to a point where the feed mechanism was stalled, and

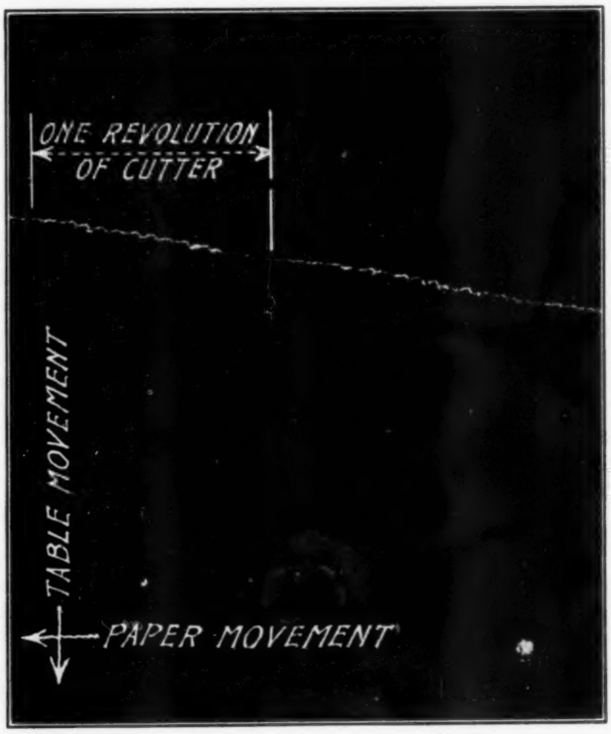

FIG. 20 RECORD OF TABLE MOVEMENT UNDER INTERMITTENT CUT ON HYDRAULIC-FEED MILLING MACHINE

occasionally the work slipped from its proper position. In no case, however, did the machine or cutter suffer any serious damage.

5 *Simplicity.* From an inspection of Figs. 11, 12, and 13, it is obvious that this hydraulic feed mechanism, as a self-contained unit, is far simplier than a corresponding mechanical feed transmission with its numerous shafts, gears, clutches, etc. Auxiliary transmissions are completely avoided, and, as shown above, it provides many valuable features unobtainable with a mechanical feed drive.

# The Development of Hydraulic Feeds on Multiple Drilling Machines

By R. M. GALLOWAY,[1] RICHMOND, IND.

*The author tells first of the three types of hydraulic pumps in general use for feeding machine tools: namely, the gear pump, arranged to operate at pressures up to 250 lb. and capable of delivering a constant volume at a constant pressure; the multiple-piston pump with variable stroke, built to deliver a variable amount of oil at pressures up to 1000 lb.; and a combination of these two arranged to deliver a large volume of oil at 250 lb. pressure from a gear pump and a smaller volume from a variable-delivery piston pump, both pumps being built into the same housing and interlocked as to control.*

*Following this, he relates experiences encountered in adapting hydraulic feeds to multiple-spindle drilling machines, and in the development of smaller machines with less expensive pumps.*

*The success attained led to the development of self-contained units which could be built into designs of special drilling machines, as it was found that a single gear pump could be arranged to supply all the feed cylinders. These have been built into machines having from 2 to 7 units. The paper concludes with a statement of some of the lessons learned during the development.*

MACHINE TOOL manufacturers are just beginning to realize the possibilities in the use of hydraulic means for feeding and traversing the various units of the machines they produce. It is only within the last few years that standard machines have been designed with a hydraulic feeding mechanism, built in as a part of the machine.

About the first tools to be hydraulically operated were broaching machines. The great increase in production and ease of operation of these machines, together with a low maintenance cost, brought the use of hydraulic feeds forcibly before the machine-tool builder and user.

Later grinders and drill presses were hydraulically equipped with equal success in increased production. At present several lathe and chucking-machine manufacturers, and at least one large builder of milling machines, are experimenting along the same line. It is evident from the interest shown in hydraulic feeds, both by manufacturers and users of machine tools, that the time is fast approaching when this type of feed will be in general use on all kind of tools.

### Types of Pumps Used in Feeding Machine Tools

At present there are three types of pumps in general use for feeding machine tools:

1 An accurately made gear pump capable of delivering a constant volume of oil at a constant pressure. These pumps are usually arranged to pump at pressures up to 250 lb. A relief valve is used in connection with this type of pump for maintaining an even pressure.

2 A multiple-piston pump with variable stroke. This type of pump is built to deliver a variable amount of oil at pressures up to 1000 lb.

3 A pump which combines the first and second types and is arranged to deliver a large volume of oil at about 250 lb. pressure from a gear pump, and a smaller volume at a higher pressure from the variable-delivery piston pump. Both pumps are built into one housing and interlocked as to control.

The National Automatic Tool Company started experiments about six years ago with the idea of adapting hydraulic feeds to multiple-spindle drilling machines. The first experiments were carried out using the combination pump manufactured by the Oilgear Company. These experiments were not entirely satisfactory, due partly to the mechanical control of the pump, and partly to the fact that the attempt was made to adapt the hydraulic mechanism to a standard vertical machine designed to use mechanical feeds.

However, the experiment did convince the company that there were great possibilities in the hydraulic feeds if properly applied and controlled; that hydraulic feeds should be applied to machines particularly designed for them, and that these machines should be very rigid and as free from vibration, under working conditions, as possible.

### Types of Machines Designed

With these ideas in mind a vertical multiple-spindle drilling machine was designed, using an Oilgear automatic pump and a $6^1/_8$-in. cylinder. This equipment would furnish a maximum pressure of 24,000 lb. for feeding the drills, with a rapid traverse to and from the work of 80 in. per min.

The mechanical part of the control was arranged so that the operator could set the feeding mechanism to perform any one of its functions, that is, rapid down, either of two rates of feed, rapid up, or stop. Also by means of the same lever the feed could be started and would go through a cycle of operations, automatically stopping at the end of the rapid up movement. The distances traveled at the different rates of feed were controlled by the position of dogs, adjustably mounted on the column of the machine. (See Fig. 1.)

The machine was constructed unusually heavy and rigid to stand the added load of the hydraulic feed and to reduce vibration. Upon being tested it proved entirely satisfactory.

This design has been used with only minor changes during the past two years. Every machine built has shown a decided increase in production with very low maintenance cost as compared to mechanical-feed machines of equal capacity.

A somewhat smaller machine built along similar lines but using a $5^1/_2$-in. instead of a $6^1/_8$-in. cylinder has been equally successful.

The success of these machines led to the development of still smaller machines on which it was desirable, if possible, to use a less expensive pump.

With this in mind, after a careful investigation, it was decided to experiment with a well-built gear pump. The Heald pump was selected, and especially equipped with a 200-lb. relief-

[1] The National Automatic Tool Company.

valve spring. This pump was capable of delivering 15 gal. of oil at 200 lb. pressure, and required approximately 3 hp. to operate.

A machine was wanted for a particular field which would have approximately 7500 lb. feeding pressure. In order to get this feeding pressure with 200 lb. line pressure, it was necessary to resort to the use of two cylinders of 5 in. diameter. In order to avoid interference with the work-holding fixtures the cylinders were mounted near the top of the column, pushing at each side of the head. The two cylinders worked in perfect harmony without noticeable side thrust on the ways. (See Fig. 2.)

The control of the feed on a machine equipped with a constant-pressure, constant-flow pump was very simple.

A slide valve was arranged so that the straight-line motion of the slide connected a supply port with various other ports in turn as the motion progressed. At the same time other ports were connected to a drain line. The valve was operated through

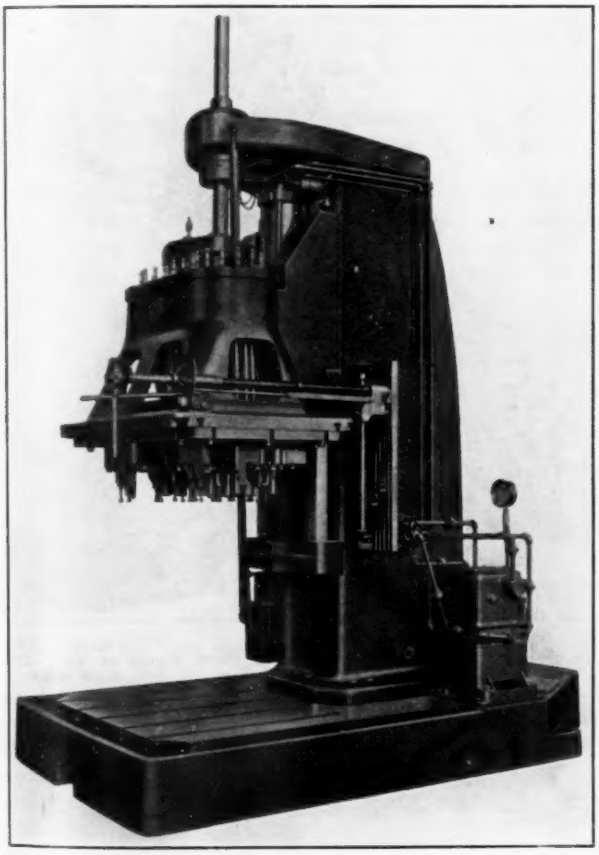

Fig. 1 Vertical Multiple-Spindle Drilling Machine Equipped with Hydraulic Feed

a "load-and-fire" device. This device could be loaded by a hand lever, or by a small oil or air cylinder. It was arranged to discharge or unload by steps or stations, each station causing a rearrangement of the port connections in the valve.

These machines were so well received by the trade that it became necessary to develop a series of machines, for way drilling and for special applications.

Up to that time (1925) special two-, three-, or four-way drilling machines were very expensive to build, because they were usually designed new throughout for each job. The new design required new patterns, and caused foundry and shop delays. It was necessary to bring parts through the shop in lots of one or two. This all led to high cost and to slow delivery of the finished machines.

The expenditure for a special machine of this type was only justified under very high productive requirements, and when the part being operated upon was not apt to be changed. The result was that a very small proportion of the total number of drilling machines built were way machines, most drilling operations being performed on standard vertical machines which could be obtained at a reasonable cost and on short notice, and could be adapted to the changing requirements of the work.

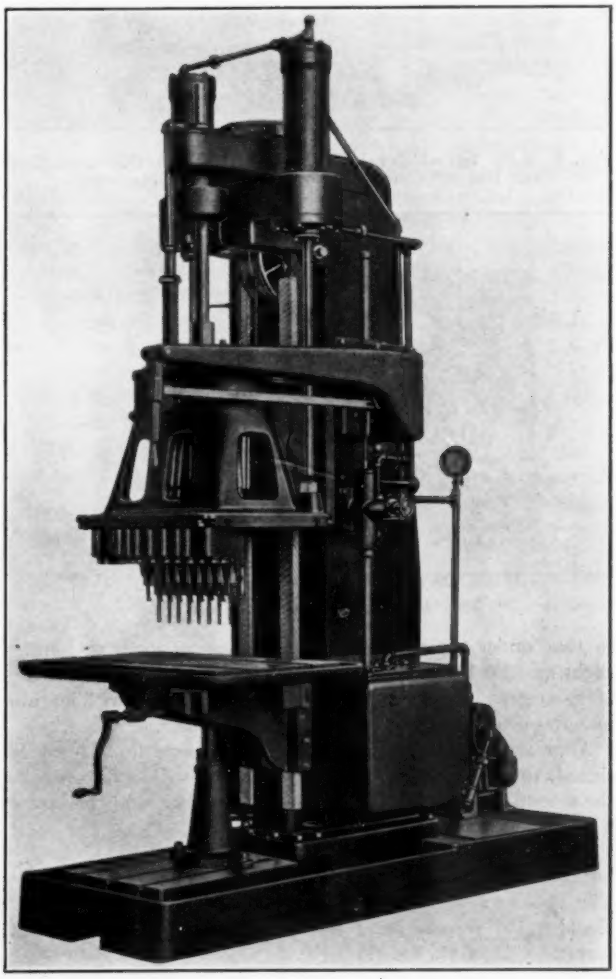

Fig. 2 Smaller Type of Vertical Machine with Two Hydraulic Cylinders

In developing the hydraulic way drilling machines, it was decided to so design a self-contained unit that it could be used, mounted in various positions, to form a way machine, composed of one or more self-contained units arranged on a base, bed, or column, or a combination of these.

### Units Developed for Assembly into Way Drilling Machines

It was desirable to have several sizes of units in order to handle the range of work. It was also important that several units should be operated from one supply pump in order to simplify the machine and keep the cost as low as possible.

Experiments showed that several cylinders could be operated simultaneously by oil supplied by a single gear pump. It was further found that if sufficient oil was being pumped at all times,

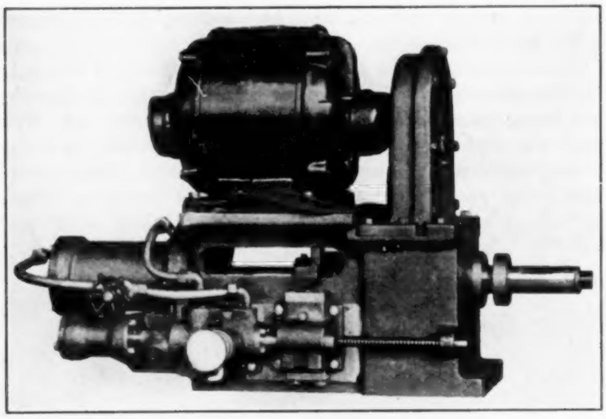

FIG. 3 3-IN. SELF-CONTAINED HYDRAULIC-FEED DRILLING UNIT FOR USE IN CONSTRUCTING WAY DRILLING MACHINES

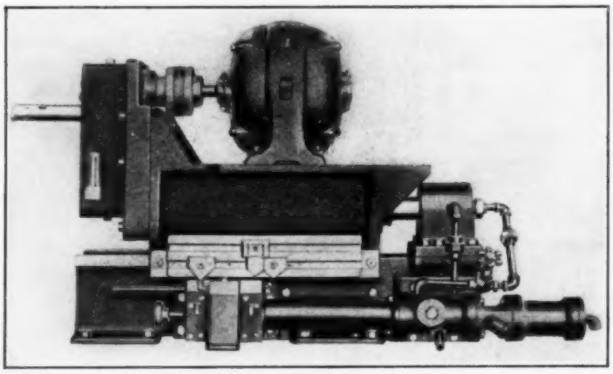

FIG. 4 4-IN. TRAVELING-HEAD UNIT

so that under the worst conditions of usage there was still a slight amount being bypassed through the relief valve, the rate of movement of any cylinder could be changed without any material change in rate of travel on the others.

After the investigation was completed, three units were designed, the smallest having a 3-in. cylinder with a 6-in. stroke, the second a 4-in. cylinder with a 12-in. stroke, and the largest a 6-in. cylinder with a 16-in. stroke.

In the case of the 3-in. unit a cylinder was mounted directly back of a single live spindle. The unit proper remained stationary, the spindle being traversed to the work, fed through it, and returned to a stopping position by the thrust of the piston rod. A motor was mounted on the unit above the cylinder, for rotating the spindle, the desired speed of the spindle being obtained by changing the gears connecting the motor shaft to the spindle. A slide valve, operated by a "load and fire" mechanism, was mounted on the side of the unit for controlling the feed cylinder. (See Fig. 3.)

These units were tried out, and later built up into special machines having from two to seven units. One reservoir and one pump were assembled in each machine. All units were standard and were started—and could be reversed in case of emergency—from a single air valve mounted conveniently for the operator. All units in one of these special machines would start simultaneously, and each had its own length of rapid traverse forward and feed forward, and its own rate of feed in inches per minute. This arrangement made it possible to handle a great variety of work on one machine; that is, one unit could be drilling a $^1/_4$-in. hole, the next unit a $^5/_8$-in. hole, while another could be reaming, and still another counterboring; and all of the units would be operating at the proper speed and feed for the tool being used, and to the correct depth.

The 4-in. unit was designed somewhat differently, being a

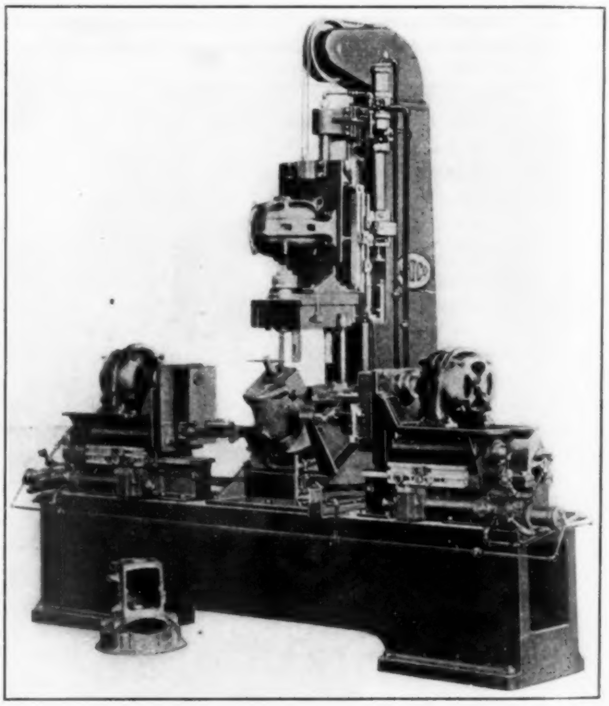

FIG. 5 WAY MACHINE CONSTRUCTED FROM UNITS OF THE TYPE SHOWN IN FIG. 4

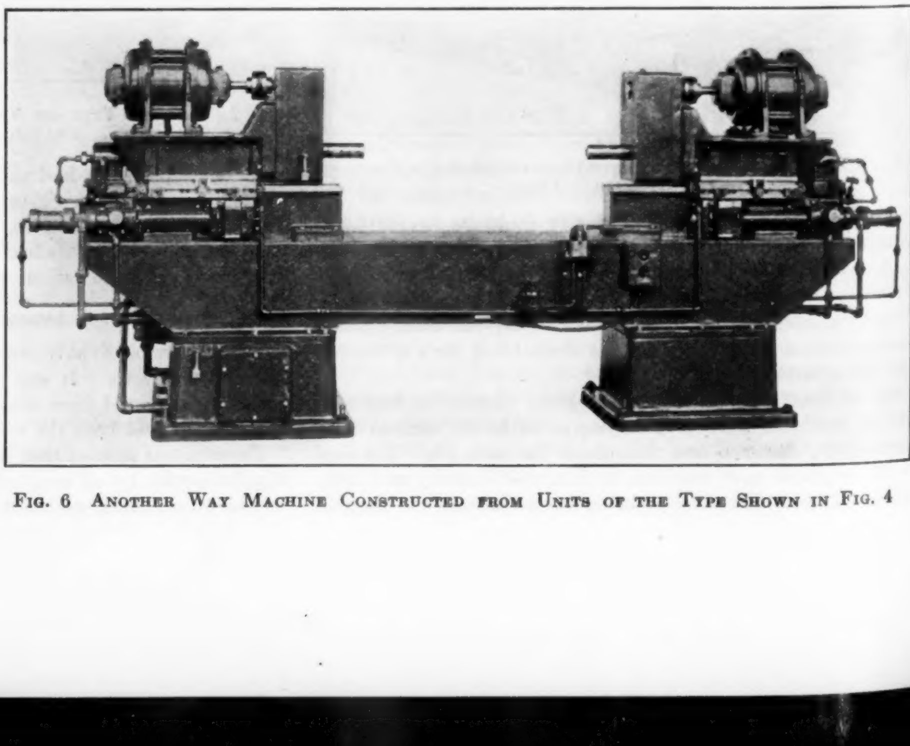

FIG. 6 ANOTHER WAY MACHINE CONSTRUCTED FROM UNITS OF THE TYPE SHOWN IN FIG. 4

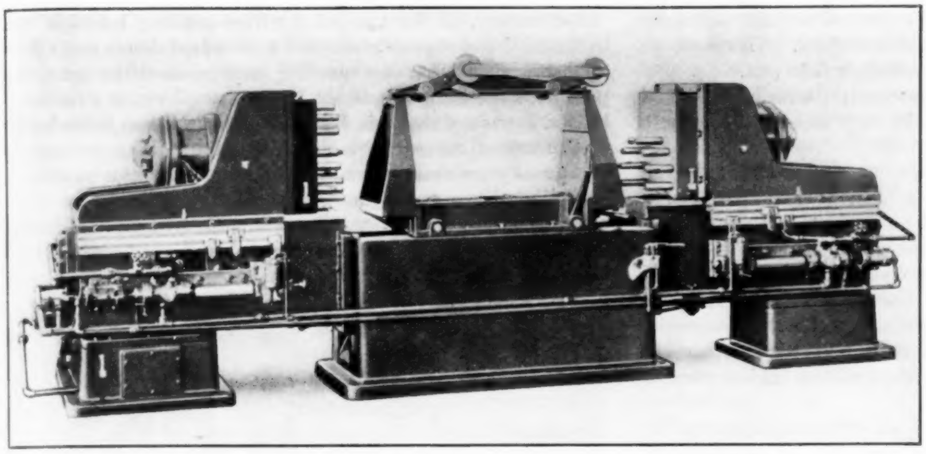

FIG. 7 ONE TYPE OF TWO-WAY MACHINE CONSTRUCTED FROM 6-IN. UNITS

traveling-head unit mounted on ways instead of a traveling-spindle unit. (See Fig. 4.)

In this unit, in order to get a long travel in as compactly as possible, the cylinder was made part of the head and traveled with it, while the piston rod remained stationary. This type of unit was arranged to carry a motor and a "spindle cluster" box, the size of the motor and arrangement of the "spindle cluster" being determined by the work to be done.

Units of this type can be combined into way machines as shown in Figs. 5 and 6.

The 6-in. unit was similar to the 4-in. except that, compactness not being so important in this size, the cylinder was mounted in the bed. The combination of this size of unit into a two-way machine is illustrated in Figs. 7 and 8.

The units are produced in quantity and carried in stock together with several sizes of pumps and tanks.

To build a special machine it is only necessary to build specially the spindle, cluster boxes, and mounting frame. The remainder of the machine is standard.

### Advantages of Unit System

This system has worked out very satisfactorily, both from a delivery and a cost standpoint. The machines have been well received by the trade, and have proved highly productive.

The construction of special machines from standard hydraulic units has made it possible for the manufacturer of moderate quantities of parts to profitably use this type of machine.

In conclusion, it might be well to mention some of the lessons learned during the past two years in the manufacture of hydraulic equipment. Our experience has been that seamless brass tubing in iron-pipe sizes should be used instead of ordinary piping, and that up to 300-lb. pressures, bronze fittings are satisfactory. In the higher pressures heavy-duty steel fittings should be used in all cases. Compression fittings are not satisfactory at 200 lb. or over. All tubing should be machine-threaded rather than hand-threaded. All unions should have ground seats.

On machines employing a gear pump, a reservoir holding not less than $1^1/_2$ times the capacity of the pump per minute should be provided. The return flow of oil, both from the relief valve and from the cylinders, should always enter the reservoir at a point below the surface of the oil in the reservoir so as to have a closed circuit.

It has also been found that cast iron containing from 10 to 15 per cent of steel and high in chromium and nickel is very satisfactory for cylinders on 200-lb. work. A cast-iron piston head without rings but provided with very shallow V-shaped grooves at $^1/_4$-in. intervals is satisfactory. Cylinders and pistons when made of this material show practically no wear after a year of service.

It has also been found that the cup leathers or packing of any kind on the piston head are unsatisfactory when used in cast-iron cylinders.

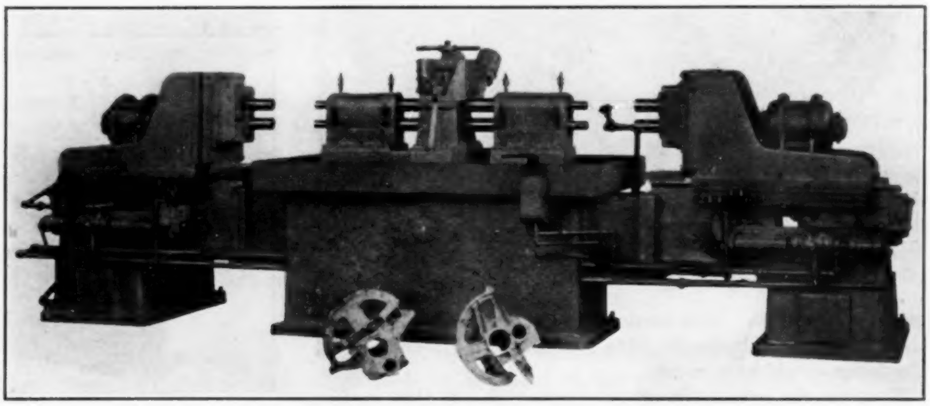

FIG. 8 ANOTHER TWO-WAY MACHINE CONSTRUCTED FROM 6-IN. UNITS

## Discussion

W. F. J. FORWARD.[1] Our first order for machines equipped with hydraulic feed was accepted with more reluctance than enthusiasm, and principally to satisfy a customer who insisted on hydraulic feed or nothing. However, these machines exceeded our expectations as to flexibility on production, and as a result changed our entire attitude toward hydraulic movements on machine tools.

Generally speaking our experience justifies the statement that all the advantages Mr. Ferris mentions in his paper are common to hydraulic feed, providing it is properly designed and installed. By properly designed I mean that the cylinder area chosen and the type of pump used to operate the cylinders must be given careful consideration if the machine is to perform as anticipated. By properly installed I mean that piping for 1000 lb. oil pressure is entirely a different matter from piping for city water pressure. Seamless steel tubing with compression fittings and long-radius bends wherever possible instead of elbows, give the best results.

[1] Engr., Consolidated Machine Tool Corp., Rochester, N. Y.

It is almost impossible to prevent some oil leakage especially during testing, getting air out of the system, etc. Therefore, we prefer setting the entire machine in a shallow floor pan.

Good workmanship is also important; particularly should the cylinder walls and piston rods be very smooth if a smooth travel is expected.

We have found hydraulic pumps to be very reliable pieces of mechanism. Our first troubles were blamed on the pumps, but were usually found elsewhere—such as wrong piping or some dirt carelessly left in the piping during assembly.

As to cost, sometimes the use of hydraulic movements tends to simplify a machine, and sometimes it does not. However a machine incorporating properly designed hydraulic movements is usually more flexible, safer, and more reliable, and therefore should be worth whatever it costs compared to a similar machine with mechanical movements.

It seems logical to expect that the use of hydraulic pressure for clamping, locking, feeding, main driving, etc., on machine tools will expand as fast as suitable equipment becomes available.

George T. Huxford.[2] Mr. Ferris made some mention of the application of the hydraulic-drive principle to heavy face-

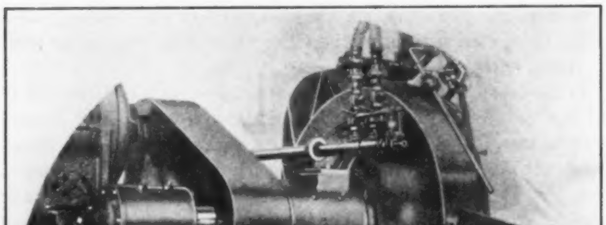

Fig. 1 Hydraulic Control on Grinding Machine

grinding machines. This particular type of machine illustrates the possibilities of hydraulic drive so well that a little additional discussion should be in order.

Consider the inherent needs of these machines, that is, fast table speeds with frequent reversals of heavy tables ranging from 7 ft. to 18 ft. in length. With the standard gear drive three speeds were provided, the maximum, except in special machines, being 35 ft. per min. This made the grinding of hardened steel, for example, slow, often injurious, and sometimes prohibitive, due to the relatively great concentration of local heating, and difficulty in maintaining sufficient coolant at the cutting points. Much greater speeds were not used because of limitations in the table-reversing mechanism. Even the speed variations available were seldom made use of by the operator due to a general reluctance to shifting belts.

[2] Engineer, Diamond Machine Company and Builders Iron Foundry, Providence, R. I.

Fortunately, in the case of our face-grinding machine, the hydraulic drive was easily adapted to standard design and allows further concentration of controlling mechanism at the operator's position. We were able to set the rotary oil motor referred to by Mr. Ferris and shown in Fig. 1 conveniently close to the initial drive shaft of our regular main gear train so that one pair of additional gears could transmit the power, and by this means any desired maximum speed can be built into the machine.

Speed variations are instantly obtainable by simply adjusting the oil control lever indicated by the arrow. This regulates the pilot valve of the pump shown in Fig. 2. The range of

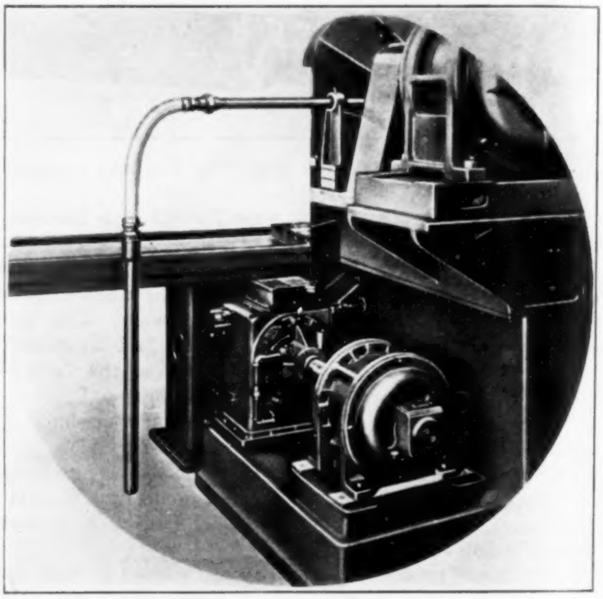

Fig. 2 Hydraulic Pump on Grinding Machine

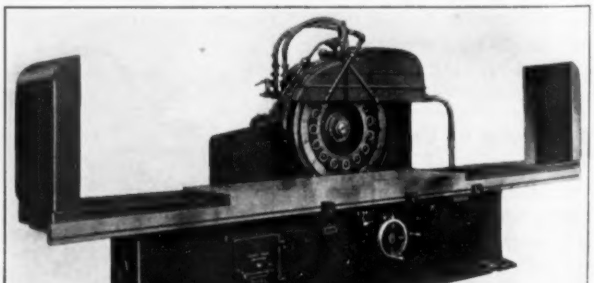

Fig. 3 Grinder with Hydraulic Feed

from 5 to 75 ft. per min. includes the usual required speeds and a substantial high- and low-speed reserve as well.

The advantage of the high table speeds is well illustrated by results at a large steel mill where they had trouble grinding high-speed steel on our belt-driven machines. With their present hydraulic-drive machine this trouble is definitely eliminated. Another firm doing similar work reports over twice the production with its hydraulic-feed machine.

The operator speeds up the table for roughing cuts and reduces speed for the final cuts if accuracy or special requirements of finish demand it. (See Fig. 3.)

The question of rapidly reversing a heavy table has always

been an important one to the face-grinding-machine designers. With the machine operating at a fast table speed working on a relatively small casting, 30 in., 18 in., or even less in length, the time required to reverse the table becomes an important factor in the total grinding time, in some cases exceeding 50 per cent.

It is obvious that in these cases production may be doubled by the oil drive which is sensitive and dependable and may be so set as to reverse without running the work entirely off of the wheel, thus making cutting continuous. So hydraulic drive, with its ability to handle the reversal of a rapidly moving, heavy table, has opened new fields for face grinding.

One vital function to be governed is the speed of the work table and for any given machine a definite quantity of oil delivered to the working cylinders produces a definite movement of the work table. It should be recognized that this question of volume per unit of time which determines "speed" is independent of pressure. That is, the pressure required to operate a machine is a constant for a given load, irrespective of the speed, and varies only as the load except for irregularities at the time of reversal.

If a central supply system is used, as has been suggested, letting a little oil into each cylinder a lot of power is wasted because the pressure must be built up to the maximum required by any machine, and probably used in some machines where much less is required. On the other hand, with a heavy pressure available, if it were freely connected to the cylinders opposed by a relatively small load, the speed of the table would be rapidly accelerated from its initial to an excessive point. In other words, each individual unit should be controlled in the same way as the speed of an electric motor driving an individual machine, by building up only the necessary driving force.

In regard to power required, the individual constant-delivery pump stands about half-way between the individual variable-delivery pump which uses the least power, and the accumulator which uses the most power. With the individual pump it is only necessary to build up a pressure in the cylinder equal to the resistance of the cut. It takes only half as much power to deliver, say, 500 lb. to the cylinder as it does to deliver 1000 lb. which might be needed for the maximum load. Therefore, if an accumulator is used for the 500-lb. job, half the necessary power has been wasted.

In our surface-grinding machines where the total driving power is small, we use gear pumps and also control valves which bypass part of the oil for slower speeds. We can regulate the oil bypass valve to suit the load and thus regulate the speed. In this case we do generate more power than we use on slow speeds but as the total power required is only 2 hp., the loss due to bypassing oil at slow speed is negligible. For our face-grinding machines where the total power is 7 1/2 hp., we use the variable-delivery pump, thus securing maximum efficiency.

A. M. Hammond.[3] Mr. Ferris mentioned the application of hydraulic drive to face-grinding machines briefly and Mr. Huxford has gone into more detail in regard to this. It occurs to me that as engineers you will be interested in the troubles which we had, at first, and how we have done away with them.

One of the most annoying troubles came with oil leaking through threads due to the high pressure. After considerable experimenting we found that this could be corrected by sweating solder on threads. It was found advisable, too, to use welded joints and pipe bends in some parts of the system.

Another difficulty was due to noise caused by vibration which was, of course, especially prominent at reversals. This was corrected by the addition of an oil dashpot.

The important thing is that the troubles have been overcome and without sacrificing any of the advantages. So, briefly, we believe that the face-grinding machine is indebted to hydraulic drive for slower speeds, faster speeds, smoother operation, and greater ease of control.

R. E. Flanders.[4] Both Mr. Ferris and Mr. Einstein have emphasized the advantage of elasticity in hydraulic feeds and that is rather surprising to the man who still sticks to screws and nuts and pinions, because he has always found that as elasticity is eliminated conditions improve. What is the difference between hydraulic and mechanical elasticity? Is it a difference in kind or in degree. If it is in kind, I would like to have it described. If it is in degree, is it a fact that there is more elasticity in hydraulic feeds than in mechanical? If that is all there is to it, it is the easiest thing in the world to put more elasticity in the mechanical feed.

The elasticity of the oil has been mentioned. How is the elasticity of the oil separated from the elasticity of the chambers, cylinders, and pipes within which it is confined? Is not, perhaps, the elasticity of the cylinders and communications fully as much concerned as that of the oil itself?

O. W. Boston.[5] In the papers which have been presented practically nothing has been said about tool life. The time element and the flexibility of the reciprocating motion and different feeds were emphasized, however. I have been particularly interested in hydraulic feeds from the point of view of their influence on the cutting action of the tool.

A number of people representing manufacturers of drilling, broaching, and milling machines equipped with hydraulic feeds, have made the statement that they have found greater tool life with hydraulic feeds than with mechanical feeds. I have a machine at the University of Michigan which will measure the force on a tool while it is cutting. I find whenever chatter occurs, particularly in cutting brass, that the force is much less, because of the chatter of the tool. I was unable to explain this phenomenon. I later heard from Professor Smith, of the University of Manchester, who is the author of the report of the Lathe Tool Research Committee of the Manchester Association of Engineers, and who reported that in his own experiments he was able to duplicate tests which showed clearly that the life of a tool while turning steel was greater under conditions which caused chatter. May there not be something in the nature of a natural period of vibration set up between the machine parts because of the compression of the oil or expansion of the oil containers, as the individual chip element is formed, which is so small as not to be noticed during the cutting action and which has very little effect on the finish? This to my mind, may have something to do with the increased tool life, if it exists.

M. Sklovsky.[6] We have been using hydraulic feeds on machine tools for a period of five years, beginning with special milling machines and later, drilling and boring machines and grinders. We have noticed particularly in nearly all cases that the chatter is reduced in the first place, secondly, that the feeds permissible are increased to a greater degree than was formerly possible, and thirdly, that the number of pieces per machine for a grinding of the tool is materially increased. All together, we have noticed about a 25 per cent increase in production on machine tools equipped with hydraulic feeds, and in some cases an increase of 50 per cent and more. That may not be due en-

[6] Chief Engineer, Deere & Co., Moline, Ill. Mem. A.S.M.E.

tirely in every case to hydraulic feeds, but the chief feature has been that of the hydraulic feed. On that account, we specify hydraulic feeds for machine tools, particularly for heavy-production machine tools.

There is just one objection we have to hydraulic feeds, and that is the cost. On that account we limit its application to machines costing several thousands of dollars or more each. Some day we probably shall simplify the hydraulic-feed element on every machine tool by installing a central system in the shop. We do not put in a generator with every machine tool, we do not put in a compressor with every machine tool, and there is no reason for installing a pumping system with every machine tool where a number are to be equipped with hydraulic feeds. It would very materially reduce the cost of building a tool if there were just a few simple pipes and valves furnished in addition to the feed cylinder, eliminating thereby the motor and pump.

Usually the hydraulic-feed mechanism is supplied with an independent motor which adds to the expense. These motors are furnished extra large, usually two and three times too large, and the power factor naturally drops so that with a number of machines in one group the result is poor. We would like to see a central system developed for this reason.

E. F. DuBrul.[7] I can see that a good many of our machine-tool designers are going to have to brush the dust off their old textbooks on hydraulics. They became electrical engineers with the electrical application, and now they have to become hydraulic engineers with these hydraulic applications. Incidentally, the executives of the machine-tool building concerns, I think, had better begin to forecast a little about how to furnish the funds to pay for that sort of talent.

The user is beginning to see something of what has been produced for him. One speaker has said that a machine gave him a 25 per cent increase in production, but he could not afford to use it because it cost too much. It might be that for 25 per cent increase in production it did cost too much, but what about those who get 50 and 100 per cent increase?

The fact, is, however, that all three elements of the machine-tool industry—the designing, the producing, and the using elements—are witnessing a very important development. It strikes me that perhaps this development has gone just far enough to justify the men who are concerned in it in getting together in intimate groups and discussing some of the more fundamental problems that may underly these differences and the relative fields and merits of various applications, such as the gear pump, or the accumulator, or the central plant. Possibly through such a conference of hydraulic machine-tool engineers they might save each other much grief. That may be a far-visioned idea, but I submit it for the consideration of executives of machine-tool companies.

W. B. Updegraff.[8] I am connected with a company which for 78 years has been building hydraulic machinery, and for 20 years I have been following the construction and selling of that type of equipment.

As I sat here and listened I thought that the spirit of optimism that has prevailed here throughout the entire morning might lead the members present into trouble if they did not use a little caution, a little matured judgment. The pendulum might swing too far the other way. While it is not my purpose to decry the use of hydraulic machinery, there are limits beyond which hydraulic machinery may not be used to advantage. I do not say that it should not be used in the machine-tool industry. This is undoubtedly a coming field and one which will prove very profitable, both to the builder and to the user of the tools. I do approve, however, of what Mr. DuBrul has said, that a pooling of interests would undoubtedly be very helpful. Some of the remarks made here today show that within the last two or three years the people furnishing hydraulic equipment have been working at problems some of which the company with which I am connected solved many years ago. There are new problems coming up right along and it is undoubtedly a field that is going to be increasingly important.

We are using a planer which has an electrical reverse mechanism which our works management thinks is practically perfect and which we prefer to hydraulic mechanism. I, personally, will not have hydraulic brakes on the car I drive. I simply mention these things to show that there is a definite field for hydraulics and others for which hydraulics is not thoroughly adapted.

R. M. Galloway.[9] There is no controversy between the two methods of oil feeding. We use both systems and for rather definite reasons as far as we are personally concerned. When the pressure required in the drilling is somewhere around 6000 or 7000 lb. total, we do not use a constant-flow, constant-volume pump. We use the oilgear or some similar system. When large, we use the variable pump. When the drilling load is light and where we have several heads which we want to operate with as compact and cheap a unit as possible, we use the other system.

William F. Parish.[10] Just a word about oil. In the 25 years that I have been attending meetings of the Society, we have had quite a number of notable developments, including many types of steam engines, steam turbines, gas engines, Diesel engines, automotive engines, and aeronautic engines. In the general discussion between the machine manufacturers and the operators of this machinery it has become evident that many of the difficulties that they have had during the early stages of development were largely on account of the oils used in the various systems for either lubrication or fuel. Operations have been conducted on these various developments in many plants and the machinery has been well designed, properly built; under test or in actual operation during the early stages the greatest variable and one that has made the records so widely different has been due largely to the lubricating oil and the method in which it was used and to the fact that the application as well as the nature of the oil had not been standardized for that particular class of machinery.

In connection with the development of our intricate machinery the standardization of the lubricants and fuels has not come until such machinery has been commercially acceptable and has been in operation for many years and when the supply of lubricants and fuels had become a question of considerable importance to the oil industry. The standardization of the petroleum takes place at a time when it is not particularly helpful to the engineers and machinery builders during the expensive and rather discouraging period of development.

In the development of the hydraulic systems attached to machine tools, there is no doubt whatever that all of the various manufacturers developing this machinery are using different kinds of oils as the medium of power transfer and that the systems, as far as capacity and other features that effect petroleum are concerned, vary to a considerable degree. Many of the difficulties mentioned by the speakers at this meeting are un-

[7] General Manager, National Machine Tool Builders Association, Cincinnati, Ohio. Assoc-Mem. A.S.M.E.

[10] Construction Lubrication Engineer, 17 E. 42nd St., New York, N. Y.

doubtedly due to the changes which take place in the oil through conditions under which it is forced to operate and to possible contaminants of one kind or another which invariably enter circulating systems operating with oil. Oil that circulates rapidly in a closed system will undergo gradual change in character dependent upon the rapidity with which it is circulated, upon the heating and cooling, upon pressures, and upon contamination. If there is a small amount of oil in the system and it is circulated at high speed under high pressure, meeting with temperature at the point of contact of the gears or at some other point in the system, volatile matters will be liberated and these form gases that will have the same effect in a pressure system as air. With the liberation of volatile matter, as a rule, gums are formed which collect solid matter and result in deposits in the clearances. Moisture or water always gets into a circulating system. This can be caused by condensation of the air or by outside leakage and the effect of water working with oil in such a system is to cause emulsions, which gradually solidify into deposits.

In the continual circulation of petroleum it undergoes a gradual change that is indicated by an increase of acidity; when oils build up in acidity there is a point where they will form emulsions much more rapidly with water and undoubtedly will undergo many other changes due to forces that are acting upon them, such as the continual agitation and possibly oxidation. Then there is the final question of contamination. When such a system is working on a machine tool there is, of course, the lubricating oil, the cleaning oil, and the cutting oil used around the same machine and the possibility of contamination from these sources.

I have this to suggest to the research men: that they arrange their force-feed systems for a maximum quantity of lubricants so that a large amount of the oil can be brought to a complete rest in the tank provided with settling compartments so that the heavier matter can be settled out; that they arrange for temperature control either by heating or cooling for such installations where exposure to wide range of temperatures will be encountered; that every care be taken so that the lubricants, cutting oils, or soap mixtures will not enter the system. The character of oil to be used in the system should be what is known as a neutral oil filtered by the refiner and having a viscosity of not over 125 sec. at 100 deg. fahr. on the Saybolt Universal. This oil should be a highly finished lubricant, preference being given to that lubricant which contains the least volatile matter.

W. J. Peets.[11] It has cost us a great deal in the past to design special drilling machinery. When the design of a piece changes so that even one or two holes are changed, the entire machine is likely to be scrapped or become obsolete. The ability to get units which can be fed independently and shifted around on a machine at will, will, I think, give us cheaper machinery, machinery that can be changed over very easily and quickly, and will make it possible to tool up production in much smaller lots than at present.

D. H. Montgomery.[12] In our work we ran into a problem that seemed interesting—the elimination of the high cost of air in operating ordinary air-operated chucks, the use of which is proposed on a machine under development. It took from one to one and a half horsepower to maintain the operation of a chuck and, in addition, the pressure was variable. The whole shop depended not only on a stated pressure but there must always be a reserve on hand. The accumulator was then tried.

The usual accumulator is leaky and bulky. The air accumulator has the disadvantage of high variation in pressure. In holding work in the chuck we had to be sure that the instant the chuck was closed, a predetermined pressure was available. We then got the idea of using a small pump driven by a motor. The pumps would actuate the chuck itself in probably less than 30 or 40 sec., but by means of a bypass valve unaffected by back pressure we could discharge air into the accumulator and built up gradually a pressure equal to the pressure originally set on the pump, the back pressure on the pump being always available at the chuck.

The small power consumption, of course (a quarter and a half horsepower) proved to be a big advantage. It gives air flexibility and an extremely simple mechanism, and to get away from the difficulties with oil leaks, we have put the entire mechanism within the tank so that the whole unit takes up a small space.

J. J. Crain.[13] We have been manufacturing hydraulic variable-speed transmission for about 20 years and most of our products have gone to the Navy. Someone asked about the time required for reversals. We have had some interesting experience along that line. The Navy Department specifications require that we reverse the turrets from full speed in one direction to full speed in the other direction in two seconds. We are always able to meet this specification. We do it in from $1^3/_4$ to $1^5/_8$ sec. A modern turret weighs nearly 1500 tons, and full speed is 100 deg. per min. The older turrets weighed somewhat less and had a speed of 1 r.p.m., or 360 deg. per min. These reversal requirements are way beyond anything required of even the largest machine tools. But the characteristics of variable speeds are well adapted to quick reversals, and for the small weights in machine tools, the reversals can be made in a fraction of a second without difficulty.

Walter Ferris. Mr. Montgomery spoke of the adaptation of a small pump to an air chuck. We have long had the machine chuck in view as a device that we think can be operated hydraulically to greater advantage and with more economy than by air. If this chuck were operated by an oilgear pump, the diameter of the piston used would be about one-third what is now necessary to get an amply strong application. If a small pump is used, quick advance will be gotten by an oil and spring accumulator, or by an oil piston with compressed air over it which will be ready to unload instantly just as does the air piston. Only one-tenth of the power will be used and the oil will hold a chuck better than air will.

Mr. Updegraff spoke of the electric planer and said that his company considered it perfect. The electric reversing planer is now a very beautiful machine, but five or six years ago when we tried to introduce hydraulic feeds in place of mechanical, users asked what was the matter with the mechanical feed. There seemed to be no reason for hydraulic feeds. As I watch the electric planer, it requires probably a foot of travel to get up to full return speed and many times it is never reached. If I were suggesting the possibility of hydraulic planers I would say that the strongest reason for the hydraulic planer is that a much quicker reversal is feasible. We would probably not reverse the pump at all because it takes the pump about a second and a half to bring about the complete reversal. A 4-way piston valve will reverse the flow instantly. As I visualize the large planer hydraulically operated, I see the table going backward and forward on a 4-in. stroke, and I see that table accelerating from its reversal point to a reasonable cutting speed within 2 in. If the hydraulic planer can do this, and perhaps it can, I submit that the electric planer is not the best that can be imagined.

[11] Engineer, Charge Factory Methods, Singer Mfg. Co., Elizabethport, N. J. Mem. A.S.M.E.

[12] Engineering Agent, National Acme Co., Berlin, Conn. Assoc-Mem. A.S.M.E.

[13] General Manager, Waterbury Tool Co., Waterbury, Conn. Mem. A.S.M.E.

The next subject I would like to discuss is the nature of the cutting action. We can only guess at the nature of cutting action as affected by a multiple-plunger pump operating in a closed circuit. We built a broaching machine, and as the broaching machine was originally driven by a screw we compared the characteristics of the hydraulic with the screw method of operation. We can now state, as I think it has been proved, that it takes 5 to 8 per cent less force to pull the same broach through the same piece of work at the same speed when it is pulled hydraulically than when it is pulled by a screw. This saving is not important commercially, but if a hydraulic piston will do the work with less force than a screw, there is something to think about.

Sol Einstein. As we build various machine tools, our problems in the application of hydraulics will be somewhat different. A circuit, as it is applied to a certain tool, cannot be transferred to a different tool. The problems are different and therefore it is best to apply general principles to the particular problem.

When we made our experiments on hydraulic feed on milling machines, we found that on the same machine, using either hydraulic or mechanical feed, there was a tremendous increase in the rate of feed possible with the hydraulic feed. This feed naturally varies with the nature of the cut, but there has been from 50 to 350 and 400 per cent increase of feed rate on the same type of machine. We feel that sooner or later the large majority of machine tools, with exceptions, naturally, will have to make use of the hydraulic arrangement for feeding purposes in order to maintain the standard which the American machine-tool industry has not only in this country, but throughout the world.

H. Ernst. In regard to the compressibility of the hydraulic medium: We all know that oil is really compressible to a considerable degree, the relation between compressibility and pressure being generally expressed by the term "bulk modulus." Up to the present time, however, very little information has been published relative to the effect upon compressibility of such variables as viscosity, temperature, and pressure.

We know, too, that compressibility of the hydraulic medium is very closely associated with the increase in tool life which we get with hydraulic feed as compared with mechanical feed. We are not yet prepared to give definite figures in regard to increase in tool life; we know it exists, but the actual increase is affected by a great many factors which, at present, are a little beyond exact determination.

A table moved by hydraulic pressure acts differently from one moved by mechanical means. In both cases there is a yield under increase of load, and a forward acceleration upon release or reduction of load; but the extent of yield under impact and the rate of advance on release of load are radically different in the case of hydraulic feed. Here we have a true "cushioning" effect. As each cutter tooth strikes the work the table definitely yields a minute amount, thus absorbing the shock and reducing the impact, energy being dissipated by a momentary increase in leakage and by internal friction in the oil column. Furthermore, by the use of the locked hydraulic system, the small forward jump (which occurs on release of load) is greatly retarded due to the counter pressure automatically built up on the opposite side of the piston. The table thus, in effect, executes a highly damped free oscillation, automatically adapting itself to the load variation.

The differential control valve, as described in the paper, acts to maintain a desirable relationship between the pressure acting on opposite sides of the piston, in accordance with the cutting force. That is, in accordance with the horizontal component of the force produced by the action of the cutter on the work. This valve also acts to retard the forward jump of the table under release of load, by virtue of its stabilizing action on the entire hydraulic circuit.

One of the principal reasons for adopting the locked hydraulic system in preference to a more conventional type of circuit was to insure a positive control of table movement, independent of the direction of action of the resultant cutting force. Under certain conditions of milling, particularly in face milling, the normal direction of the cutting force may be completely reversed at the end of the cut and the cutter may then tend to drag the table in the direction of the feed. Furthermore, in certain instances downward movement of the cutter upon the work is highly advantageous. Thin slotting saws work much better when operating in this way, and in some cases this method may also be profitably used in ordinary spiral milling. With the locked system, irrespective of the direction of the cut, the table can advance only as fast as the oil is metered out from the discharge end of the cylinder.

In answer to Mr. Flanders' question regarding the use of a booster pump in connection with our system: In order to maintain an active forward pressure under all conditions of operation and to compensate for the difference in displacement on opposite ends of the cylinder due to the piston rod, it is necessary that there be always available a small excess of oil. This is supplied by the booster pump and in hydraulic parlance, is generally referred to as "make-up oil."

It is true that the excess oil supplied by the booster pump and not required in the circuit may be returned to the reservoir by way of a simple relief valve instead of by the more complex differential valve which we use, and in our early work the simple valve was actually successfully used. The differential valve, however, possesses the following advantages:

Analysis of our circuit shows that the amount of forward pressure sets a definite limit to the amount of cut that can be taken. For instance if we use a simple relief valve set to maintain a constant forward pressure of, say, 600 lb. per sq. in., and acting on a piston area of, say, 10 sq. in., there will be a total forward pressure of 6000 lb. When the table is idling, the back pressure will be approximately equal to this. Now, if a cut be taken in a direction opposite to the feed and if its amount be such that the horizontal component of the cutting force be equal to 6000 lb., then the forward pressure will be completely balanced by the cut, and thus the back pressure will be reduced to zero. This, then, is the limit of the cut which can be taken. It is impossible to feed faster than a rate which produces a cutting resistance equal to the amount of the forward pressure.

With the differential valve, on the other hand, and reduction of back pressure due to the action of the cutting force causes a corresponding increase in the amount of the forward pressure. Thus, for a given idling pressure the capacity of the machine will be greatly increased and, conversely, for any desired maximum pressure the necessary idling pressure will be correspondingly reduced. By varying the ratio of the areas of the two valve portions, any desired pressure regulation may be obtained. We have adopted a compromise ratio of about 3 to 1, which is satisfactory for the various conditions encountered.

A further advantage of the differential valve is its effect upon the stability of the table movement. On account of its action in maintaining a proper pressure balance in accordance with the instantaneous requirements of the circuit, it acts to dampen the table oscillation under fluctuation of the cutting force. Thus it tends to increase the true "cushioning" effect of hydraulic feed.

This apparently irregular movement of the table—the characteristic natural adaptation of a hydraulic feed to changes in the cutting force—must not be confused with chatter. It is not chatter, and does not affect the finish produced on the work.

# The Economics of Machine-Tool Replacement

## Present Market Conditions and Tendencies in Machine-Tool Design; Comparison of New with Former Types of Machine Tools and Savings Effected by Replacements

By MYRON S. CURTIS,[1] PAWTUCKET, R. I.

THE ECONOMICS of machine-tool replacement is a subject that is of vital importance both to the machine-tool builder and to the machine-tool user. This is the sole excuse for this paper, for the information given will be found to be neither decidedly new nor of a radical nature.

There is no question but that the period of enormous expansion in practically every manufacturing line, and particularly in the automotive industry, which has been witnessed in the last fifteen years has ceased, at least for the present. While it is entirely possible that there may be extensive development and expansion of certain lines, which will in turn affect certain branches of the machine-tool industry, still it is extremely doubtful that we shall see any general expansion. For example, the automotive industry is beginning to realize that it must depend for its dividends upon increasing the profit per unit rather than upon increasing production. As opposed to this we find the machine-tool industry in an over-expanded condition due to the enormous demands made upon it by the growth of the automotive industry and by the conditions brought about by the World War. Also, machine tools of today are of a much more rugged nature, and are more foolproof in construction than those of a few years back, thereby extending the probable life of the machine tremendously. Again, improvements in the design of machine tools have generally increased the productive capacity from fifty to in some cases six hundred per cent, again reducing the potential market. It is easy to figure that if a tool put out by a machine-tool maker today will do twice as much work as one put out by him five years ago, all other things being equal, he will only sell one half as many machines as formerly.

Outlet must be found for at least a reasonable percentage of the capacity output of the machine-tool industry. If it cannot be absorbed by expansion it necessarily follows that it must be absorbed by replacement. This, in turn, may be caused either by the development of improved methods of manufacture, that is to say, the replacement of a machine tool by one of an entirely different nature, or else by improvements in the machine tools themselves, whereby a lathe is replaced by a lathe, a milling machine by a milling machine, and so forth. The machine-tool builder has had and always will have an increased field by developing improved methods of manufacture, not only in hundreds of shops where obsolete methods of manufacture still exist, but even in the up-to-date production shops of today.

This question of machine-tool replacement is also vital to the machine-tool user. There is no doubt but that, with the keen competition now existing in all manufacturing lines, the organizations which survive will be those which have equipped themselves with the best plant and personnel. This particularly applies to industries in New England.

The tendency to cling to obsolete machinery simply because it is in good condition and is capable of doing about the same amount of work which it did when it was installed, will eventually put any concern out of business. There should be no more hesitation in scrapping an old or inefficient machine than there is in getting rid of inefficient men. As a matter of fact, the obsolete machine is a greater liability to the plant than the inefficient man. J. A. Smith, the general superintendent of the General Electric Company, which is one of the biggest users of machine tools in the country and a concern which has to meet the strongest kind of competition, says,

> I believe it is thoroughly bad for shop morale to keep a lot of superannuated machine tools standing around. They occupy valuable space that ought to be devoted to a productive machine. They tie up motors that ought to be working. If your equipment is obsolete, sell it. If you can't sell it, scrap it. It is too expensive to have around the shop.
>
> No concern equipped with obsolete tools can hope to compete these days, and the only cure for the ailment is amputation and replacement.

What makes a machine tool obsolete? Two things: first, the nature of the tool and the way it has been treated; second, the developments of the art through which the modern tool produces more than the one it supplants. In regard to the first reason, a tool may be in such shape that it is unable to produce sufficiently accurate work, or it may be that repairs are altogether too frequent, and result in excessive waste of productive time. This may be due to faulty design of the machine tool or to careless handling, particularly in regard to keeping the machine clean and oiled. A machine tool may be obsolete for the work it is performing, but may be very useful and economical on some other job. In such cases the tool should be transferred to the other work and a new tool provided for the work which is beyond the capacity of the first one. If, however, there is no job on which the tool can be economically placed, it should be immediately scrapped, as it is too costly to use.

The second reason for machine-tool obsolescence is due to the improvement in the art. The machine-tool industry has made enormous strides in the last five years. During the war and for some years previous a machine-tool builder, no matter what his product, was able to sell the capacity production of his shop, and therefore the average manufacturer was not particularly interested in making any radical changes in his product. He was concerned solely with production. Immediately after the Armistice, however, conditions changed, and the market for machine tools became a buyer's market instead of a seller's market. This caused the up-to-date manufacturer to start redesigning and improving his line, so that today it is safe to say that nearly every type of machine tool built prior to 1921 is totally obsolete for production. The machine-tool builder is designing to take feeds and speeds which were unheard of even five years ago, and is taking full advantage of the developments in high-speed cutting tools. Five years ago the art of making cutting tools was far ahead of machine-tool design. Few if any machines were capable of forcing high-speed steel to the limit. Today this condition has changed, and the capacity of the modern machine tool is dependent wholly upon the ability of the cutting tool to stand up. Of course, all machines built five years ago are not obsolete for all classes of work. Certain jobs are inherently too weak in themselves to withstand heavy feeds and speeds, or can be machined just so fast because of the distortion due to heat and the limits required.

[1] Potter & Johnston Machine Co.

Presented at the First National Meeting of the A.S.M.E. Machine Shop Practice Division and the New Haven Machine Tool Exhibition, Mason Laboratory, Yale University, New Haven, Conn., September 6–9, 1927.

### Tendencies in Modern Design

It will be well at this time to point out some of the improvements in design by which these results have been brought about. There are three main tendencies.

1 Increased power and rigidity together with the correlative ability to withstand abuse
2 Increased convenience for the operator
3 More foolproof construction.

Some of the tendencies toward increased power and rigidity follow:

More and better placed material is used in beds, gear boxes, carriages, etc. Thirty years ago most machine tools, especially those of British manufacture, were extremely heavy. Gradually the lines were refined and excess material was done away with. Then came the introduction of high-speed steel, and nearly every machine tool on the market proved to be too light to withstand the heavy duty imposed. The metal which was removed has been gradually put back, especially since the importance of freedom of vibration to cutting-tool life has been learned. Today, machines are made not only strong enough to withstand the strains imposed, but also heavy enough to absorb all vibration at the cutting edge of the tool.

There is a definite tendency toward the use of alloy steels for shafts, gears, etc. This is a direct result of knowledge gained from the automotive industry, and today, every good machine tool has its high-duty gears and shafts made of heat-treated alloy steel. Another direct result of the influence of the automotive industry is the use of anti-friction bearings for all fast-running high-duty shafts. A more recent development has been the use of anti-friction bearings for spindles of lathes and milling machines. Certain light high-speed machines, such as woodworking machinery, drill presses, grinders, etc., have long employed anti-friction bearings for spindle mountings but it is only lately that successful applications of anti-friction bearings to high-duty spindles such as those of lathes and milling machines have been accomplished. This is a long step forward, resulting as it does in increased accuracy, lessened friction, and longer life of bearings.

Increased convenience of operation has been accomplished by well-thought-out design in the grouping of levers, the accessibility of change gears and cams, etc., all of which cut down the setting-up time materially, and by reducing fatigue, make it possible for the operator to produce more work in a given time.

More foolproof construction is absolutely necessary today, as the class of help operating machine tools under production conditions has definitely changed to unskilled labor. A production tool is no longer operated by a mechanic—a man who understands its various functions, and who takes pride in keeping his machine running smoothly and efficiently. This type of man can no longer be found in sufficient numbers to operate our shops. The use of interlocking levers, safety devices such as slip frictions and shear pins, and, on some of the simpler tools, hydraulic feeding mechanisms is therefore noted. The matter of oiling has also received considerable attention. Five years ago most machine tools were oiled by the old-fashioned oil can and the tool with any well-thought-out system of oiling was an exception. Today are to be noted the use of enclosed gear boxes running in oil, mechanical oiling systems such as have been for a long time used on engines, unit oiling systems usually with a sight-feed drip whereby one or two oil reservoirs oil the whole machine, and more recently, the development of the one-shot oiling system.

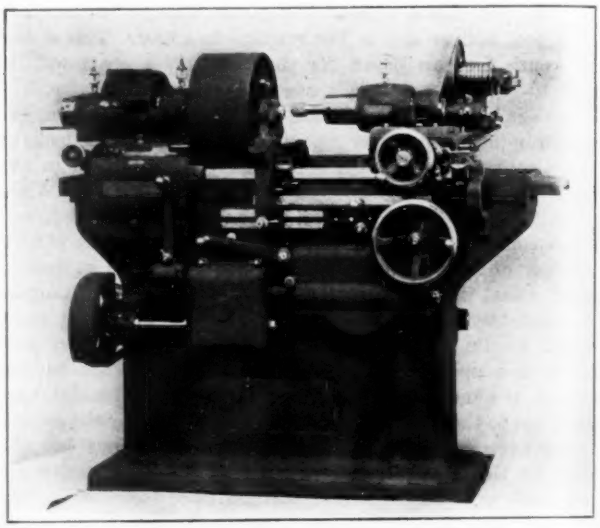

Fig. 2 Internal Grinder

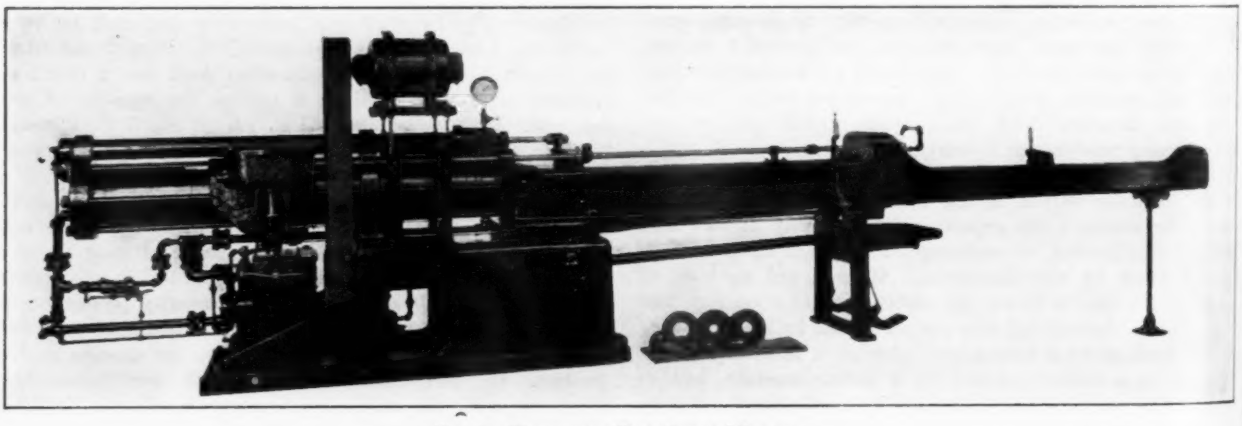

Fig. 1 Hydraulic Broaching Machine

These three general developments, namely, increased power and rigidity, increased convenience for the operator, and foolproof construction, have resulted in an enormous increase in the productive capacity of machine tools, and increase in production hours because of freedom from breakdowns.

### Comparisons of Present and Former Machine Tools

In the standard type of screw-feed broaching machine the

broach is pulled through the work by a rotating nut and non-rotating screw.

Fig. 1 shows the latest developments in hydraulic broaching machines. The crosshead and the draw head for adjusting the broaching tools are similar to those previously used in the screw-type machine. However, the crosshead is pulled by a piston rod instead of a screw, the piston rod being attached to a piston in an 8-in. diameter hydraulic cylinder. This hydraulic cylinder is connected with a variable-stroke pump, the displacement of which is controlled during the pulling

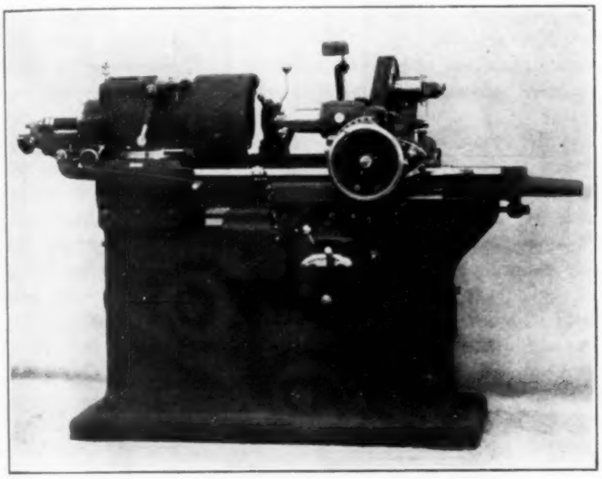

FIG. 3 PRESENT DESIGN OF INTERNAL GRINDER

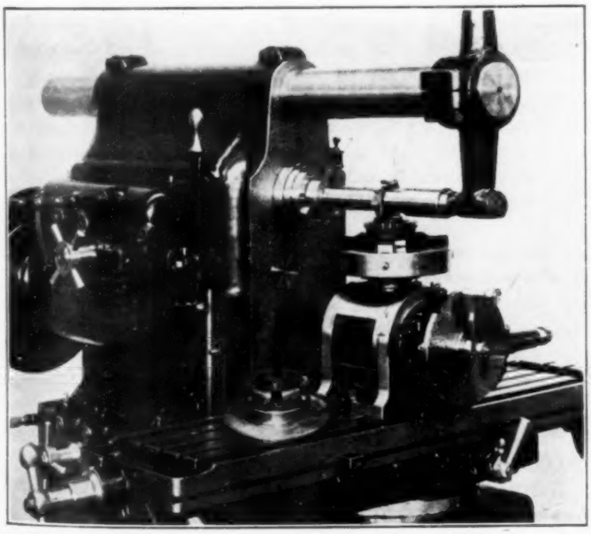

FIG. 4 MILLING MACHINE

and return strokes of the broach by tappets operated at the two ends of the stroke. These tappets operate the pump valve so as to give a slow feed and a quick return, and the feed can also be adjusted from zero to maximum by varying the stroke of the pump, thus allowing the best broaching speed to be obtained. In the pipe line is a release valve which may be set at any predetermined load. If for any reason the pressure rises above this amount, the valve operates to bypass the pump, relieving the pulling force on the broach to zero. With this safety attachment a serious breakdown is impossible, and the feed may be set near the capacity of the broach without fear of overload if the broach becomes dull, or if extra hard subjects are met with.

The great increase in production obtained by the hydraulic method is due to elimination of the great power loss from the friction of the screw and nut, which makes it impossible to run a heavily loaded screw broach at more than 4 or 5 ft. per min. cutting speed. Experience with the hydraulic method has proved that the hardest commercial material can readily be broached at a cutting speed of not lower than 12 ft. per min. while low-carbon steels are frequently broached at 25 to 30 ft. per min., an increase of from 250 to 600 per cent. The adaptation of the hydraulic pulling mechanism has also permitted broaches to be designed to take a good-sized chip, thus allowing a job to be done with one broach which formerly required two or three. The efficiency of the hydraulic broach is also about $4^1/_2$ times the efficiency of the screw broach.

A standard engine lathe of approximately five years ago was equipped with cone-driven backgeared headstock, countershaft shipping, and hand change-feed gears at the head end.

A recent model of this lathe has a single-pulley drive, ball-bearing headstock running in oil, and the speed change levers conveniently mounted on the headstock. The feed gearing is changed by a tumbler gear and cone, these gears being made of steel. The operating lever for starting, stopping, braking, and reversing the spindle is placed so that it travels with the carriage,

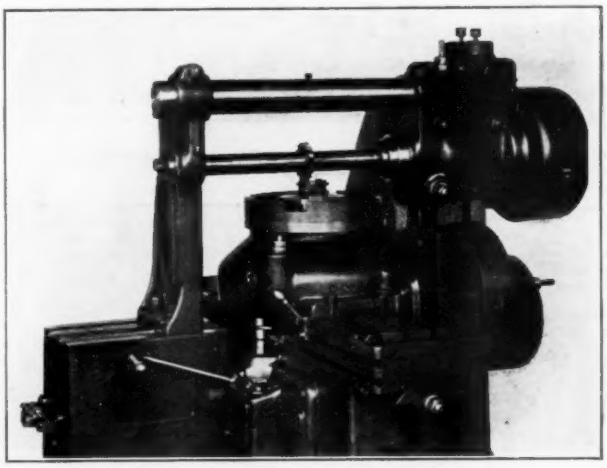

FIG. 5 PRESENT DESIGN OF MILLING MACHINE

thus always being within reach of the operator. The longitudinal feed is provided with multiple stops which can be set so as to automatically trip the feed at any desired position, thus enabling distances between shoulders to be duplicated without the use of measuring instruments. Multiple-diameter stops mounted on the cross feed screw allow diameters to be readily determined without the use of callipers. This machine is also equipped with a pan, pump, and tubing for applying cutting compound to the tool, thus materially lengthening the life of the tool and permitting increased cutting speeds. Although every one knows that higher cutting speeds and longer tool life are gained by the use of coolant, it is safe to say that at least 75 per cent of the lathes operated in New England shops are cutting without the use of compound. These various improvements in design have so increased the productive capacity of this lathe that the makers claim that a time saving of from 25 to 75 per cent may be made as compared to the ordinary engine lathes.

In a former type of flat-turret lathe, the head was of the cone

type with friction backgears. There was but one carriage, having power longitudinal and cross feeds which could be changed at the feed box on the head end of the machine, the feed reverse also being contained in this box. All changes were made through the shifting of drive keys, and to engage the longitudinal or cross feed in the apron, it was necessary to engage a worm with a wormwheel. The machine had no rapid traverse to the carriage and no centralized control.

In the present model of the same machine, the geared head has single-pulley drive, hardened alloy-steel gears running in oil, and automatic disengagement of the multiple-disk driving clutch when the gears are shifted, offering not only a practically instantaneous change, but also a foolproof construction. A cross turret has been added, and all feed changes are incorporated in the aprons, allowing instantaneous shifting of feeds without walking to the end of the machine to shift tumbler gears. These feed

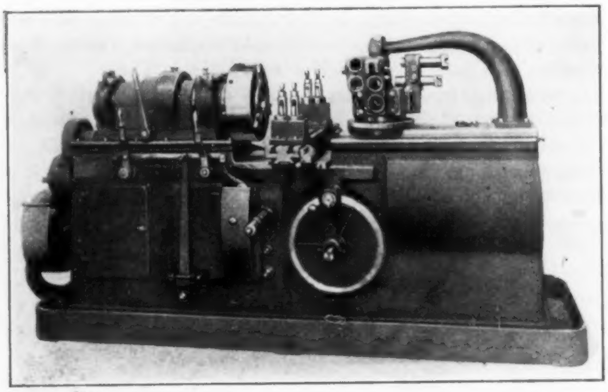

Fig. 6 Automatic Chucking Machine, Model 6*A*

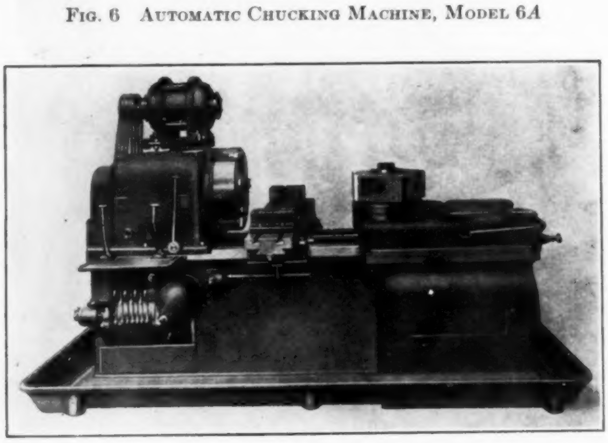

Fig. 7 Automatic Chucking Machine, Model 5*D*

gears are hardened, run in a bath of oil, and are mounted on square shafts running in ball bearings. A rapid power traverse in either direction is accomplished by a lever located on the apron. The operation of this lever automatically disengages the feed and the turnstile, another instance of convenience and foolproof construction. The added features in this machine have resulted in increased production of from 50 to 100 per cent, some users paying for the machine in six months by increased production.

Fig. 2 is an internal grinder of a few years back. It would seem from a glance that this machine was about the latest word in convenience, having as it does all levers centrally located, a quick-change gear box giving three rates of table travel for each work speed, automatic wheel guard, etc.

Fig. 3 shows the present design of this machine. The table is hydraulically driven, giving unlimited speeds, quick traverse for bringing the wheel to and from the work, and complete control of speeds and direction of movement at all times. An automatic short-stroke dog and a convenient wheel-truing device allow the operator to true his wheel just before finishing the work and are of great assistance in obtaining production and finish. The water starts and stops simultaneously with the work. Hand and automatic feed pawls for the wheel are provided.

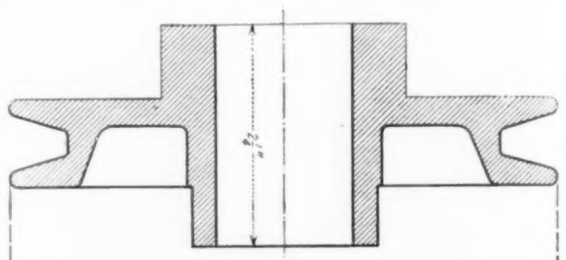

Fig. 8 Cast-Iron Fan Pulley

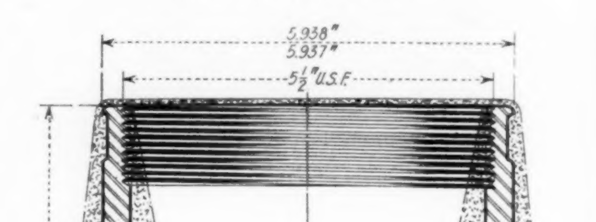

Fig. 9 Forged Differential Housing

These improvements and others result in the following increased production times:

Hardened steel bushings, $\frac{3}{4}$-in. hole, $1\frac{3}{4}$ in. long, limit 0.0005 in., increase from 45 to 100 per hr.

Hardened gear, $1\frac{7}{16}$-in. hole, $1\frac{9}{16}$ in. long, 0.0005-in. limit, increase from 22 to 70 per hr.

Bronze bushing, $1\frac{5}{8}$-in. hole, 2 in. long, 0.001-in. limit, increase from 18 to 60 per hr.

Ball race, $1\frac{3}{16}$-in. hole, $\frac{7}{16}$ in. long, 0.0005-in. limit, increase from 50 to 140 per hr.

Note that the increase in production ranges from 100 to 350 per cent.

An interesting comparison showing gain in production by the use of a modern-type milling machine is shown in Figs. 4 and 5.

Fig. 4 illustrates the old method of milling clutch teeth. The machine is of the old knee-and-column type with old-style round over arm, and tumbler construction for the drive. The time per piece was 7.65 min.

Fig. 5 illustrates the present method of machining the same piece. The machine used is a fixed-bed-type automatic milling machine. All operations including the indexing of the fixtures are automatic, and all that the operator has to do is to remove and load the work and start the machine. The time per piece is 3.58 min., less than half the time on the old-type machine, and due to the automatic features, one man can run several machines.

Fig. 6 is a model *6A* automatic chucking machine. The spindle gearing is located in the bed of the machine, all shafts run in plain bearings, and none of the gears runs in oil. The cross slide is fed by rack and pinion from the cam drum, and the turret drum is of cast iron with inserted hardened-steel strips. This model was standard five years ago, and is still satisfactory for certain classes of light work, but has, however, been superseded for heavy production.

Fig. 7 is the new model *5D* chucking machine. Some of the improvements in this model are as follows: an all-geared headstock, all gearing and shafting being of chrome-nickel steel hardened; all shafts running in anti-friction bearings, and the spindle itself running in anti-friction bearings. All high-speed gears are helical making a practically noiseless gear box. The bed of the machine has been strengthened throughout and is provided with hardened-steel ways ground in place in absolute alignment to the spindle. The turret slide is provided with hardened-steel bearing surfaces, and has been increased in size and strength. The turret seating has been greatly increased in diameter and is provided with a clamping device which does away with the old-style overhead arm. The turret cam drum has been changed from a cast-iron drum with steel strips bolted on, to a solid steel forging with the cam path milled from the solid and the whole drum case hardened. The cross slide is driven directly from its cam drum, and both the turret and cross-slide cam rolls are ball-bearing mounted. The feed mechanism has been simplified and at the same time improved so that any particular feed may be automatically obtained. The automatic changes of feeds and speeds are instantaneously operated by power, making it possible not only to drop from a high to a lower cutting speed, but also to jump from a low to a higher speed. The advantage of this improvement in doing long facing cuts is obvious. Besides being provided with safety couplings, the machine is oiled by a unit system.

Some of the results of these improvements have been startling, to say the least. Whereas a 10-hp. motor drove the first machine to capacity, it has been possible to put 48 hp. into the later machine without doing anything but stall the motor, and a number of machines are regularly using 25 hp. This is in spite of the fact that the anti-friction-bearing headstock shows an increased efficiency over the old-type plain-bearing head of from 30 to 50 per cent. Increase in production on this machine over the earlier machine has been anywhere from 50 to 300 per cent.

### Savings by Replacements

It is very apparent from the foregoing comparisons that the machine tool of today is incomparably more efficient than that of five years ago. There are however other elements which enter into the economics of replacing a machine tool besides the simple one of increased production.

The figure desired for comparison is the operating cost per hour which consists of the prorated annual charges plus labor plus power. These annual charges take into consideration depreciation; the average interest on the cost of the machine minus the interest earned by depreciation reserve; rent; repairs; and maintenance, such as oil, cutting compound, tools, etc.

The cost of the machine installed is equal to the cost of the

TABLE 1

**Machine: *6A* automatic**
**Subject: Cast-iron fan pulley**
**Production: 10 pieces per hour**
**Cost of machine and tools, \$3700**

| | |
|---|---|
| Annual charges | |
| Depreciation (10-year life) | \$370.00 |
| Average interest | 122.10 |
| Rent (same as *5D*) | |
| Repairs | 60.00 |
| Maintenance | 250.00 |
| Total | \$802.10 |
| Operating cost per hour (250 hours per month) | |
| Prorated annual charges | \$ 0.27 |
| Labor (1 man operating 3 machines) | 0.25 |
| Power | 0.07 |
| | \$ 0.59 |

$$\text{Cost per piece } \frac{0.59}{10} = \$0.059$$

TABLE 2

Machine: *5D* automatic
Subject: Cast-iron fan pulley
Production: 24 pieces per hour
Cost of machine and tools, \$5300 — \$600 = \$4700

| | |
|---|---|
| Annual charges | |
| Depreciation (10-year life) | \$ 470.00 |
| Average interest | 155.10 |
| Rent (same as *6A*) | |
| Repairs | 60.00 |
| Maintenance | 350.00 |
| Total | \$1035.10 |
| Operating cost per hour | |
| Prorated annual charges | \$ 0.35 |
| Labor (1 man operating 3 machines) | 0.25 |
| Power | 0.10 |
| | \$ 0.70 |

$$\text{Cost per piece } = \frac{0.70}{24} = \$0.029$$

Saving per piece \$0.059 — \$0.029 = \$0.03 or 50 per cent

| | |
|---|---|
| Cost per hour for 24 pieces *6A* | = 1.42 |
| Cost per hour for 24 pieces *5D* | = 0.70 |
| Saving per hour | \$ 0.72 |
| Saving per year | \$2260.00 |

TABLE 3

Cost of machine and tools, \$6050 — \$600 = \$5450

| | |
|---|---|
| Annual charges | |
| Depreciation (10-year life) | \$ 545.00 |
| Average interest | 179.00 |
| Rent (same floor space as *6A*) | |
| Repairs | 60.00 |
| Maintenance | 400.00 |
| Total | \$1184.85 |
| Operating cost per hour | |
| Prorated annual charges | \$ 0.40 |
| Labor (1 man operating 4 machines) | 0.19 |
| Power | 0.15 |
| | \$ 0.74 |

$$\text{Cost per piece } = \frac{0.74}{4} = \$0.185$$

**Saving per piece \$0.45 — \$0.185 = \$0.265 or 59 per cent**

| | |
|---|---|
| **Cost per hour for 4 pieces *6A*** | **\$1.77** |
| **Cost per hour for 4 pieces *5D*** | **\$0.74** |
| **Saving per hour** | **\$ 1.03** |
| **Saving per year** | **\$3090.00** |

new machine installed less the salvage value of the machine replaced. As has been stated before, this may be anything from scrap value to the book value of the machine if applied to some other job.

A direct comparison between the operating costs of the two automatic chucking machines follows:

Tables 1 and 2 compare the two working on a cast-iron fan pulley as shown in Fig. 8. Tables 3 and 4 give a comparison on the 0.35-carbon-steel forged differential housing which is shown in Fig. 9.

It will be noted in Table 2 that the saving per piece amounts to 50 per cent and that the saving per hour to $0.72, thus giving a saving per year of $2260. This particular piece is not one of the best for purposes of comparison, as the material of the work makes it impossible to push the machine to anything like capacity. The 6A machine does not do the grooving operation, this being done on another machine, the operating cost of which should really enter into the above comparison.

In Table 4 the saving per piece amounts to $0.265 or 59 per cent, the saving per hour $1.03, and the saving per year $3090. In the first case with the fan pulley, the machine will pay for itself in a little over two years, and in the second case, in less than two years. This plainly shows that it is economically unsound to use the old-type machine where such a saving can be accomplished.

In closing, the author wishes to acknowledge his indebtedness to Norman R. Earle of the Potter & Johnston Machine Co., for aid and advice in preparing this paper. He also wishes to acknowledge information kindly supplied by the Oilgear Co., the Lodge & Shipley Machine Tool Co., the Acme Machine Tool Co., the Cincinnati Milling Machine Co., and the Heald Machine Co.

## Discussion

F. O. Hoagland.[2] The author refers to the opportunity of disposing of machines. It is to be hoped that conditions in the machine-tool industry will be similar to those in the automobile-tire industry. Tires last 200 per cent longer than they did 15 years ago, but more tires are used than ever before. The foreign market may become a factor again in the machine-tool industry if quality is the watchword.

Anti-friction bearings are being pushed to the front. There is much merit in the movement but it behooves us to see to it that clever advertising does not cause the pendulum to swing too far. High-grade ball and roller bearings are guaranteed to run within 0.0005 in. and how is it possible to true up a piece of work within 0.0002 in. if the spindle is equipped with such bearings? When the load is heavy the antifriction bearings meet the requirements in a highly satisfactory manner, but on precision machinery, where accuracy is required, a well-designed plain bearing is superior.

Statements in regard to the importance of providing convenient means for lubrication are well made. Seventy-five per cent of all breakdowns in machine tools are probably due to lack of lubrication. If a proper oil film is maintained at all times, there never being metal-to-metal contact in the bearings, they should run indefinitely, and with very little friction.

In providing single-pulley drives, the Pratt & Whitney Company did not consider it consistent also to build cone-pulley lathes for customers who wish to cut good threads free from gear chatter marks. The gears in the spindle train are ground after hardening. Cuts can thereby be taken producing results fully as smooth as with an open-belt drive.

[2] Master Mechanic, Pratt & Whitney Co., Hartford, Conn. Mem. A.S.M.E.

The savings in replacing old machines with production tools speak for themselves. It is a case of the survival of the fittest. In preparing statements in regard to comparative costs, it is difficult to get data from the prospective customer as to his present production. Unless these are available, it is very hard to work out a formula. A formula is important and convenient and it should be provided in the printed forms. It is then possible to show the present and the proposed cost and the customer can see the saving very readily.

E. P. Blanchard.[3] The author has brought up the question of the increase of profit per unit. In the automotive industry there is a slogan, "Greater profit per unit," but the salesmen are not sent out to sell the products at higher prices. The industry knows that expansion is over and looks to the machine-tool builder to lower costs.

On the matter of obsolescence, the author also made two very interesting points. Two others were hinted at by Mr. Morrow[4] but were not entirely discussed. First, is the demand of the use of machine tools for certain facilities that are not available in any existing machine. If this requirement exists, every existing model is obsolete, and some live machine-tool builder must build equipment for this purpose.

Another point is especially important here in New England. Mr. Hoover pointed out the necessity for a flexible production program. That means flexibility in machinery and in machine tools and adaptability for the work for which they are intended. Therefore standard machines are far more flexible than single-purpose machines, and obviously of wider use, and naturally it is this type of machine to which New England must look for flexibility. There must be flexibility in cost, flexibility in quantity, in the nature of design, in the ability of the machine to cut metals, and finally in answering the market demand, for today business is not merely manufacturing. It cannot be kept separate from marketing. Quality of work produced is often directly established by the machines, and there is a matter of obsolescence in some machines that should be taken care of.

As far as the use of alloy steel and lubrication is concerned, it was not so long ago that I pointed out in an article in the *American Machinist* that out of 59 machines installed recently in one shop, three were equipped with acceptable lubrication.

The technical press and other forms of advertising can do a better job in some respects than the machine-tool salesman. Those who have had some experience on the road know that there is a barrier to that personal contact, and that the greatest resistance to machine-tool sales comes at a point beyond where the personal contact stops, where the salesman's efforts are blocked. The only way to get over that barrier is by machine-tool advertising. As much information can be given in an advertisement, in a catalog, and in other printed literature that can be put beyond that barrier, as the purchaser requires, for usually higher executives are men who, if the idea of a machine is presented to them with a hint as to how it can be applied, have brains enough to work out the application themselves, or at least see enough of the advantages to delegate some one else to work out the specific proposition in which they might be interested.

Another point in the economics of machine tools is a glance into the future. We have talked about relative quantities and mass production. If we talk about automatic machinery and the advantages to be gained by it, the greater economies, etc., that is all true, always in relative stages. We are ready to admit that the

single-purpose machine on one job that is going to run indefinitely is the machine to have, and that flexibility and changeability in application of machinery is necessary for the smaller producers. Every stage of quantity production from the jobbing shop to the mass-production plan will justify a certain refinement in machine-tool equipment and accessories which go with it. Beyond that is a point of diminishing returns which the investment cannot afford. Let every man who is equipping for a certain volume buy equipment suitable for that peak for which he has planned his production, and a little beyond to allow for possibility of expansion, and he will then get all the advantages that could accrue to him in the quantity which he is manufacturing. Machine tools will be designed not entirely for mass production but for all of the intervening stages down the line, and that complete line of machine tools is what I can see not so far ahead.

EARLE BUCKINGHAM.[5] In figuring depreciation on a machine should the total amount credited to the depreciation fund be equal to the original investment, or should it be more?

In a small steel foundry in the Middlewest there was a ten-ton cupola. At the end of a period of years when the cupola had practically served its useful life and the reserve fund for depreciation had amounted in actual cash to little more than the original cost of the furnace, the owners were faced with the necessity of buying larger and more expensive equipment than that which was being scrapped because it was no longer economical to operate the smaller equipment. Should the original calculation for depreciation have been sufficient to cover the changed conditions at the time of replacing the equipment?

C. R. BURT.[6] The question of depreciation is a factor which must be considered more and more by manufacturers and it is possible that during the next few years they will find it necessary to write off their equipment over a period not to exceed ten years, and in many cases over a period of five years. Proper reserves should be set up to place the company in a better position to weather storms, take care of dull periods, and provide for new equipment and the replacement of obsolete equipment. This is primarily due to the fact that we are living in an age of speed and new developments, and no one is prepared to say what we may be forced to face in the line of increased production requirements five years from now.

There may be a misunderstanding in regard to the automotive industry's scrapping machine tools, and while it is a fact that they do expect a new machine to pay for itself within one year, this does not mean that the machine should be scrapped at the end of that period.

Machine-tool builders are alive to the necessity for providing proper lubrication, and during the past two years there has been a remarkable improvement made in developing new lubricating systems.

In regard to figuring cost, it is obvious that no one system will apply to every case, but the important point to get across is that the users of equipment must figure their costs accurately. It is a sad fact that many firms do not figure true costs and do not realize the necessity for installing up-to-date equipment in order to make a reasonable profit.

We are all convinced that the up-to-date manufacturer is going to spend more time in the future in investigating modern up-to-date machinery as well as improved methods. The best-equipped factories with the best personnel are the ones that are going to survive in business over the next few years.

THE AUTHOR. The machine-tool builder is in a fix. He is asked to furnish standard machines which will pay for themselves in increased production in a comparatively short time. Several concerns require that this shall be done in two years, others in five, and others specify no definite time. Of course special machines are required to pay for themselves in a much shorter time. Consequently the machine-tool builder must spend a lot of money in engineering development, and instead of increasing sales he is cutting down sales because if he puts out a machine that will do twice as much work as the former he will sell only half as many. This cuts down production and makes it absolutely necessary to make a profit on a small-production basis.

If machine-tool users who require the machine tool to pay for itself in two years would scrap that machine at a fair interval after the two years and buy a new one, it would be all right. However, at least one concern having such a policy has running in its shops today machines which were obsolete twenty years ago. The conclusion to be drawn from this is that the machine-tool user must gradually reconcile himself to the spending of more money for machine tools.

# The Prerequisites of Successful Polishing

By BRADFORD H. DIVINE,[1] UTICA, N. Y.

*The author discusses those conditions which must be obtained in the polishing department to procure the highest quality of work with the least cost of material and wages. The most important consideration in successful polishing is the glue used in bonding the abrasive to the wheel and its treatment. The next most important consideration is the selection of the abrasive. These are discussed in detail. Other important factors are: the design of the article to be polished, relation of operations preceding polishing, absence of vibration, housing of the polishing department, polishing machines, automatic polishing, and polishing tools.*

THE TERM "polishing," as it is used in the metal-finishing industry, is a misnomer. Strictly speaking, the term should be applied only to those operations which produce luster. As a matter of fact, in the industry it is applied to three distinct processes—flexible grinding, polishing, and buffing. In this paper, however, the term will be used in its commonly accepted meaning.

Flexible-grinding processes are those employed for the reduction of metal where only bright, clean, or smooth surfaces are desired; or as the base for luster or for plating, painting, enameling, or other finishes. Polishing, to use the term correctly, is the process employed where luster only is desired, usually following flexible grinding. Buffing is also a process where luster only is desired, usually on plated surfaces or on non-ferrous metals. Both flexible grinding and polishing processes employ flexible wheels with abrasives glued to them, while buffing operations employ only buffing wheels impregnated with buffing compositions as the abrasives. In the final analysis all three processes are simply varying degrees of grinding.

Polishing is a very old art, dating back to the Stone Age; and, while it has become one of the largest and most important departments of metal manufacture, it has not been developed along engineering lines as have other departments. It has been, with some exceptions, a matter of rule-of-thumb, tradition, or just plain habit or ignorance.

The industry, in general, is in a state of chaos. Costs are altogether too high, mechanical operations are often performed in a crude and inefficient manner, and standardization is conspicuous by its absence. One of the most prominent men in the polishing industry in England, whose company has been in the business of manufacturing polishing equipment for more than one hundred and fifty years, wrote to the author a short time ago: "Polishing is one of the things which have developed from the experience of the workman rather than through scientific investigation." As a result, we have an industry in which engineers and executives have, until recently, manifested little interest.

Dr. Hutton, head of the British Non-Ferrous Metals Research Association, in discussing this question recently wrote as follows:

> For some reason or other, most manufacturers in the metal industry over here seem to be much more keen on devoting time and money to developing other sections of their manufacture, and the polishing room is left as the "Cinderella" of the works. Whereas, of course, it is one of the most expensive factors of production in many manufacturing plants, and would yield great economies if properly brought up to date.

Under present conditions when the executive or engineer seeks information on polishing, he usually runs into difficulties. If he tries to get information from the polishers, he is likely to encounter a smoke screen. He is brought to the realization that the polisher's job has been to polish, not to record statistics or set standards, and that polishing foremen are more interested in getting out production than in studying the science of polishing.

The experiences of two engineers, as recently stated to the author, is typical of what is found when information is sought on polishing problems. One, connected with a concern well known for its efficiency methods, was delegated to standardize the polishing department. After spending some time in the department, he was obliged to report that he was unable to find a point from which to start. The other, an engineer prominent in the brass trade, accepted a commission to provide an industry in France with standard processes for finishing a certain metal, thinking his experience in brass would provide the data. He soon found his mistake. He then searched the libraries of universities and engineering societies for textbooks on the subject. He found absolutely nothing.

There are no textbooks, no recorded information generally available, and no standard terminology in the industry. Even encyclopedias and dictionaries contain little information, and some of them do not even use the words, "polishing" and "buffing."

The subject, "The Prerequisites of Successful Polishing," comprehends the entire problem of the equipment, tools, materials, processes, and standardized control of the polishing department. The points to be considered in this paper are:

1 The design of the article to be polished
2 Relation of preceding processes to polishing
3 Absence of vibration
4 Housing the polishing department
5 Polishing machines
6 Automatic polishing
7 Polishing tools
8 Abrasives
9 Glue.

## Design of the Article to Be Polished

Polishing begins in the drafting room. Wheels of large diameter are more economical to use than wheels of small diameter. The article to be polished should be designed, therefore, to eliminate all unnecessary projections, depressions, angles, recesses or reverse curves, which can be polished only with narrow or small wheels at excessive costs. Usually the cost of any extra metal involved can be more than offset by the saving in polishing.

## Relation of Preceding Processes to Polishing

The polishing department receives the work in either rough or tooled condition. When castings are to be polished without previous operations, they should be as free as possible from excessive sprues, ragged edges, lumps, or other similar surface defects. With forgings, as much scale as possible should be removed by pickling or other methods. In drawn or stamped work deep drawing marks or scratches caused by imperfect dies should be eliminated by correcting the dies. Work which is tooled, or which is ground on solid wheels, should be so processed that the surfaces will not be too rough. Deep tool or grinding marks necessitate the removal of too much metal to reduce the entire surface to the level of the bottom of such marks.

Work should be delivered to the polishing department in such

[1] President, Divine Bros. Company. Mem. A.S.M.E. Fellow, Royal Society of Arts, London.

condition that it will not be necessary for that department to correct the errors of other departments. The cost of correction in the polishing department usually exceeds the cost of correction in the department where the incorrect condition originates. There is often continual strife between the polishing and other departments on this point, whereas care in planning would prevent such conditions. This is one of the underlying causes of the high cost of polishing.

An example of what can be done to help polishing by a study of previous processes is the experience of an ax factory. The forged ax when it left the dies was true to contour, but with an extra thickness of metal to allow for grinding off the scale. The solid-grinding operation to remove the scale destroyed the contour and left the surface in scallops or waves. It required at least three operations, which should not have been necessary, to restore the contour and prepare the surface to take a polished finish. The installation of a cheap and simple process for removing the scale while the metal was red hot eliminated the solid grinding and several polishing operations, and greatly reduced the cost of finishing.

### Absence of Vibration

The absence of vibration is necessary for successful polishing. A polishing wheel, like any high-speed unit, is susceptible to vibration. A vibrating wheel makes scatches which cost time and money to remove. A polishing wheel works at best efficiency only when the entire face of the wheel comes in contact with the article being polished at every revolution of the wheel.

Vibration comes from several sources—the building, the machine, or the polishing wheel. The building may be of light construction, or the floors may be too light to provide a sufficiently rigid foundation for the machine. The machine may be too light, or not well designed. It may not be properly secured to the floor, or may not have the necessary rigidity in the column, the shaft, or the bearings. The polishing wheel may be of such a type, or may be so designed, that it is difficult to balance. Then, too, the wheel may be so headed that high spots or hard spots are developed, which throw the wheel out of balance.

Fatigue of the operator is another reason for eliminating vibration. The author was approached by a polisher in a local plant in which had been installed wheels of a type which ran much more smoothly than those previously used. The polisher said that the vibration from the old wheels caused such lameness in his arms that he was used up by two o'clock in the afternoon. At the end of the day, he was completely exhausted. The new wheels, having no vibration, enabled him to work with less fatigue, and he could enjoy his evenings with his family. Moreover, he was making more money on his piecework rate.

While the vibration in this instance arose from the wheel, it may be assumed that the effect would have been the same had it been due to other causes.

### Housing the Department

The building housing the polishing department should be of solid construction. Floors should be heavy so that polishing machines may be firmly fastened to them. Rooms should be well lighted so that the operators can critically inspect their work. The department should be clean, both for sanitary and mechanical reasons.

There is no reason why the polishing department should be treated as "the Cinderella of the works," as Dr. Hutton says. Conditions in this respect are, however, improving; but many polishing departments are still to be found in basements or other unsuitable places. The idea seems to be that polishing is such a dirty business that the location of the department makes little difference.

Good dust-collecting systems should be installed in order that the dust from the wheels may be quickly removed. Abrasives will fly from the wheels; and if the grains from the coarse wheels come in contact with work undergoing finer operations, deep scratches will be caused which oftentimes the operator cannot account for. It costs money to take these scratches out.

### Polishing Machines

Rigidity and durability are the factors of greatest importance in polishing machines. The items which enter into these factors are the size of the machine, its weight, the floor area of the base, the design and construction, the size, the location and type of bearings, and material in the shaft and its diameter.

Rigidity, preventing vibration, has a direct bearing on the efficiency of the machine and the cost of the polishing done on it. This is not always evident until it is analyzed, but the following experience shows it to be true.

A concern establishing a polishing department bought the best electric belt-driven machines it could find on the market. After using them a while, trouble developed, and it decided to build some machines of the same general type as those purchased. After the machines were constructed, comparative tests, made by the same operators using the same wheels on the same class of work, showed that the new machines enabled an operator to produce from 12 to 20 per cent more work due to the absence of vibration.

Another factor that enters into the question of rigidity and durability in machines is that, with improved glue handling methods, peripheral speeds of from 7000 to 10,000 ft. per min. can be used, requiring a better class of machines than those used a few years ago when peripheral speeds rarely exceeded 5000 ft. per min.

Another question of considerable importance in polishing machines is that of variable speeds. This is particularly true in buffing machines. All buffing wheels, and a great many polishing wheels, wear down in diameter. They operate, therefore, at a constantly reduced efficiency, due to decreased surface speeds. The most common form of direct-connected, electric-driven machine is that using alternating current which, of course, operates at a fixed speed. Direct current, permitting the use of variable-speed motors, is found in only a few localities. To transform alternating current to direct current has been found to be too expensive to be generally satisfactory.

The best answer to this variable-speed question seems to be the machine with the electric motor built into, or attached to, the column of the machine and belted to the wheel shaft. This type of machine is rapidly replacing all others where variable speeds are necessary.

Another form of variable-speed machine recently introduced uses bevel gears, in which, by changing the gear ratio, variable speeds are secured.

### Automatic Polishing

Automatic polishing is rapidly taking its place in the industry for processing large productions of flat pieces, or pieces having a portion of their surfaces flat such, for instance, as the flat parts of pliers; or such articles as plane blades, flat-irons, monkey and pipe wrenches, sheet metals, strip steel, flat bars, knife blades, and any work which is flat or practically so.

While, at present, interest in the automatic polishing of flat work predominates, round bars, tubes, and contoured pieces are also being successfully produced on automatic machines. The variety of work capable of accomplishment by automatic processes is rapidly increasing.

Automatic polishing is not, however, as simple as many people have thought it to be. Many conditions arise not present in

hand work, for the machine is without the human "feel." The work and the wheels are in fixed positions in relation to each other, and the machine cannot correct imperfections in the work as the hand operator can. It is necessary that the work be brought to automatic machines in better condition for polishing than for hand work. Flat work must be absolutely flat, and it is often necessary to straighten or flatten work before polishing.

The difficulties encountered in automatic polishing are not so much in the machines as in the lack of ability of the operators in charge of them to tool them and operate them properly. The wheels must be manufactured especially for the work. Wheels of different character than those used for hand work usually are necessary. Absolute trueness and perfect balance are essential. The wheel must contain within itself the characteristics and qualities which will take the place of the human "feel" in hand work.

The heading of the wheels is a problem requiring much more expertness than in hand work. The head must be as strong as possible to avoid too frequent wheel changes, causing stoppage of production. Provision must be made for keeping the wheels cool, for the almost continuous application of work to the wheel generates much more heat than in hand work.

That automatic polishing reduces costs and speeds up production is shown by the following examples. On one automatic machine, hot-air registers 40 in. square are being solid-ground, flexibly ground, and polished ready for enamel (a ten-wheel operation), in 5 min. and 40 sec. each. On another machine 2400 flat-iron bottoms per hour are finished—one every $4^2/_3$ seconds. In another case 3500 small flat pieces per hour are turned out by one man operating three machines. In the steel trade a ton of cold-rolled sheets 36 × 60 in. has been polished, one side at a time, in 38 minutes.

An interesting effect of automatic machines on the polishing problem was illustrated by an experience in one factory where operators were turning out 175 pieces per hour by hand, claiming that was their limit. An automatic machine was installed with a guaranteed production of 500 pieces per hour. It did as guaranteed, and then the polishers said they could do as much as the automatic machine did. It is not likely that operators on other work in that plant continued to retard production.

## Polishing Tools

A tool usually has some particular characteristic and quality which enables it to perform an operation better than some other tool. When a tool wears out it must be possible to replace it with an identical one. Like all other tools, there is one best polishing wheel for every operation.

Polishing wheels, unfortunately, have been considered and purchased altogether too much from the standpoint of merchandise; and the fact that they are tools of very considerable importance has been somewhat lost sight of. In the manufacture of polishing wheels, too much consideration has been paid to something to sell at a competitive price rather than to the development of the tool itself in the proper relationship to the work it is to do. The general theory has been that anything round, which will yield, and provide a cushion on the face, and to which abrasives can be glued, is a polishing wheel.

The function of the wheel is to act as an agent for carrying the abrasive, and to provide the necessary cushion so that the wheel may properly execute its cutting function. The wheel should be perfectly round and true in order that the entire surface of the face of the wheel may be cutting at every revolution. A wheel which has high spots on it, or is uneven on the face, will present only a part of the abrasive head to do the cutting, with the result that the operator has to employ more time to reduce a given amount of metal—and time as represented by operators' wages is the most costly item in the whole operation of polishing.

Polishing wheels may be separated into three general classes varying according to their characteristics and adaptation to the different flexible-grinding or polishing operations, grading from the coarsest grinding to the finest finishing operations. One class is that in which the wheels are made in disk form, the materials commonly employed being disks of leather glued together; disks of canvas sewed or cemented together, or held in position by metal side plates; disks of woven felt sewed or glued together; disks of sewed buffing-wheel sections, each section individually sewed, and then the sections either sewed or glued into the unit of the wheel, or held together by side plates.

Another class of wheels is that which may be designated as the "crosswise" type. This class of wheel has steel or wood centers around which are placed blocks of leather, canvas, felt, or other materials, the blocks lying radially to the axis of the wheel and crosswise of the face. This position of the material is diametrically opposite to that in the disk type of wheel.

The third class is the wheel with a solid one-piece face. The leather-covered wood wheel is the commonest type of this construction, although leather strap faces are used on solid paper wheels or as a covering for the crosswise type of wheels. Solid felt and solid walrus wheels come in this class of solid-faced wheels.

In general, the disk type of wheels are used for the roughest, coarsest grinding operations. The crosswise types of wheels are more commonly used for practically all operations from the coarsest grinding to the finest finishing, depending upon what the degree of coarseness and what the degree of fineness is. The strap-faced wheels are, or should be, used almost entirely for the finishing operations which produce the lustrous or mirror finishes, or on flat work.

In considering the type of wheel to be used comes the question of the shape of the piece to be polished. A piece which is curved will require the softer types of wheels either of the disk form or the crosswise type. If the piece is flat, all of the operations may be performed to better advantage on the crosswise or strap-faced wheels. There are, however, very many degrees of gradation in these questions, upon which the selection of the proper type of wheel is based. It is impossible to attempt to cover the many phases of the question in this paper.

The selection of the proper character of wheel also requires consideration of the cost of using the wheel. It is characteristic of all wheels of the disk form that the face wears out of shape, and also that the wheel wears down in diameter. Where a flat piece of work is operated upon with a disk form of wheel, it frequently is necessary to true the face of the wheel, reducing its diameter, in an effort to keep the face flat. With this reduction in diameter and lessened surface speed, the element of time is increased.

In wheels of the crosswise type there is less tendency for the wheel to wear down. The fact that the pieces of polishing material are across the face of the wheel, and are not disks, prevents the wheel from wearing in ridges. Such wheels often remain practically full size and in a condition almost as good as new for many years, whereas the wheels of the disk construction are constantly worn out and replaced.

With the strap-faced form of wheel, while the body of the wheel may remain practically full diameter, it is necessary to replace the leather strap frequently.

Wood wheels with the leather strap faces are made in layers to prevent warping and splitting. Such wheels, unless the wood is thoroughly seasoned and set, commonly expand and contract unevenly in the different layers, causing ridges on the face. It is difficult to keep any wood-block wheel round and true.

The amount of cushion in a polishing wheel is a very important

factor in the polishing operation. The amount or degree of cushion in a wheel is secured either by the use of different materials or by the manner in which the materials are arranged in the wheel. The object of the cushion is to permit the face of the wheel to flatten and cover as much area on the work as possible, to grind away as much metal as possible at each stroke, and to provide a smooth cut. The degree of cushion also has a decided effect in securing the finished surface desired.

For the classes of work for which the disk wheels are more commonly used, such as the rough grinding of agricultural tools, the exact degree of cushion is not so essential; but for hardware or other work requiring well-finished surfaces, the proper degree of cushion is highly essential. On some classes of work density is such an important factor that a difference of one degree will render a wheel too hard or too soft for a particular operation.

In wheels of the disk or the solid-faced types, the range of densities is quite limited, usually to three degrees: hard, medium, and soft. In the crosswise types the range of densities is much greater. In some types it is possible to secure as many as eight degrees. In this type also it is possible to regulate the density to a much more accurate degree than in other types, and this type also permits the exact duplication of density when replacing or duplicating wheels.

A factor in wheel economy is the diameter and width of face of wheels. It is advisable to use a wheel as large in diameter as the article being polished will permit, in order to secure the maximum contact of the wheel with the work necessary to remove the greatest amount of metal at each stroke.

Large wheels have less tendency to heat than small wheels. Heat is generated only at the point of contact between the wheel and the work. On the large wheels the heated area has a greater opportunity to cool before returning to contact with the work than would be the case with smaller wheels.

It is also advisable, where possible, to use a face much wider than the piece being polished in order that the piece may be moved about on the face of the wheel and not wear the head in one spot.

The use of wheels of large diameters and wide faces reduces the investment in wheels because of the smaller number required. It reduces the cost of caring for wheels, and of reheading them. It also reduces the time lost by operators in changing wheels.

If time permitted, it would be interesting to follow out the details of the wheel question—the treatment of new wheels, the application of the preliminary sizing coats, the number of them, the manner in which they should be applied; the application of protective coats of heavy glue placed upon the sizing coat and preparatory to receiving the working head; the different kinds of heads, the methods of applying them to the wheel; the uses of the rolled head and the paste head; the number of coats of abrasives; the dressing off of the old head after it ceases to cut; the manner of handling the wheels in wheel drying rooms; the characters of the various processes for coarse grinding, fine grinding, glazing, coloring, greasing out, and oiling and other similar questions. Any one of these phases of the question would provide enough material for an entire paper of itself.

## Abrasives

The abrasive grain, which does the actual cutting, is one of the two most important prerequisites of polishing. Glue is the most important, and the grain is secondary only because the grain cannot be given a chance to do its best work unless firmly bonded to the wheels by the glue.

There are two kinds of abrasive grains in common use—emery, which is a natural product, and grains which are manufactured from bauxite.

Emery is impure or low-grade corundum containing magnetite or hematite. The corundum is that portion of emery which does the cutting. The other materials are inseparable from the corundum particles; they have no function in the cutting operation, and tend to modify the cut of the emery. This modification of the cut is considered by some to be advantageous in the finer operations employed for the actual production of luster. For flexible-grinding operations, the manufactured abrasives are far superior to emery.

Examined under the glass, the manufactured grain appears very much like sharp pebbles, uniform in size, and containing no foreign matter. It differs from emery in being more uniform in hardness or temper. Each grain is so constructed that when properly bonded to the wheel it will fracture away piece by piece, each fracture presenting a fresh cutting edge until the grain is consumed. Wheels headed with manufactured abrasives have less tendency to glaze than those headed with emery.

Care should be taken in selecting manufactured abrasives to see that they are free from slivers or elongated grains which would scratch the work.

Manufactured abrasives are treated to provide capillarity in order that the glue may grasp them firmly. In the storage of them it is important that they be kept free from moisture which might tend to deteriorate this capillarity and weaken the glue bond.

A great many concerns have been unable to secure as satisfactory results with manufactured abrasives as with the natural emery. The difficulty was not due to the grain itself, but entirely to the use of inferior glue, or to improper glue handling equipment and methods. The manufactured grains are harder than emery, and, therefore, require a stronger bond.

Care must be used to see that the proper sizes of grains are used in the proper sequence from the coarser to the finer operations. For instance, in certain cases where a No. 46 grain may be followed by a No. 80 grain, the gap between the grains may be too wide, and a much faster reduction of metal would be secured by following the No. 46 by a No. 60 or No. 70. If the gaps between the grain sizes are too great, the effort of the operator to reduce the metal by increased pressure against the wheel to make it cut, often burns the ridges, causing discoloration. Then, too, the coarse ridges have a destructive effect upon the wheel head of the finer abrasives following.

One of the evidences of the wastage caused by the improper bonding of the grains to the wheels is the fact that a business has been made of reclaiming abrasives, which have been torn bodily from the wheels, resizing and selling them. This on the face of it may seem like a good thing; but a little thought will show that, had the grains been properly bonded to the wheels and consumed by fracturing away in the polishing operation, as previously described, there would be no necessity of a reclaiming process and no grains to reclaim. Where the grains are torn from the wheels through improper bonding, and not reclaimed, they are, of course, wasted.

Another important feature in handling grains is the proper consistency of the glue for the different sizes of grains. If the glue is too thin for coarse grains, it will not provide the proper body to hold the grains. If the glue is too thick for the finer grains, the cut of the grains will be modified, a glazed condition of the wheel face will result, and wastage occurs. As in other conditions when the wheel ceases to cut freely, the inclination of the operator to force the wheel by excess pressure is likely to burn the metal, to require extra time for an operation, and to soften the glue on the face of the wheel (which in itself decreases the cutting ability of the abrasives), and the whole process becomes destructive and expensive. Researches are now being made to determine the correct consistency of glue for the different sizes of abrasives.

### Glue

Glue is the most important prerequisite of polishing. When it is realized that the abrasives glued to polishing wheels have to perform practically the same operation of grinding away or tearing down metals as solid vitrified wheels do, it will be evident that glue as the bond between the wheels and the abrasives is the most important factor in polishing. The efficiency of the combination of the wheel and abrasive as the cutting tool depends almost entirely upon the strength of the glue bond. The ability to secure the desired finished surface, and the cost of securing that surface, depend upon the strength of the glue bond. In fact, glue is the keystone of successful polishing.

The reduction of the processes of glue handling to a definite formula has been one of the most important steps toward the standardization of the polishing industry. However, to utilize such a formula to the best efficiency, the glue, handling equipment, and all factors pertaining to it, must likewise be standardized.

In spite of the fact that the use of glue in the mechanical arts is traceable over 3300 years, the use of glue seems to be little understood. One glue manufacturer has stated that with the consumption of 80 million pounds of glue annually, he doubts if 20 per cent of those using it have the vaguest conception of what glue is, or how it should be applied. The author would go farther and say that not three men out of a hundred in the polishing industry have a proper conception of what glue is or how it should be applied. Also, the influence of glue and glue processes upon polishing operations and costs is little recognized.

Every pound of glue wasted through inefficient methods carries with it a considerable wastage of abrasive grain. A recent experience showed that by simply changing the process of using glue, the same amount of work was produced with one-half the quantity of glue and abrasives. Going farther, the right kind of glue reduced the quantity again so that the same amount of work was produced with from 20 to 25 per cent of the glue and abrasives originally required. In other words, by using standard processes w h the proper glue, four and five times as much work was produced from each wheel head.

Glue is commonly purchased on a price basis rather than on a quality or performance basis. If price alone is to be considered, the basis of comparison should be the cost per quart of liquid glue ready for use. Glues of the better qualities will take more water to the pound of dry glue than glues of inferior qualities, resulting in a lower cost per quart of melted glue. The price of glue, generally speaking, is indicative of its quality.

The higher grade glues have greater strength, and are better adapted to polishing than glues of lower grades. However, the strength of glues of higher quality can only be brought out by proper handling methods. Ordinary processes of glue handling often reduce the strength of high-quality glue to that of inferior glue. The author has actually seen 30-cent glue so reduced in value by the handling processes that it gave no better results than a 10-cent glue.

The glue which gives the most satisfactory results for polishing is the best quality, first-run, straight hide glue. The characteristics necessary are jelly strength, toughness, viscosity, and—what is more important than anything else—flexibility. Many glues set hard and brittle, and are broken up and torn out by the bending action of the face of the wheel.

The first step in organizing a glue department and standardizing glue processes is the arrangement and equipment of the glue room, which should be entirely separate from the polishing department. Glue is a rather delicate thing to handle. It is easily affected by either high or low temperatures. The glue room should, therefore, be arranged so as to be free from drafts which would chill the glue. Windows when open should be equipped with deflectors. Doors should be on double-swing hinges to remain closed constantly.

The glue apparatus, and in fact the whole glue room, should be kept as clean as a dairy. Glue brushes, when not in use, should be kept in a weak solution of carbolic acid in order to destroy the bacteria which may accumulate in them.

The glue heater should be of a type which will furnish a constant supply of fresh glue in its strongest condition. Glue should be mixed and used in small batches so that it may be consumed in four hours from the time it is melted. Otherwise, it deteriorates rapidly. The individual glue pot should be of a size, therefore, to contain only a four-hour supply of glue.

The multiple-pot system is preferable to the large single pot. The size and number of pots should be such as to provide for the different consistencies of glue required for the different size grains, and also to allow extra pots for hot water and for sizing. Aluminum is the best material for the glue pots on account of its property of holding heat, and the ease with which the pots may be cleaned.

The glue heater should be equipped with a thermostat to maintain the glue at a uniform and correct temperature. Thermometers should be provided to check up the temperatures. Psychrometers should be provided in order to determine, when wheel heads do not last, whether the trouble is due to softening the wheel head by humidity or to some other cause.

Ovens should be provided to heat the wheels to 120 degrees. The abrasive troughs should be provided with heaters to heat the grain to the same temperature as the wheels to prevent chilling the glue.

In addition to the glue handling equipment, the glue room should be equipped with an accurate device for balancing the wheels each time after they are headed. The room should also be equipped with tools for removing the residue of old wheel heads. Water should not be used for this purpose when it can be avoided.

The wheel room should be separate from the polishing department. The partitions or walls should be arranged with openings both at top and bottom to permit a rapid circulation of air to carry away the moisture evaporated from the glue while it is setting. The temperature of the wheel room should be that of the working departments. Artificial heat should not be used, nor should the wheels be chilled. Both of these practices have a very detrimental effect upon the strength of the glue bond. Nature will take its own time in setting the glue, and it must not be interfered with.

There are two elements in glue handling which must be recognized and controlled. One is heat, the other is bacteria.

Heat makes glue, and heat destroys glue. The maximum strength of the glue bond, which enables it to resist the frictional heat generated in polishing, is secured only by a proper control of heat in the preparation of the glue.

Glue loses five per cent of its strength for every hour of heating. Laboratory tests have shown a loss of 67 per cent of strength after 12 hours under heat. Tests of a high-grade glue, made by the United States Forestry Bureau, showed a loss of one-half the glue strength in seven hours at a temperature of 176 deg. fahr. Glue is in its strongest condition at a temperature of 135 deg. fahr.

In order to secure certain definite results from the preparation of glue, certain definite procedures must be followed. Glue is somewhat like a chemical in that a slight change in the materials or in the formula used will make a considerable difference in the results obtained.

The conversion of dry glue into liquid glue of the strongest character is made by adding certain definite proportions (by weight) of either pure or distilled water to the glue, soaking it a

definite time, and melting it by raising the temperature to about 135 or 140 deg. fahr. Different makes and qualities of glue require different proportions of water.

Ground glue should be soaked in cold water at least three hours; flake glue, eight hours; and cake glue, twelve hours. After the glue is soaked it does no harm if it stands twenty-four or even forty-eight hours, providing the temperature of the room is not over 70 deg. fahr.

The glue when placed in the heater should be melted, not cooked or boiled.

To secure the different consistencies of glue required for the different sizes of abrasive grains, hot water should be added to the liquid glue. The proper consistency, once determined, should be recorded by instruments and standardized.

In applying glue to the wheel, no draft of air should come in contact with the glue brush, for instant chilling and serious weakening of the glue will result. The wheels and abrasives, having been heated to at least 120 deg. fahr., will then allow the whole mass of abrasives, glue, and the wheel to cool gradually without detriment to the glue strength.

Glue hardens in the process of setting much as concrete does. Setting begins with the cooling, but continues long after the cooling has reached its stopping point. A wheel head may be cold in an hour or so, appearing to be ready to use. As a matter of fact, a minimum of 48 hours is required to complete the natural process of setting glue to its maximum strength. The process of setting is, of course, the evaporation of moisture from the glue.

It is altogether too evident that very few people appreciate just what is taking place in the process of preparing and applying glue to polishing wheels. The idea seems to be to spread on the glue, apply the abrasive, and, as soon as the wheel is cool, start cutting metal with it. The usual result is extravagance, inefficiency, and waste.

The author has seen wheels headed up with a paste head $^1/_4$ in. thick, and within fifteen minutes used for grinding away metal. This was exhibited by a man who had been a polisher for 45 years, and who took pride in his so-called expertness in handling wheels.

A fact not apparently well known is that glue handling is a fight with bacteria, and again the question of heat comes in. Glue chemists tells us that the bacteria increase rapidly, consuming the strength of the glue, at temperatures higher than 140 deg. fahr. This is recognized in the manufacture of glue, which is cooked at temperatures of about 140 deg. fahr., and then the temperature is reduced as quickly as possible in the process of solidifying the glue to the point at which the bacteria become virtually inactive.

This is the reason why everything in and about a glue room should be kept as clean as in a dairy. The bacteria in glue which is left over night will contaminate fresh glue the next morning and decrease its strength probably 50 per cent. Bacterial action is one of the reasons why glue loses its strength either under prolonged heat or at temperatures above 140 deg. fahr.

One of the abuses in the use of glue has been the use of formulas for improving the glue, such formulas containing alcohol, dry carbonate of white lead, precipitate of chalk, and glycerine. Such formulas are entirely worthless. Another idea in common use in certain parts of the country is that the addition of a certain "gum" to glue will increase the strength of the glue bond. Analysis showed that the "gum" was nothing but wheat starch containing coloring matter to disguise it. Glue chemists tell us that there is nothing that will increase the strength of glue except Russian isinglass, the strongest adhesive known. Its cost is so high, however, that its use in the polishing trades is prohibited.

In addition to the points considered in this paper, there are two other prerequisites of successful polishing. One is the correct methods of processing the various polishing operations; the other, the supervision and standardization of the polishing department. However, to discuss the many points involved in the numerous and varied kinds of operations, and the use of those prerequisites already discussed in the execution of them, is not possible in the time allowed for this paper.

As to the supervision and standardization of the polishing department, the author's observation of the industry, both in this country and abroad, has convinced him that it is to the advantage of executives and engineers that they analyze their polishing problems; that they do not try to correct conditions by remedying the weak spots, but by making a complete and fundamental analysis as a basis for a systematic control and standardization of polishing departments.

## Discussion

ROBERT T. KENT.[2] In the very last paragraph the author says: "It is to the advantage of executives and engineers that they analyze their polishing problems; that they do not try to correct conditions by remedying the weak spots, but by making a complete and fundamental analysis as a basis for a systematic control and standardization of polishing departments." There can be no question but that the author is absolutely sound in this statement. At Bridgeport we have a considerable polishing problem, and we are running into difficulties all the time. Probably the cause of many of the difficulties is that we have been trying to remedy the weak spots instead of making a study of the fundamentals of polishing.

The author has outlined nine variables which may affect the polishing problem. Each one of those variables can be subdivided into a great many others, so that if the advice that is given in the last paragraph of this paper is to be followed, the problem involved will be an enormous one. Industries which have large problems in polishing can well afford to take this advice and start an investigation into the fundamentals of polishing and the standardization of our problems.

H. E. BOOTH.[3] Will the author make clearer what he means by the supervision and standardization of the polishing room? Each room is so different and each polishing shop is so different from the others that the standardization of one does not seem to have any relation to that of another.

THE AUTHOR. That question can be answered only in this way. Standardization should start with each department in regard to its own particular methods of work. The industry cannot be standardized. For instance, Mr. Booth's plant manufactures cutlery. It is almost impossible to standardize the ways and means of polishing cutlery. Oftentimes two concerns will use successfully different speeds, different abrasives, and different sequences of abrasives. The question is, which is standard? Each individual concern has to study its own problems.

What is meant by standardization is starting from the forge room or the foundry and following the work to see that the operations preceding polishing are so standardized in relation to it that this operation, which is the most expensive in the factory, is not unduly loaded with cost. That is one phase.

The other phase is more particularly the standardization of wheels to determine the density of wheel necessary, the speed at which it should be run, the kind of abrasive which should be used, and the methods of putting the abrasives on. One

[2] Bridgeport Brass Co., Bridgeport, Conn. Mem. A.S.M.E.
[3] Winchester Repeating Arms Co., New Haven, Conn.

method of standardization is to have one man in the wheel room to do this, rather than permitting individual polishers to do it as they see fit.

A. J. Carmichael.[4] The author says that work to be polished by an automatic machine must be absolutely flat. In most of our experience we find that there is no such thing as absolutely flat work. It is impossible, particularly on sheet-metal work, to make parts that are absolutely flat, and there is a question whether it is not cheaper to have the hand polisher who can get around those imperfections go ahead and do the work, rather than pick over parts to get them ready for this machine. How does the author procure flat work, and how does he get it ready for the automatic polisher so that the machine can do the work efficiently?

The Author. The word "flat" is used relatively. Latitude was allowed in the paper by using the phrase, "or practically flat." It has been the custom to send work up to the polishing department in any old condition and expect the polishing to correct it, and with automatic polishing this cannot be done. Usually the straightening or flattening process is a flat stamping process. If the work is a perforated piece which has been bulged so as not to be noticeable to the eye, it may be all right for the purpose for which the part was made, but it is far cheaper to flatten it before putting it into an automatic polishing machine.

F. D. Lane.[5] Has it been the author's experience that with the automatic polisher it is possible successfully to polish a strip of sheet stock as it comes from the rolls of a mill, commercially flat?

The Author. Polishing sheet stock as it comes from the rolls is quite a problem. The constant application of the wheel or wheels to the work generates heat that is likely to burn the metal and glaze the wheel. The problem is still being studied. There are possibilities in it. We have a job on hand now in our concern of exactly that character—safety-razor stock, but this is not being accomplished by headed-up wheels. It can only be accomplished by an abrasive moistened with oil (kerosene usually) and putting it over free wheels—not headed-up wheels.

Ordinary commercial strip stock has not been successfully polished, although I think it can be done.

Chas. F. Schaffer.[6] I should like to defend the polishing foreman. Executives say that polishing costs are tremendous, but they do not realize the condition in which articles come to the polisher.

The engineer should know more about polishing. He should know what it costs to polish an article. It makes a difference whether the article has contours or is flat. It seems to be the impression that work can be sent to the finishing room in any condition and that the finishing room will fix it up. No one seems to realize what this costs. When the engineer designs his work he should have in mind that the finishing department will represent one of the cost items.

H. A. Kirberg.[7] What does the author consider the logical type of polishing machine—one with a sleeve bearing or one with a ball bearing?

The Author. I should say the ball-bearing type. Frankly, all of the polishing *lathes* on the market are altogether too cheaply built. There are very few well-designed lathes. If ball bearings are used, the bearings are cheap ones. But ball bearings are all right if they are properly designed and properly located in the housings.

William Buxbaum.[8] Has the author had any experience with the effect which the length of time it takes wheels to dry has on the inventory in a factory of any size?

The Author. Nature takes its own course. It takes forty-eight hours for any glue to set. If a wheel is properly headed up and has set forty-eight hours, the first thought is that many more wheels will be required, but this is usually found not to be true. Even if more wheels are required, the efficiency of the wheel due to the fact that it has set forty-eight hours is enough to pay for additional wheel equipment.

# Shop-Equipment Policies in Representative Plants

## Reasons for Discarding Equipment; Time During Which New Equipment Must Pay for Itself; Methods of Buying and Discarding; Faults of Machine Tools; Methods of Drive; Records; Human Equation

By L. C. MORROW,[1] NEW YORK, N. Y.

THE TERM "shop equipment" in the metal-working industries properly includes all of the equipment used within the shop; machines, motors, conveyors, small tools, hand tools, transmission units, and so on. It is obviously impossible to treat of each kind of equipment in a paper that will not be unduly long, except as the principles laid down for one class may be applied to the others. It is with machine tools, primarily, that every metal-working shop is concerned, and therefore it is with keeping machine tools up-to-date that this paper deals.

How big is the machine-tool industry? What is its economic importance? The answers to these two questions will indicate the position that equipment policies should occupy in the affairs of users and builders.

The answer to the first question, "How big is the machine-tool industry?" is taken from the United States census of manufactures.

The Census gives certain figures for the value of machine tools, and metal-working machinery produced during 1919, 1921, 1923, and 1925 as follows:

| | 1919 | 1921 |
|---|---|---|
| "So-called" machine tools | $212,400,158 | $67,782,232 |
| Machine tools by "other" establishments........ | * | 1,524,926 |
| Metal-working machinery | 57,541,482 | 19,287,572 |
| Maximum, all products... | $269,941,640 | $88,594,730 |

| | 1923 | 1925 |
|---|---|---|
| "So-called" machine tools | $136,871,096 | $148,598,285 |
| Machine tools by "other" establishments........ | 3,787,527 | ** |
| Metal-working machinery | 56,817,437 | 47,352,746 |
| Maximum, all products... | $197,476,060 | $195,951,031 |

For more conservative figures, deduct the items which are not complete machine tools or metal-working machines:

| | 1919 | 1921 |
|---|---|---|
| "All other products"....... | $32,652,932 | $ 7,319,211 |
| "Parts and attachments"... | * | 8,936,547 |
| "Portable tools"........... | 10,907,928 | 4,480,611 |
| | $43,560,860 | $20,736,369 |

| | 1923 | 1925 |
|---|---|---|
| "All other products"....... | $ 8,571,124 | $24,946,320 |
| "Parts and attachments"... | 25,397,185 | 32,192,602 |
| "Portable tools"........... | 9,312,814 | 11,896,325 |
| | $43,281,123 | $69,035,247 |

* Not given.
** Included in above.

Minimum, complete machines only, $226,380,780 in 1919; $68,058,361 in 1921; $154,194,937 in 1923; and $126,915,784 in 1925.

The minimum figures represent an unknown number of machines, but one sub-division of "machine tools," valued at $137,525,963 in 1919; $41,506,657 in 1921; $70,717,797 in 1923; and $58,334,175 in 1925;[2] represents the following numbers of machines: 163,892 in 1919; 56,675 in 1921; 68,836 in 1923; and 38,855 in 1925. The average value at factory per machine was $840 in 1919; $733 in 1921; $1030 in 1923; and $1506 in 1925.

A word of caution must be said with respect to the average value. It should not be construed that it is comparable from year to year, nor can it be significant as an average price of a machine tool, because lathes, milling machines, grinders, hacksaws, etc., of widely different values are produced in different proportions in different years.

However, the average value, being large (about 1000) shows rather conclusively that no portable and small tools are included as machine tools, and tends to confirm the reasonableness of the figures.

The economic importance of the machine-tool industry cannot be measured by the size of the industry. It is the bit of yeast in the bread that is important—without it the bread would not rise. In answering the second question, "What is the economic importance of the machine-tool industry?" it is enough to say that back of all labor-saving machinery, back of the economical production of every mechanical necessity or labor-saving machine in the world, stand the machine tools that made them possible. Without them we could have no industry as it now exists. There could be no factories for the making of either necessities or luxuries.

Since 1914, while the population of the United States has been increasing 18 per cent, the productivity of the nation has increased 35 per cent, a rate almost double.

The railroads today are carrying 20 per cent more freight than in 1914 with practically the same number of employees.

The farms are producing 35 per cent more in volume of crops with an actual decrease in the number of farmers.

In these thirteen years, the automobile industry has multiplied almost eightfold in the number of cars built per year and over sixfold in the total annual value of the product, yet with a steady decrease in the hours of human labor per car. Whereas in 1914, the average medium-priced car required 1260 hours of labor, today it requires but 220 hours. Yet with all this decrease of human labor, the quality of workmanship per car has steadily increased.

Seven years ago, one man could handle only 800 tons of pig iron per year. Today his capacity is 1200 tons a year. Eight years ago a pair of shoes required one hour and forty minutes of human labor. Today a pair of shoes requires but 54 minutes.

The machine has brought about this advance everywhere in national productivity, this decrease everywhere in the number

[2] Returns incomplete.

of human-hours or human-minutes per piece, per ton, per dozen, per acre.

In the past thirteen years, over 6500 new metal-working machines and tools have appeared on the market—improvements on old types, new developments, new creations of mechanical genius—all designed to increase output and accuracy, and to reduce upkeep and labor.

It is gratifying that there is a growing recognition of the importance of the machine-tool industry in the economic scheme. An indication of this increasing recognition is the thoroughness with which many large users of machine tools are studying their equipment problems from the engineering and profit points of view. It is true that even in some of the larger plants there still exist hit-and-miss methods of discarding and buying equipment, and that education to substitute definite policies is needed. Likewise in the plants of medium size and in the small shops ideas are not so well defined as they should be. There is a duty to be performed on the part of the machine-tool builders, on the part of the machine-tool salesmen, and, perforce, on the part of the educators of the machinery industries, to supply the deficiency.

The subject of keeping the machine-tool equipment up-to-date falls very naturally into these sub-divisions:

- Reasons for discarding equipment
- Time during which new equipment must pay for itself from earnings
- Methods of buying
- Disposition of discarded equipment
- Faults of machine tools
- Method of drive
- Single-purpose vs. standard machines
- Machine-tool records, especially those of repairs
- Importance of the human equation in equipment policies.

### Reasons for Discarding Equipment

Equipment is discarded because it is worn out or because it is obsolete. Almost all machine tools are made up of several castings proportionately large, with smaller parts of other materials. There is seldom a great amount of wear on the castings, and the deterioration of cast iron is not rapid. Of the parts made of other materials, new ones can be made or bought. Inasmuch as wear upon all parts is seldom uniform, it would seem that if each part were replaced as it became worn the machine would never wear out. Experience proves, however, that there is a relation between the cost of repairs and the cost of new machines, that, if determined accurately, will indicate when expenses for repairs are no longer justified. There are to be taken into consideration the losses due to the non-productiveness of the machines while in course of repair. The repair cost is being maintained by some of the largest users of machine tools. If the plan should be adopted universally much of the ancient equipment now in use would be withdrawn from active service. Moreover, the records of the costs of repairs, used with the records of initial costs, would enable all users of equipment to arrive at sound rates of depreciation.

Obsolescence is brought about by several influences. They are:

- Improvements in the design of machine tools
- Increased output requirements
- Changes in the design of the product of the user
- Elimination of uneconomical manufacturing operations
- Changes in the methods of manufacture of the product of the user
- The effect upon the investment in materials in process
- The effect upon floor space
- The effect upon power consumption.

One manufacturer gives the definition of obsolescence by saying that a machine is obsolete when it will no longer pay the dividends obtainable from some other machine. Another, that obsolescence as applied to productive machine tools is the result of the elimination of uneconomical manufacturing operations. Still another, that a machine tool is made obsolete by the development of the art through which the modern tool produces more than the one it supplants.

Some of the reasons that have been given for discarding equipment and for buying new are:

- Repairs too frequent
- The new machine is a better investment
- Worn out
- Too light for heavy duty
- Machine does away with hand labor
- Cannot afford to waste the time of a high-priced mechanic on a low-production machine
- Difficulty of keeping operator interested in old machine
- Cost per productive hour of operation shows that machine is not economical for the production loaded on it
- There is a constant pressure from the customer for lower prices on the product—a pressure that must be met by lower costs of production
- To secure maximum output with the greatest possible protection of the employee's health and life
- To secure increased production
- To secure better quality
- To reduce the cost of manufacture
- To reduce the items of expense that make up the cost hour
- For manufacturing a new line of apparatus
- To reduce the cost of direct labor
- To reduce the investment in materials in process
- To eliminate the necessity for highly skilled operators
- To reduce the power consumption
- Changes in the design of product
- Changes in the methods of manufacture
- Availability of machines of new design
- To get more out of the dollar invested.

### Time Allotted Machine to Pay for Itself

There arises the question, "How much better than the old must a new machine be?" From the data available it seems that the consensus of opinion is that it must be very much better indeed. The automotive industry is very strongly inclined toward the belief that the new machine must be so much better that it will pay for itself from increased earnings within one year. Other manufacturers, whose products include tractors, ball-bearings, automobile starting, lighting, and ignition systems, universal joints, vacuum sweepers, roller bearings, cash registers, and machine tools, vary from a limit of one year to a limit of several years, say four or five. A railroad repair shop allows as much as six or seven years. One or two refuse to set a limit, taking the stand that each purchase must be made strictly upon the merits of the case. The principal argument advanced to substantiate the claim that one year is the proper limit, is that there are yearly changes in the product manufactured that are likely to make much equipment worthless. No doubt that argument carries weight when special machinery is being considered. So-called standard machines should have more in their favor, especially in view of the fact that the volume of sales of machine tools does not indicate that any immense number of standard tools are written off the books within one year or anything like that period.

Surmise aside, existing conditions call for continual and marked advance in the design of machine tools. Certain it is that the users of machine tools have given the matter serious consideration. They have at times reduced their calculations to formulas

las. For example, one manufacturer uses a formula to say that the number of months in which a piece of equipment will pay for itself is equal to the total of expenditures for the new equipment divided by the total of savings per month. Stated more elaborately, it says that *the number of months in which the equipment will pay for itself* equals *the cost of the new equipment installed* plus *the cost of tooling the new equipment* plus *the cost of interest for X years at 6 per cent* (*X* equaling the number of years determined upon as the maximum time during which the equipment must pay for itself) plus *the cost of depreciation for X years at 10 per cent* plus *the book value of the displaced equipment,* that sum divided by the difference between *the existing rate (or cost) per piece* and *the estimated rate per piece on the proposed new equipment* multiplied by *the number of pieces to be produced per day by the proposed equipment,* multiplied in turn by *the number of working days per month,* to which product is added *the savings in overhead per month.*

In that formula it is considered that the savings are made up of productive labor, and that if the expense of productive labor is cut in half, the percentage of overhead to productive labor is increased 10 per cent. This conclusion is reached as a result of cost determinations, and there is no doubt that it applies in the plant using the formula.

Another manufacturer uses practically the same formula, except that he determines his change in overhead from a "burden control record," that shows direct labor charges; direct burden charges (under which there are 14 sub-divisions); indirect burden charges (under which there are 8 sub-divisions); and fixed charges (under which there are 6 sub-divisions).

These two examples are cited to show to what extent some users of shop equipment have gone to determine on an engineering basis their policies of discarding and purchasing equipment. For the most part they have been left to do these things for themselves, although it might seem quite logical to believe that such definite methods of determining the value of new equipment should have been worked out and presented as sales arguments by the machine-tool builders.

### Buying Methods

There is a definite movement away from the selection of machine tools and equipment of like importance by the purchasing agent or purchasing department. There are exceptions, where the purchasing agent is a man of engineering training or caliber, who could properly be called an equipment engineer. However, in almost all plants of appreciable size, the formal order is issued by the purchasing department, which is responsible also for follow-up. Many times the requests for quotations are written and signed by the purchasing departments. In some plants, where the purchasing department has nothing to do with the acquisition of equipment except the clerical work, it is nevertheless necessary for salesmen to make their overtures to that department, and upon all visits to go through the formality of gaining admittance by applying first to the purchasing agent.

No fault should be found with the arrangement just described where it exists. Each plant has its own problems to solve in taking care of visitors. Where there are many of them some routine must be followed in the interests of the seller and his time as well as the buyer and his time.

Some of the methods of buying with which I have become acquainted are, in brief, these:

*Plant No. 1.* The shop superintendents and master mechanics make their recommendations annually, at a stated interval before the equipment budget is made up. The supervisor of equipment passes on the recommendations. The financial man of the organization authorizes the procuring of data. The purchasing agent obtains proposals. The machine-tool committee selects.

*Plant No. 2.* The superintendents of individual plants, who are responsible for their own equipment, ask for it as they need it. Their requests are sent to the plant managers, of whom there is one for every three or four plants. The plant managers act upon the requests, and send those considered favorable to the general works manager, who authorizes or rejects. An equipment engineer studies all of the requests sent to the general works manager and advises him.

*Plant No. 3.* Recommendations originate with the time-study department. They are approved by the head of that department, by the production manager, and by the factory manager. The equipment is bought on guaranteed production.

*Plant No. 4.* Requests originate with the foremen. They are investigated by the research department and approved by the factory manager. The purchasing department prepares the order, issues it, and does the follow-up work.

*Plant No. 5.* Demonstrators recommend that certain machines be bought. Recommendations also originate with machine-tool supervisors, who make a physical review every three months and report through their superintendents on equipment needed for greater production, to replace less suitable equipment, or to replace worn-out equipment. Action is then taken by the director of works equipment.

*Plant No. 6.* Foremen make recommendations to the production manager. All details of proposals and quotations are handled by the purchasing department. All salesmen are dealt with through the purchasing department.

*Plant No. 7.* The heads of the factory engineering department, tool equipment, and metallurgical department make recommendations for the approval of the purchase of equipment to an operating vice-president. Foremen are consulted by those heads on problems of great detail. Details of ordering and following up are carried on by the purchasing department. Equipment is bought on trial.

*Plant No. 8.* The men who control the acquisition of equipment are the superintendent, supervisors, efficiency engineers, foremen, and job foremen. Any one of these men has the privilege of requesting shop equipment to improve method or product, reduce cost, or conserve floor space. All requests are studied by the efficiency engineering department. The purchasing department obtains proposals and quotations. Formal order is made by the efficiency engineering department. Purchasing department follows up.

*Plant No. 9.* Anyone in the organization has the privilege of recommending the acquisition of equipment. Every recommendation goes first to the "plant committee," made up of leading foremen and superintendents and presided over by the general manufacturing superintendent. Recommendations of this committee go to the "manufacturing committee," made up of the heads of all departments, including purchasing and engineering. The committee's decisions are referred to the board of directors for approval or rejection.

*Plant No. 10.* The production, manufacturing, and methods and tools departments have the privilege of requesting equipment. The works manager decides upon the machines to buy. The purchasing department issues the formal order. In investigating equipment the mechanical man looks to the mechanical details. The purchasing agent looks to the purchasing details. Visiting engineering representatives of manufacturers talk to the foreman, superintendent, or works manager.

*Plant No. 11.* Equipment specialists determine the need for new machinery, development engineers work out new methods of manufacture, and standardization engineers have charge of the replacement of obsolete and worn-out production equipment. The duties of the standardization engineers include the development of machine specifications, assistance to and coöperation

with machine-tool builders, and the development of new models of standard types of production equipment.

*Plant No. 12.* Orders for new and replacement equipment originate in the master mechanic's division. They are approved by the superintendent of production. Purchasing details are cared for by the purchasing department. The master mechanic's division is responsible for obtaining deliveries.

*Plant No. 13.* When machine foreman and department foreman agree that replacement is necessary, they consult the tool supervisor. When the three agree, they consult the superintendent, who makes the decision. Foremen may suggest the make of machine wanted. The tool supervisor issues requisitions, which pass through the hands of the division superintendent, general superintendent, and works manager. The purchasing agent issues the orders.

In connection with the methods of buying, it is of more than passing interest to know what are the sources of the information required by users of machine tools to enable them to keep pace with developments. In the contacts that I have had I have found an almost unanimous agreement upon these sources:

- The new-equipment sections of the technical press
- The advertisements of the technical press
- Machine-tool salesmen
- Machinery expositions
- Plant visits.

These sources speak for themselves.

### How Discarded Equipment Is Disposed Of

Discarded equipment is disposed of by being sold to other users; by being sold to dealers in used equipment; and by being scrapped. As the scale is descended from the high-production shop and the shop working against keen competition, it is found that there is a market for discarded equipment in the shops where not so much is required from a machine and where competitive conditions are not so severe. It is not good economics to throw into the scrap machines that possess a good part of their life and of course they are going to be sold and resold just as automobiles are.

Whether the machines are sold direct to the new users or to dealers in used machinery depends upon market conditions, and the effort that the seller is willing to make to find customers. Evidently there is an economic need for the dealer in used machinery, since he retains his place in the industry.

Among certain users of machine tools there is a policy not to allow discarded machines to stand around for long periods. If there is no market available within a reasonable length of time (about six months) after the machines are taken from the equipment, they are broken up for the scrap. One of the reasons advanced in favor of rapid disposition is that antiquated machines have a bad influence upon shop morale when they stand around. Another is that the floor space is too valuable to give over to them.

### Faults of Machine Tools

In selecting equipment that will give better service and bigger profits, the user of machine tools must, of course, take into consideration what to him are the faults of the machines he is using. There are two things to be desired in this matter of faults: One is that the user would report all shortcomings to the builders and the other is that the builders would give such reports the consideration that they deserve.

Among the faults that have been charged up to machine tools by users who constitute on the whole a very desirable market, as to volume, are these:

- Some parts made of wrong material
- Improper lubrication
- Improper tooling
- Wrong application to work in hand
- Overloaded
- Too wide a range in speed and feed variations
- Cost of repair parts too high
- Repair parts frequently do not fit
- Loose-pulley bearings poor
- Bearings too small to take care of the added load due to dull cutters
- Table bearings and knee slides of milling machines need greater attention
- Locking devices do not lock
- Heavier tables are needed on drilling machines, and more adequate arms needed to support them
- Fly-wheels are needed to absorb shock
- Flexible mounting of driving pulleys would be an improvement. Machines equipped with them would fit into line manufacture whether set parallel or at an angle to the line
- Something should be done toward uniformity of the heights of tables
- Further study of the causes of chatter is needed to improve design
- The master tools of industry should be started in life with greater accuracy
- Some machine tools are built too hurriedly, in order to offset a competitor's lead
- Poor workmanship
- Wrong selection of materials
- Not enough oiling capacity
- Not enough ball and roller bearings
- Present-day multiple-spindle operations require too long a time in indexing
- Slides are too short on some machines
- Punch presses should be heavier
- On some machines collets are too light
- On some machines shear pins should be provided. On others the shear pin should be closer to the work to protect more of the mechanism
- Standard machines are seldom capable of operating at speeds as high as desired
- Punch presses could be equipped with friction wheels to drive against the inside of the rim, and with soft brass wire shear rings between screw and pitman, so that overloading will cause the friction wheel to slip, and double-heading or other interference will cause the wire safety ring to shear.

No attempt is made to justify or deny the faults enumerated. All of them have been named by very earnest users of machine tools.

### Drive

There is a great difference of opinion as to the best method of drive for modern machine tools in modern shops. Individual motor drive and group motor drive with belts from overhead works to the machines are receiving most attention. The method of transmitting all of the power from a single unit by means of line shafts seems to be out of the running.

The proponents of the group drive advance as their principal argument the lowering of the power factor when many motors are running at less than full load. They point also to the greater investment in motors when individual motor drive is the method adopted.

Those who favor the individual drive are inclined to believe that the advantages of the absence of belts, with greater cleanliness and better light, and with accessibility for service by overhead cranes, more than offset any increased costs. They point out

also, that, with group drive, when a transmission line or motor goes out, the entire group is out; that there is much waste when only a single machine or a few machines are run overtime; and that the advantage of the flexibility of the individual drive in positioning and moving machines is of itself a sufficient claim in favor of that type of drive.

To me it appears that each shop must work out the problem for itself, and I point out the situation as a suggestion to the machine-tool builder that the prospective buyer of his equipment may have very good reasons back of his desire for just the kind of drive that the builder is not furnishing, no matter which kind it be.

Favor is sometimes shown the single-pulley drive because machines so equipped are more readily sold as second hand. The fact that electric current differs in different localities is another point in favor of the single-pulley drive.

### Single-Purpose vs. Standard Machines

To some extent the selection of single-purpose or standard machine tools is comparable to the selection of one or the other type of drive. Some manufacturers lean very heavily toward the special, single-purpose machine It is probable that they do so because they find that it pays, even when no such machine is available on the market, but must be designed and built in their own factories. There are others who will almost go out of their way to stick to standard machines. In favor of the single-purpose machine is the fact that it can be shown to pay on work of great volume and of fixed design. On the other hand, the standard machine has greater resale value and does not limit changes in the design of product.

### Machine-Tool Records

The importance of machine-tool records has been brought to my attention. If we agree that plants should be kept modernized, we must agree, I think, that the machine-tool record is indispensable, not alone for cost, depreciation, and inventory purposes, but for carrying a record of the costs of repairs and comparative data needed in dealing with the equipment problem.

In writing of his equipment policies for the *American Machinist*, the factory manager of a famous plant said,

> Our repair cost records serve as a guide as to the time when a machine should be placed in the obsolete class. They serve also as a guide in the matter of rebuilding, of which we do probably more than the average amount. We consider repair costs so important that we budget the payroll of the repair department monthly, projecting the budget three months ahead. The budget is based on productive labor according to our output schedule. When the cost of the repair payroll exceeds the budget allowance, one or both of two things must be wrong. Either our repair gang has not worked efficiently or we are repairing where we should be buying, or both. Since we are able to check our repair labor very closely, we are most likely to find that we are nursing along some machines that we should be better off without.

### The Human Equation

One of the advantages of up-to-date machine equipment is the effect upon employees. It is only human nature to want to live in a modern house, to own an automobile with the latest improvements, and to want to work with the latest equipment. I was told recently in a big and comparatively new shop where there are none but individually motor-driven tools, that when the men were moved from an old shop, with older methods of drive, into the new one, some of them said that they grew six inches.

It is not uncommon for managers or equipment engineers to believe that there is a noticeable increase in production when new and modern equipment is used, due to its effect upon the morale of the operator and entirely aside from increase due to the greater productivity of the equipment.

It seems quite possible, as has been explained to me, that there is a psychological effect upon men of the movement of materials, for example, on conveyors, and for that matter, on rapid-production machines, that induces an ambition to maintain the movement, or even to accelerate it.

Modern machinery has taken much of the onerous heavy labor from the backs and hands of the workmen. Power rapid-traverse mechanisms have eliminated the heavy and time-wasting cranking formerly necessary to elevate cross-rails and to traverse heads and tables. Improvements such as push-button control have reduced danger to both machinery and men and have saved much time formerly wasted. Proper and complete guards have greatly reduced the hazards of machine-shop work, have saved much suffering and much money. Convenient controls have added to the day's production and have made it possible for the operators of the heaviest machines to leave the shop after a day's work still comparatively fresh. These improvements, inherent in up-to-date equipment, have benefitted machine-tool-building and machine-tool-using industries greatly because of the increased satisfaction of the shop personnel.

These facts are being recognized, and with that recognization there is a growing appreciation of the value of the opinions of the men in the shop concerning equipment. Usually expression of shop opinion is secured from the foremen. More and more wide-awake concerns are giving their foremen a voice in the selection of equipment. A large concern, to which I have referred previously, has gone so far as to insist that all recommendations for equipment must originate with the foremen of the plant. To follow such a policy does not mean that the superintendent, or the manager, or the president, need sit by and wait until the foremen have discovered needed equipment. It does mean a tactful plan for getting the foreman to sell himself in regard to that equipment and finally to recommend and request it.

Where high-production programs are in operation there are two methods of introducing new machine tools into the production. One method is to put them into the line as soon as received and the other is to try them on a production basis in an experimental department. The choice of method depends upon the type of management and the type of operators. It is needless to say that the experimental method is necessary in some shops, and there is much in its favor even when not necessary, especially if the man who is to operate the machine is allowed to help put it through its experimental paces. Prejudices that exist in the shop can be overcome by proper management, which includes the introduction of new equipment in a way that allows for existing conditions. Perhaps the fact that prejudice exists is not often enough recognized. However, most machine-tool builders will probably believe that it has existed if they will recall an experience with some machine that was thoroughly proved in the builder's shop yet could not make guaranty for the buyer.

### Conclusion

In conclusion there are several interesting facts that seemed to have no place in the paper up to this point as it is sub-divided.

In the matter of loading machine tools there are two policies followed: One is to load them well within their rated capacities; and the other is to give them all the load they will stand. Without going into great detail, the reasons for underloading are to secure long life with a minimum of maintenance and repair expense. The reason for crowding, or overloading, is to get out of the machines all the production they can deliver before they become obsolete. The overloading is done with full expectation of shorter life and higher repair costs.

An instance of the profit accruing because the overloading policy was followed came to my attention. The introduction of a single change in the method of making a part caused the replacement of 300 of one type of machine by 30 of another, for the same

output. It is quite a task to dispose of 300 machines of one type in the second-hand market, and in the case cited the manufacturer's consolation was that while the machines were in use he had made them much more than pay for themselves by loading them to capacity.

Replacement of machines by groups is many times advisable. Especially is this true in piece-work departments, where a new or improved machine tool would give one operator an advantage over the others.

Machine-tool salesmen as a whole receive the praise of some buyers and the adverse criticism of others. What seems to be certain is that most users of machine tools, of the type that understands the equipment problem, want real engineering service in selling. Expressed very succinctly, what is wanted is a kind of salesmanship that will have as an objective, before everything else, the interests of the buyer.

The last point is that automatic operation and feeding are growing in favor. The magazine is preferred to the hand feed where applicable, and the hopper feed, where the parts can be shoveled in, is preferred to the magazine. The limits to the magazine and hopper feeds are recognized, of course. However, their use is increasing, and must be taken into consideration.

There is more to the equipment problem than I have told. There is a great deal more that I do not know. I have been glad to contribute what I could for two reasons: To help bring to the attention of those users of machine tools who are not keeping their equipment up-to-date those instances in their plants where the judicious spending of money on new equipment will pay them a profit; and to help to uncover for the machine-tool builder those opportunities for sales that are hidden because of the failure of that division of management responsible for equipment to understand the possibilities of the machinery available to reduce its costs.

## Discussion

F. O. Hoagland.[3] The author called attention to many interesting and cold facts. Prior to the War machine-tool production amounted to about, $50,000,000 per year. This was thought to be an enormous figure, but comparing it with the figures which the author gives, it seems rather insignificant.

The period of obsolescence for a standard machine tool is very indefinite; it may be written off in ten years; a special machine, in three years. There are cases where a machine must pay for itself within a year because the product may be changed. It is chiefly important, however, to keep the machine busy earning profits, otherwise all calculations come to naught. A machine running, say, 30 per cent of its capacity because it can turn out in that time the required amount of product, will require three or four years in which to pay for itself, whereas if it could be used nearer 100 per cent of the time it would not only pay for itself in a comparatively short time but in a few years it would show a handsome profit running into several times its cost.

The various methods of buying new equipment are probably working well enough under various shop organizations and conditions. It is hard to say which one is the best. I think it depends on the individual and on the requirements.

From both the buyer's and the seller's point of view, however, it is essential that the salesman, in order to be successful, know his line. It gives confidence to the prospective customer and closes the order for the machine to mutual advantage.

A short time ago we were in the market for a certain kind of machine. There was one machine which was particularly attractive, but there was one operation required of the machine which had not been done before and there apparently was no reason why it could not be done. The manufacturer's representative, however, thought that it could not be done. Before the representative got in contact with headquarters and found the operation could be performed on the machine, the order had already been placed with another concern. If the representative had known the possibilities of his machine and had been willing to fight for it he would have received the order.

The present tendency is definitely towards individual motor drives. For some time to come, however, the single-pulley drive meets the requirements as it is applicable to lineshaft drive also and can be easily converted either way.

[3] Master Mechanic, Pratt & Whitney Co., Hartford, Conn. Mem. A.S.M.E.

H. S. Beal.[4] One of the interesting things that we discuss with our customer sometimes is the amount at which a man should be capitalized when replaced by a machine tool. In our minds we arrive rather loosely at the figure of $15,000 per man. Any machine which can be purchased inside of $15,000 and thereby eliminate one man appears to represent a proper saving.

J. H. Connolly.[5] There was mention in the paper of equipping power presses with friction drives with shear rings between screws and pitmans. The shear rings in the screws have proved not so attractive on small presses because the continual pounding of the press causes the ring gradually to shear through until, after some continuance of that action, it finally lets go under very light load. A somewhat brittle washer might be used that would break under an excess of load instead of gradually shearing through.

The installation of motors on either new machines or old machines in service may be somewhat simplified by the use of belt-tightening attachments which are now readily furnished. They are mounted on the motor and if the machine is built for an ordinary belt drive the motor can be easily installed and connected to it.

Charles F. Marquis.[6] The policy of the General Electric Company in regard to the replacement of tools is to put a machine tool on the retired list when it is found to be unprofitable. It is either sold or scrapped. Very frequently a new design alters the plant equipment and makes a machine unfit for the particular purpose for which it was furnished. Lists of these retired tools are sent to the different plants, no matter where they are located—Erie, Ft. Wayne, Pittsfield, Lynn, or Schenectady. Any machine out of use in any one of the plants is put on the list, and the executives from any of the other plants can select any of the tools if they have a use for them.

As Mr. J. A. Smith, who has charge of the machine tool purchases in Schenectady said, "We have no sentiment about machine tools. If they are not profitable, we take them out and either sell them or scrap them." In his organization there is one man who is delegated to try to dispose of these machine tools. If he does not find a purchaser within a reasonable length of time, the machine is scrapped. It is all purely a matter of dollars and cents, and if profitable use cannot be made of a machine tool it is put out of commission.

Industry, of course, is changing very rapidly. First we are particularly busy on one line, and when we get equipped for that, something happens to the sales organization and it does not get the orders, or perhaps there is a lull in that line and another branch will come up, and then of course the tools are taken wherever they are applicable.

# Recent Developments in the Application of Anti-Friction Bearings to Machine Tools

## Illustrations of a Variety of Designs; Importance of Proper Lubrication and Methods of Preventing the Accumulation of Dust in Bearings

By R. F. RUNGE,[1] NEW YORK, N. Y.

THE SUBJECT of this discussion is rather far-reaching, if consideration is to be given to the numerous details entering into the proper application of anti-friction bearings. Due to limited time, it will be quite impossible to deal directly with specific details, and the discussion will therefore be confined to general principles.

It does not seem necessary to repeat here the fundamental practice in connection with anti-friction-bearing application, as that has been covered very completely in previous discussions and in the vast fund of information which has been widely distributed by the several leading ball-bearing manufacturers. This discussion will therefore deal with the newer developments with which there has now been sufficient experience to permit recommending them as proper machine-tool practice.

These principles may best be understood by referring to several illustrations which treat of the more important machine-tool elements. Certainly, anti-friction bearings have very definitely proved their superiority over other types of bearings in the more usual applications, such as change-speed gear boxes, loose pulleys, back shafts, feed screws, drilling-machine spindles, etc.

To those in the machine-tool industry who were pioneers in the application of anti-friction bearings many years ago, considerable credit is due for breaking down many of the old prejudices. This has resulted in a very decided advance and change of opinion during the last two years throughout the industry, so that we find today many important applications of anti-friction bearings in locations which only a short time back were considered questionable. The result obtained required considerable improvement in material, character of finish, and closer tolerances, accompanied by considerable metallurgical and physical research and also experience gained through actual use in the field, so that a surprising advance has been made over a short period.

It is desirable first to understand the improvement which those interested in this development are attempting to attain. Anti-friction bearings, to be successful, must show many times the life of the older forms of bearings or considerably less maintenance, resulting in greater number of productive machine hours. The application must be one which is more foolproof than the older types of bearings, where a scraping-to-fit is necessary or adjustments are required. This is becoming more and more important as a greater amount of unskilled labor is finding its place in industry.

The next item of importance is the use of a bearing which has the absolute minimum of friction. This is quite obvious, as friction means wear, and wear definitely defeats accuracy and quantity of production. In this connection, it is unquestionably a fact that the more modern types of ball bearing, made to extreme accuracy and of the highest quality of material, will certainly provide the least friction, and for the same reason require the minimum or no adjustment.

Heat also is directly coupled with the subject of bearing friction. Heating on precision machines is of decided importance, as it will be immediately understood by those who are closely engaged with machine operations on precision work that such machines do not produce close tolerances consistently until the machine has attained its operating temperature. This materially affects machines in which automatic gaging of certain forms is used, so that machine heating due to friction in bearings plays an important part in percentage of scrap production.

If the above elements are realized through the application of anti-friction bearings, then it must necessarily follow that there will be a power saving of some magnitude, or, on the other hand, a greater amount of power delivered to the cutting tools, resulting in increased production.

It can therefore be considered, in general, that the advantages of anti-friction bearings have been classed here in the order of their importance and may be summed up as providing for greater production at less cost.

Rigidity is highly desirable in most machine-tool applications, thus reducing to a minimum the possibility of vibration. In that connection it might be well to mention here that an attempt has been made, in the more recently designed machines, to provide heavier machines for a given operation, and in many cases where vibration has been present experience has shown that additional weight in the parts affected has very successfully overcome that objection. Mention is made of this condition for the reason that ordinarily the bearings are criticized for unsatisfactory results, whereas in many cases the trouble may be elsewhere.

In order to obtain proper results, it is necessary very carefully to analyze the conditions to be met with regard to the bearings as with any of the other machine elements. It is therefore most earnestly recommended that any one contemplating the use of anti-friction bearings should have the entire problem very carefully studied by the bearing manufacturer. The several high-grade bearing producers have had considerable experience, and full advantage should be taken of that experience.

The machine-tool manufacturers have been most cautious in the past in considering the application of anti-friction bearings to such parts as milling-machine spindles, lathe spindles, grinding-wheel spindles, and work-head spindles on the various types of machines. This is to be expected due to the requirements of consistent accuracy of performance and also due to the failures of past years, when the bearings had not been developed to as high a standard as at present, and improper types as well as improper mountings were used. This discussion will therefore be confined to the more important machine-tool-bearing locations, and an attempt made to indicate the more modern methods of application which are proving to be most satisfactory.

### Some Applications

Fig. 1 shows the application[2] of ball bearings to a geared-head lathe. The important consideration here is the spindle mounting. On the chuck end of the spindle there are two pairs

[1] Vice-President, SKF Industries, Inc. Assoc. A.S.M.E.

Presented at the First National Meeting of the A.S.M.E. Machine Shop Practice Division and the New Haven Machine Tool Exhibition, Mason Laboratory, Yale University, New Haven, Conn., September 6–9, 1927.

[2] The patent rights of this and other designs illustrated in this paper are protected.

or four bearings recommended. The use of four bearings provides for maximum rigidity of the spindle and sufficient bearing capacity with the minimum outside diameter and maximum spindle diameter for sufficient torsional strength. Two bearings are used at the back end of the spindle, where the load is lighter. This mounting gives the maximum of rigidity and, the accuracy of all parts being held to very close tolerance, is sufficient for load

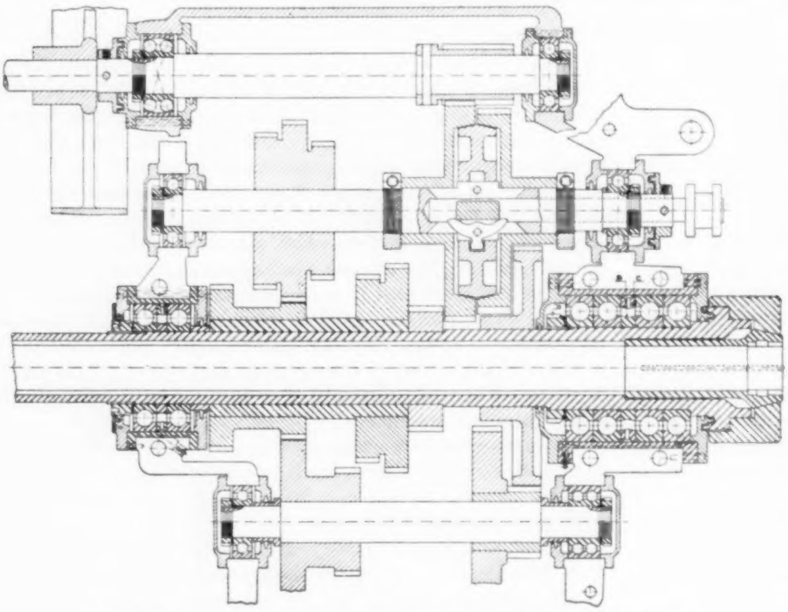

Fig. 1 Application of Ball Bearings to a Geared-Head Lathe

distribution over the several bearings. In order to permit greater accuracy in the finishing of the parts, attention is directed to the mounting of the outer rings of the bearings in a bushing. The bushing permits the use of better material for supporting the outer rings of the bearings, and may be hardened where this is an exceptional requirement. In this type of application, it is always recommended that the bushing be ground in order to provide closer tolerance for fitting and a higher character of finish. The use of bushings will further permit through-boring for both the front and back holes in the headstock in one setting, and adds further to the ease of assembling by the use of capped bearings.

Where it is found in the assembly that the spindle does not line up with the ways of the lathe, the use of the bushing permits the scraping out or reboring the bushing seat for proper alignment, and the outside diameter of the bushing can then be ground to suit the changed hole diameter.

It is obvious that it is necessary to eliminate all radial and axial play in the bearings, as well as in the fitted parts composing the bearing mounting. It is also necessary to confine the amount of movement permitted by elastic deformation between the balls and the raceways when the load is applied. This is provided for in the individual bearings, so that when the locknut $A$ is set up, the bearings are loaded both axially and radially by establishing the proper amount of elastic deformation within safe limits to a point beyond the amount of elastic deformation set up by the working load. The axial and radial movements in the bearing under the working load are therefore held to extremely close limits, which is only a small percentage of the amount that must be provided for in an oil-film-supported bearing, with which it is always possible to change the position of the spindle by squeezing out part or all of the oil film. In the case of the ball-bearing mounting, the variations imposed by an oil film can be absolutely ignored. It is only necessary to grind spacing rings $B$ and $C$ to a slight difference in width, due to the accumulated variation between the widths of the outer rings and the widths of the inner rings. The individual bearings are interchangeable with each other, are reversible, and can be individually replaced. It might be added that spacing ring $B$ is necessary to lock all of the inner rings between the nut and shoulder. Spacing ring $C$ is used for the transference of thrust load from one set of bearings to the second set, so that there will be more than one row of balls carrying the thrust or axial load.

The four bearings comprise a unit definitely clamped on the spindle and in the housing, thereby positively stabilizing the spindle

The bearings in the auxiliary shafts in this lathe head are more or less general as to type of application. A possible exception to that may be pointed out through the use of the self-aligning type of ball bearing next to the pulley. This design permits the bearing to accommodate itself to any possible deflections due to the overhung belt load.

The spindle mounting is one which is also recommended for precision machines of the centerless, cylindrical, and horizontal surface-grinding types.

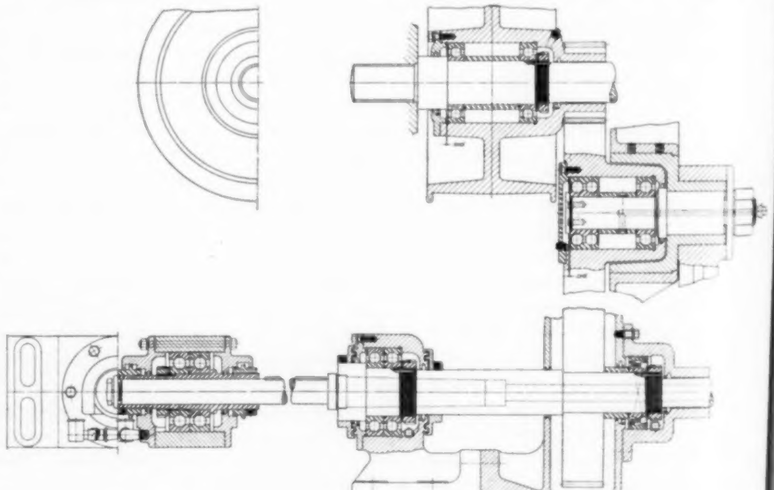

Fig. 2 Application of Ball Bearings to a Milling Machine

Lubrication is an important feature which will be covered later.

Fig. 2 shows a design which applies to horizontal milling machines, the important element of which is also the spindle. In this case, the main spindle is supported on two bearings at the front end and a self-aligning bearing at the back end. The arbor support also carries two bearings. In both of these instances where two bearings are used, the same principles of bearing construction are embodied in order to provide for initial elastic deformation between the balls and raceways. Attention

is called to the construction of the arbor support, wherein the mounting can be removed without exposing the bearings or interfering with the lubrication. Although this design does not include bushings for holding the outer rings of the bearing, this is desirable for the front end of the spindle when space will permit.

On the intermediate gear there is shown a double-row, deep-groove ball bearing which comes directly under the tooth load, and a single-row bearing at the back end, principally for more rigid stabilization. The idler pulley is the usual type of mounting with regular single-row bearings. It may be pointed out here that four different types of bearings are used, which are composed of extremely accurate spindle ball bearings, self-aligning ball bearings, double-row deep-groove ball bearings, and single-row ball bearings, each of the types having been selected very definitely to perform a particular function.

Figs. 3*a* and 3*b* show two types of live tailstock centers for lathes and similar uses. Fig. 3*b* incorporates the usual type of flat-plate thrust bearing to withstand heavier thrust loads than can satisfactorily be carried on any of the radial types of bearings. This thrust bearing is required to carry the load in one direction only, as indicated by the arrow. When the tailstock is without load, it is important that the stationary ring of the thrust bearing be prevented from dropping, and for this purpose a series of light springs (marked *A*) are provided in the backing plate to keep a slight reverse pressure on the bearing.

It will be noted that the spherical type of roller bearing is

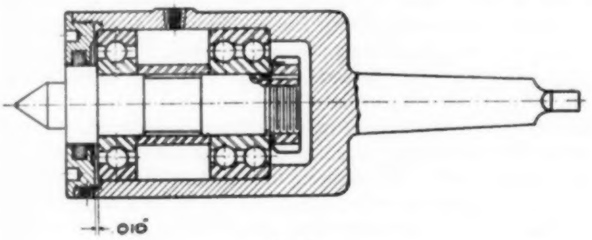

Fig. 3*a*

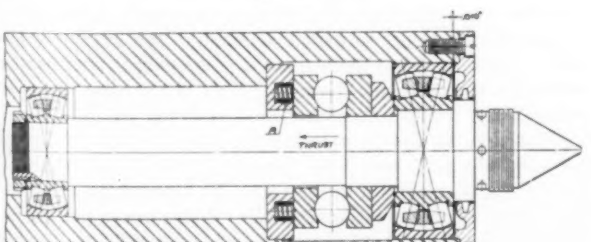

Fig. 3*b*

FIGS. 3*a* AND 3*b* APPLICATION OF BALL BEARINGS TO TWO TYPES OF LIVE TAILSTOCK CENTERS

introduced in this construction. This is for the purpose of obtaining greater bearing capacity within a limited space. It might be noted that this type of bearing has slightly more than twice the capacity of the equivalent size single-row ball bearing.

Fig. 3*a* shows a live tailstock center employing one double-row ball bearing to take the combined thrust and radial loads and on the front end a single-row bearing for radial load only. The advantages of these designs are that there is less heating set up than with dead centers, that there is a slight reduction in power required, and that there is an almost entire elimination of redressing of the center points, permitting more accurate positioning of the work, as the centers can be brought up metal-to-metal.

Inasmuch as there are many lathes, milling machines, etc., equipped with simplified countershafting, the design of Fig. 4 is recommended as one which provides for maximum efficiency, minimum space requirements, minimum weight, and minimum attention. While there is nothing particularly new about this application, attention is called to it as in many cases a very inefficient type of countershaft is supplied with the machines, and if maintenance and power saving are to be considered in the machine tool itself, they are equally important in the countershaft.

The designs so far presented have dealt mainly with moderate

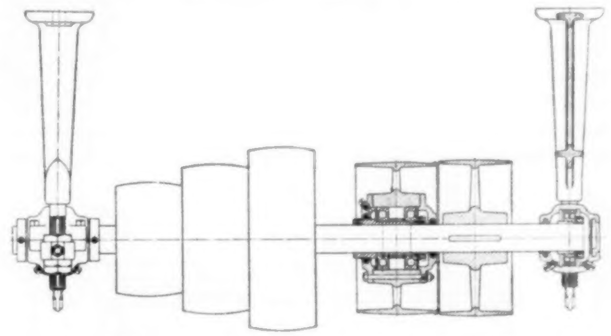

FIG. 4 COUNTERSHAFT EQUIPPED WITH BALL BEARINGS

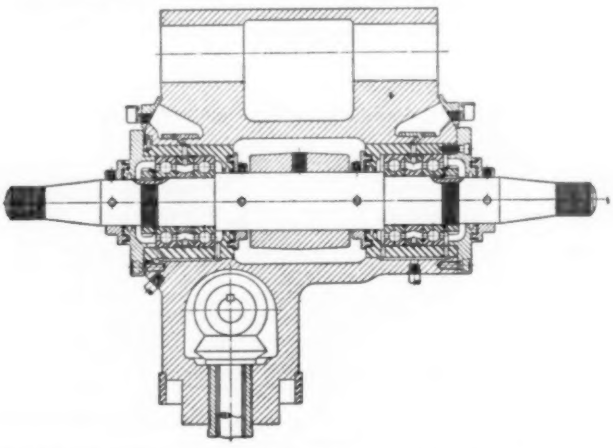

FIG. 5 GRINDING-MACHINE SPINDLE EQUIPPED WITH BALL BEARINGS

speeds and comparatively high load. In the grinding machine the conditions are generally reversed, speed being the most important consideration and load conditions secondary.

The mounting shown in Fig. 5 is for a grinding spindle for external work. In this it will be noted that the bushing principle is again used. This provides for greater accuracy of bearing mounting, which is of still greater importance where higher speeds are encountered. The same special type of spindle bearing is recommended in this design. Here, again, where load capacity is not so important, the use of two bearings at each end of the spindle is recommended.

Fig. 6 shows a small high-speed internal grinding spindle. Due to the great amount of trouble which has always been experienced with sliding bearings on high-speed work, ball bearings came in for earlier consideration on this application than elsewhere, and there has probably been more experience and greater progress made on the internal spindle than on any other type. Where a few years ago these spindles were operated at about 10,000 r.p.m., speeds of approximately 25,000 r.p.m. are now being regularly used, and in certain unusual cases from 50,000 to 60,000 r.p.m. are being attempted. In these higher speeds there are

several important considerations aside from the bearings, but without proper bearing application, any other developments, such as high-speed drives, etc., are of little consequence.

Fig. 6 shows again the double-bearing mounting at both the front and rear ends of the spindle, utilizing specially made spindle bearings. The pair of bearings at the front end are locked endwise in order to stabilize the spindle, and it probably does not require mentioning that the stabilizing bearing should always be located nearest the grinding wheel so as to keep to a minimum the amount of change of wheel position due to expansion of the spindle because of heat. While this principle applies particularly to grinding spindles, it also is of importance on any other type of spindle. This design then permits the expansion or contraction of the rear end of the spindle, as the two bearings at this point are permitted to float axially. Due to the special spindle-bearing construction, the two bearings in this design may also be locked through the inner races by a nut,

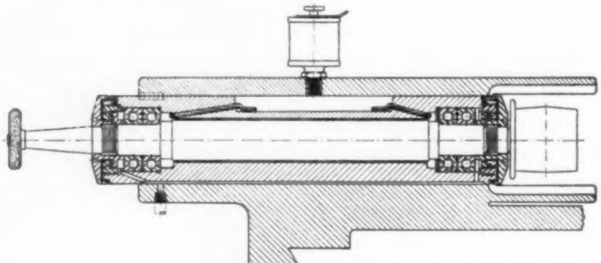

Fig. 6 Grinding-Machine Spindle Equipped with Ball Bearings

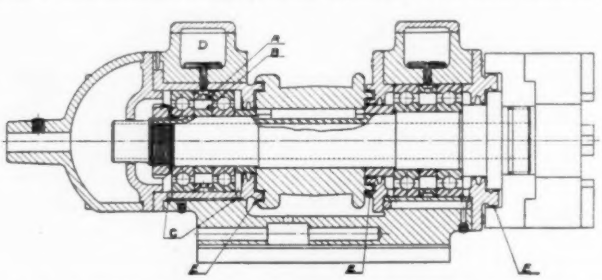

Fig. 7 Application of Ball Bearings to Work-Head Spindle of Grinding Machine

thereby taking out all of the radial and axial looseness and providing for the amount of initial elastic deformation.

The reason for providing for initial deformation in bearings for high-speed grinding-spindle mounts is somewhat different than for those on the heavier spindle applications. In the high-speed internal spindle it is not only necessary to eliminate any play from the bearings, but, due to the high speed of the balls in the raceways and very quick acceleration, it is important that the balls be not allowed to skid on the unloaded side of the bearings. When initial elastic deformation is provided for in the bearing, each ball is definitely driven through the inner race by positive contact. This skidding which takes place in the bearing will naturally set up a slight amount of wear, thus causing looseness.

Fig. 7 is a rather interesting application in view of the fact that for many years it had been considered quite undesirable to attempt to carry the work-head spindle of grinding machines on ball bearings, the general objection being that, due to the slow speed of the work spindle, any eccentricity or irregularities of the bearings would be transferred to the work being ground. The method of mounting as shown in this design, in consideration of the accuracy of the special spindle bearings, completely overcomes that objection and is responsible for even more accurate work than has been generally done on spindles having sliding bearings, as here again the variation in oil film in the sliding bearings is completely eliminated. This construction follows closely those shown previously in so far as bearings and mountings are concerned.

## Lubrication

Proper lubrication for ball bearings is important, although it is commonly known that they require a very small amount of lubrication. It is quite necessary, however, that that be of proper consistency, and care should be taken to use a lubricant free from acids and foreign matter.

There have been certain tendencies toward the use of grease in precision and high-speed applications. Grease may be used under certain conditions, but due to the great variety of viscosities of grease, and also the numerous fillers which are used, grease lubrication is subject to a wider range of variation than is oil and is therefore less controllable. For such applications as have here been discussed, years of experience have very definitely shown that oil lubrication is preferable.

In the design shown in Fig. 7, as well as in most of the others, it will have been noted that oil lubrication is provided for in that oil is fed to the bearings through wick filters. It is a very common occurrence in supplying additional lubricant for machines in operation in the shops, that the end of the oil can may contain a certain amount of grit or chips; and in the case where grease is used, many times the grease has picked up, through exposure, considerable gritty foreign matter. It is rather surprising to note the amount of fine grit which will settle into an open grease can from the atmosphere. A small amount of abrasive which finds its way into the bearings is likely to develop bearing looseness due to abrasion. This is usually misconstrued as bearing wear, which it is in a sense, but not inherently due to the bearing itself. The filtering of lubricant before it enters the bearing housing has very definitely been proved a decided advantage, and on that basis alone grease is eliminated as a proper lubricant as it is not subject to efficient filtration.

As has been mentioned in a previous paragraph, it is advisable on precision machines to reduce as much of the heating as possible. Where grease is used, there is grave danger of generating additional heat through churning. This is also true where the bearings are partly submerged in a reservoir of oil. This is eliminated in the designs presented, in that the oil is fed through the wick as a filter and from there through the spacer ring *A*. Part of the oil may find its way into the bearing through capillary action along the internal surface of the spacer ring *A*, but most of the oil will drop on to the spacer ring *B*, the result of which is that most of the oil entering the housing is atomized. A reservoir is not permitted to form, as the oil will feed through the bearings and out through drain holes *C*. This really develops into a drop feed from oil reservoir *D*, as the feed through the wick is easily controlled. This has an additional advantage in that should any foreign matter or abrasive find its way into the bearing housing, there is a tendency for the oil to carry it out through the drain holes. In certain instances where capillary feed is advisable, the wick is permitted to rub on a rotating part, which not only acts as a wiper for additional oil suction, but also for atomizing.

Where automatic lubrication, or a centralized system, is used for all of the bearings on a given machine, this same principle of lubrication can be applied.

This principle of lubrication cannot be too strongly emphasized, as foreign matter and improper lubrication in any type of bearing are extremely injurious, as has well been demonstrated.

From the standpoint of foreign matter getting into the bearing

housing, the design of enclosures is of equal importance. In the design in question, at the three positions $E$ is shown what is termed a labyrinth seal. This may be of the single or multiple type. Those shown in Fig. 7 are single, whereas those shown in the design in Fig. 6 are multiple. This construction has proved quite satisfactory, although there still remains room for improvement. In the case of high speed, grooves filled with felt, cork, or other compositions have not proved entirely satisfactory. The rubbing friction is sufficient to burn the material, and, in addition, any soft material acts as an absorbent of abrasive, and over a period of time sets up a lapping condition, accompanied by heat and wear.

In closing, the importance should again be emphasized of making a careful analysis of the conditions to be met in the various types of machines; that full advantage should be taken of the information the bearing manufacturers are in a position to supply, and that standardization should be definitely kept in mind. It is fair to say that the initial installation of ball bearings, if made standard practice on machine tools, should show very little, if any, higher cost than many of the present types of sliding bearings, to say nothing of the decidedly lower maintenance costs of ball bearings in comparison.

The machine-tool industry, in the writer's twenty-two years of observation, is now making greater headway than at any previous period in the application of better bearings, and a safe prediction would be that the next important step in the way of improvement will be a more general adoption of ball bearings as standard equipment in the machine-tool industry.

# The Manufacture and Application of Extruded Copper Tubes

By GEORGE A. FOISY,[1] NEW HAVEN, CONN.

*The paper describes briefly the development of extrusion processes. Soft metals such as lead, tin, and lead-tin alloys have been extruded by heating them to a temperature just below the melting point and forcing them under pressure through dies. Collapsible tubes for holding dentifrice have been formed from cold metal in a press by a process in which a punch, entering a die, forces the metal to flow between it and the sides of the die, the tube being stripped off the punch by hand.*

*The paper next describes the cold extrusion of copper into tubes 7 mm. in diameter, having wall thicknesses of 0.0035 in. to 0.006 in. and 9 to 15 in. long. Electrolytic copper, 99.9 per cent pure, is extruded hot into bars about 1/2 in. in diameter. These are cut up into slugs about 7/16 in. long and subjected to two preliminary forming processes which reduce them to cups with wall thickness of about 1/10 in. and pressed bottoms of paper thinness. The cups are then extruded cold in a press by means of a die and punch, the material flowing out of the die around the punch through an annular space which is the exact cross-section of the finished tube. A pressure of 50,000 lb. is applied throughout 1/15 of a second, the energy thus expended causing the copper to assume a plastic state.*

*A final operation forms hexagonal ends to the extruded tubes which permits their assembly with closely fitting sides into cellular radiators for aircraft and automobile motors, condensers for refrigerants, unit heaters, and other heat-exchanging apparatus.*

THE extrusion process offers a method of manufacturing short lengths of thin-walled copper tubes which is more economical than the usual draw-bench method of manufacturing. The relative novelty of this method can be better appreciated if it is stated that the method is comparatively new from the manufacturer's standpoint and is used by not more than three or four companies throughout the entire world at this time, the reason for this being twofold: first, because the basic patents were held in America, and second, because the small amount of obtainable knowledge of this subject coupled with the limited demand for short lengths of thin-walled tubes acted as deterrents. There is no question but that, as more and more is learned of this subject and as new uses for the finished product appear from day to day, the industry offers a very fertile field for expansion.

## History

The extrusion process is not new inasmuch as we find that the first patents on record were taken out in England in 1797. However, up to within recent years, all patents having to do with this process covered the manufacture of lead, tin, or lead-tin alloys and finally led the way in more recent times to the copper-zinc alloys which contain small percentages of aluminum, lead, nickel, iron, or other ingredients. The first extrusion machines were comparatively clumsy tools somewhat resembling hollow cylinders containing a hole in one end and fitted with a piston. A lead ingot heated just below its melting point was then placed within the cylinder and pressure applied to it by the piston which was actuated by a screw. Continuous pressure on the ingot forced the lead to emerge from the hole in the bottom in the shape of a rod.

Later on, somebody thought of partially closing the orifice at the bottom of the cylinder by means of a rod somewhat smaller than the hole and held in a fixed position. When pressure was applied to the lead ingot as before, the lead emerged in the form of a hollow tube.

In 1863 a patent was issued in this country covering the manufacture of tin-lined lead pipe by the extrusion process. Up to that time, this pipe had been made by melting tin inside of the pipe but this was unsatisfactory because the tin did not always cover the entire inner surface of the pipe, lumps were often formed, and the coating was of very unequal thickness. The means employed to manufacture tin-lined pipe consisted in fitting a hollow ingot of tin into another of lead and then fitting the assembly into a cylinder somewhat similar to that previously described. As pressure was applied to the top of the piston, both the lead and tin ingots were extruded at equal rates, causing the finished pipe to have a smooth appearance both internally and externally, and also giving the interior a uniform, homogeneous coating of tin.

In 1873 a patent was issued for the manufacture of curved lead pipe such as is used for water traps. This method was simplicity itself. In the middle of the pressure cylinder such as has been previously described, an annular diaphragm or washer was placed with an opening larger than the fixed rod previously described and which determined the inside diameter of the pipe. By moving this diaphragm a trifle to one side or the other, it was possible to vary the volume of metal flowing through the opening on various sides and this, in turn, caused the pipe being extruded to be bent to one side or the other at will, depending on the direction in which this diaphragm was moved.

At about this time, there was established in New London, Conn., the business of making collapsible tubes used to contain a dentifrice. These tubes were made of pure tin and the method of extruding differed from that previously described in that the moving punch was set down into a die with a solid bottom containing the tin matrix. Upon the application of pressure, the metal in the die had no place to go except through the annular opening between the inner diameter of the die and the external diameter of the punch and consequently shot up the punch, from which it was stripped by hand. This method of extrusion, while different from that employed in the manufacture of copper tubing, constitutes the first method on record wherein a metal was extruded without the application of external heat.

Up to 1903, all the known methods of extrusion dealt with metals of a naturally plastic nature such as tin or lead, and all of them, with the exception just mentioned, had to rely upon the application of heat in order to make the extrusion practicable. In that year, 1903, a diemaker from Binghamton, N. Y., was experimenting with tools used in the manufacture of the two-piece "Bachelor Button" which he was then making and with which everyone is familiar. During his experimentations, he happened to make a punch a trifle long and rather than scrap it, he decided to put it to some use in order to ascertain its effect on the stock he was then using.

[1] Superintendent, Radiator Department, Winchester Repeating Arms Co. Assoc-Mem. A.S.M.E.

Presented at the First National Meeting of the A.S.M.E. Machine Shop Practice Division and the New Haven Machine Tool Exhibition, New Haven, Conn., Sept. 6 to 9, 1927.

To his surprise, the finished button measured not $^1/_8$ inch long as he had expected, but approximately one inch in length, and had the form of a slender tube not in the least resembling the button he had started to make. After repeating the experiment a few times and obtaining the same result, he came to the conclusion that the metal, being confined on all sides except at the annular opening between the punch and die, was forced to flow through this opening when sufficient pressure was exerted by the punch. This, then, represents the first known case of the true cold extrusion of any metal harder than lead or tin and so, through various evolutions and improvements, but with no change in the fundamental discovery made by this diemaker, we arrive at the method in use at the present time.

### Manufacture

The tubes made by the extrusion process which is about to be described are composed of copper of a purity of at least 99.90 per cent. The tubes have a wall thickness of 0.006 inch in ordinary practice, although it is possible to make them with a wall as thin as 0.0035 inch without great difficulty.

The extrusion process divides itself into two main parts: first, the formation of a suitable cup, either from rod or sheet copper, and second, the extrusion of this cup into a thin-walled tube. As now practiced, these cups are made from extruded electrolytic-copper rods approximately one-half inch in diameter and 12 ft. long. These rods are extruded by the well-known process of heating the ingot close to its melting point, thereby rendering it soft or plastic enough to flow through the dies, which differs from the cold-extrusion method being described.

The extruded rods are cut up into small cylinders, each one of which contains nearly the same weight of metal as will be contained in the finished tube. The most economical way of cutting up these long rods consists in shearing off five lengths or cylinders at one time, each one of these lengths being $^7/_{16}$ inch long and weighing 140 grains or $^1/_{50}$ lb. This method of cutting or shearing makes high production practical since the presses doing this work have a speed of 125 strokes per minute and five pieces are cut off at each stroke.

These sheared pieces are subjected to two operations, the purpose of which will become clear if it is borne in mind that it is desired to make hollow cylinders out of these pieces preparatory to their being extruded.

The first of these two operations consists in the indentation of the small cylinder or slug and forms the start of the hollow cylinder which is the ultimate goal. After annealing, the indented slug is then subjected to a second forming operation which completes the work started by the first, and the erstwhile solid slug emerges as a small hollow cylinder with a bottom not much thicker than a piece of paper and actually perforated in the center. Both of these operations are performed on heavy draw presses with friction dials. These presses have a stroke of $3^1/_2$ inches and contain under-punches in order to push the work back up over the dies and out of the machines.

It may be wondered why two operations are necessary to form a hollow cylinder out of a slug of copper one-half inch in diameter and of the same height. This is due to the self-hardening properties of copper as it is being worked, inasmuch as the stresses set up in the displacement of so much metal become higher than the tensile strength of the steel in the punch after a comparatively short distance has been traversed by it, and it consequently becomes necessary to start the perforation, anneal the work and go through the second operation of making the slug hollow down to the bottom.

In describing the foregoing operations leading up to the actual extrusion of copper tubes, it must be remembered that the same hollow cylinder might have been obtained by forming a cup from sheet copper but the mechanical difficulties presented in such an abrupt folding, coupled with the extra operations necessary to make a base thin enough, make it much more economical to manufacture it as described.

### The Extrusion Process

After another annealing operation, this hollow cup is now ready to be extruded. At the present time it is approximately $^9/_{16}$ inch high, $^7/_{16}$ inch diameter and has a wall thickness of $^1/_{10}$ inch, and in one operation this cup will emerge as a tube 10 inches long and having a wall thickness of 0.006 inch, a reduction of 94 per cent. This offers a clear contrast between the extrusion method and that of ordinary drawing where a reduction of 50 per cent represents the usual limit.

The extrusion operation itself is done on a straight pillar drawing press having a stroke of but 2 in. This will no doubt seem all the more remarkable when it is considered that at each revolution of the machine a tube anywhere from 9 to 15 in. long is made. Fig. 1. shows the rear of the extrusion press.

The extrusion press is equipped with two sets of punches and dies but the punch holders are mounted on slides having a reciprocating longitudinal movement and operate at one-half the speed of the press, so that while there are two sets of tools, as just mentioned, but one tube is made per revolution of the machine.

The actual extrusion of the tube is somewhat as follows: The slug previously described, and which resembles a hollow cylinder, is picked up from a friction dial plate and set down within a die having an orifice in the bottom of exactly the same diameter as it is desired to obtain on the outside of the finished tube. Meanwhile, the punch which picks up this cup and places it in position within the die has a diameter equal to the desired internal diameter of the finished tube, so that a cross-section through the punch and die when in position shows a perfect annular opening which is the exact cross-section of the tube to be extruded.

On the punch, as well as the die, there is a shoulder whose purpose it is to fit tightly into the top of the die and not only to press down on the cup within the die but also to prevent the escape of metal, rendered plastic by the very high compression, up over the die instead of down through the annular opening at the bottom where it is supposed to go.

Having placed the cup in position inside of the die and with the punch directly over it and descending, the sequence of operations is as follows: First of all, the cup becomes subjected to a high pressure by the action of the press transmitted through the punch. This pressure has the effect of causing the sides of the cup to enlarge and to hug the sides of the die tightly; in fact, so much so that the work necessary to cause the outer molecules of this enlarged cup to slide in the die during the process of extrusion represents a considerable factor of the total work necessary to extrude the metal. This effect has been called surface friction, and the writer believes that this surface friction is responsible for the fact that certain metals having more plasticity than copper are harder to extrude.

Visualizing now the cup up to the point where it has bulged and has been set firmly on the shoulder in the die, continued application of pressure by the downward movement of the punch will cause either a rupture of the tools or will force the metal in the cup, now in a plastic state, through the annular opening between the punch and the die, thereby forming the tube. The reason for the plastic state of the copper is that the energy of impact, or the kinetic energy of the press, has been converted into heat at the point of impact, i.e., at the cup itself. Experiments made on an Olsen testing machine show that for a copper cup weighing 140 grains, a pressure of

approximately 25 tons, or 50,000 lb., is necessary to start the actual extrusion of the cup, but immediately the metal has started to flow, this pressure drops down to 10,000 lb., proving conclusively that the difference in pressures has gone into the creation of heat necessary to render the cup plastic before it can start to extrude.

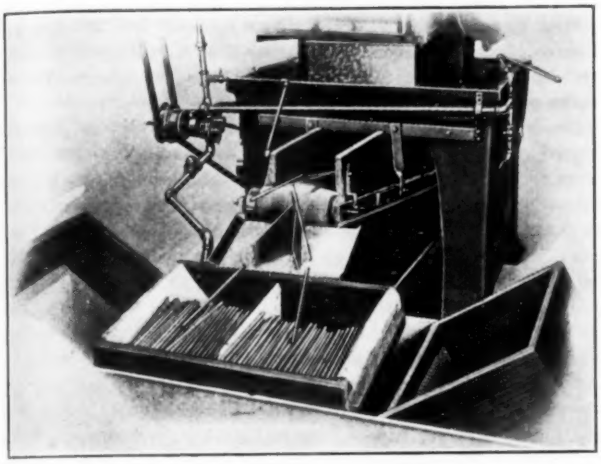

Fig. 1 Rear View of Extrusion Press, Showing Carrier Belt and Method Whereby Tubes Are Carried into Boxes

Now it will be remembered that a cup, which has been heated by the application of the energy in the press, is surrounded by steel tools which are good conductors of heat, and it may be wondered why these tools themselves do not dissipate the heat away from the cup and thereby prevent its becoming plastic. The reason for this is that the press has a speed of 125 r.p.m. and that at this speed, the work of compression and extrusion is done in one fifteenth of a second, from which it will be seen that the heat embodied in the cup does not have time to be transmitted to the tools before it is extruded. An interesting proof of this was found during the process of studying the various pressures required to extrude on an hydraulic press. Here the rate of extrusion is approximately seventy times less than on the standard extrusion presses and it was found that the heat caused by the work in the cup was transmitted through the outlying tools so rapidly that extrusion was impossible, and that fracture of the tools invariably occurred.

## Cooling and Lubrication

It is obvious from the tremendous amount of work done in extruding a tube, that a continuous succession of these operations would cause the tools used in the operation to become heated to such an extent that annealing would ensue, were a coolant not used. As explained before, an amount of heat capable of preheating the cup and thereby increasing its plasticity, would materially reduce the amount of work to be done in the actual extrusion operation and would also increase the life of the tools, but the difficulty in obtaining a satisfactory balance between an excess and a paucity of heat is still a problem which will only be solved by future research. Not only must the coolant remove heat from the tools but it must also quench almost instantaneously the extruded tube issuing from the die at a high temperature, lest annealing and spoilage of the tube result.

In addition to these two duties imposed upon the coolant, it must possess two other qualities, namely, lubrication, and relatively high viscosity at elevated temperatures. Lubrication is needed to facilitate the sliding of the cup in the compression stage immediately before extruding in order to diminish the surface friction between the outer wall of the cup and the inner surface of the die.

The only substance which has satisfactorily performed all of the above four functions is lard oil. Not only is it an excellent coolant, but its high flash point and viscosity enable it to be used where almost all other commercial types of oils have been found useless. At various times aqueous soap solutions have been tried, with and without lard oil, but the results have been disappointing. As a matter of fact, the extra friction entailed by the use of experimental lubricants, other than lard oil, was so pronounced that a decided grind or crunch could be heard every time a tube was being extruded, demonstrating an audible proof of the extra friction encountered.

## The Tool Problem

There remains one subject pertaining to the extrusion process which is the cause of considerable variation in production costs and that is the tool problem. If one considers that a pressure of 50,000 lb. is needed to start the extrusion of the tube and that this, reduced to unit pressure, becomes 200,000 to 250,000 lb. per sq. in. on the punch, it will be appreciated that it is rather a delicate problem to find steels capable of standing up under stresses almost as high as their yield points. Moreover, the proper heat treatment and design of these tools require the utmost care, since the least variation or departure from tried and tested standards means that the tools either will not function properly or else that their lives will be very short.

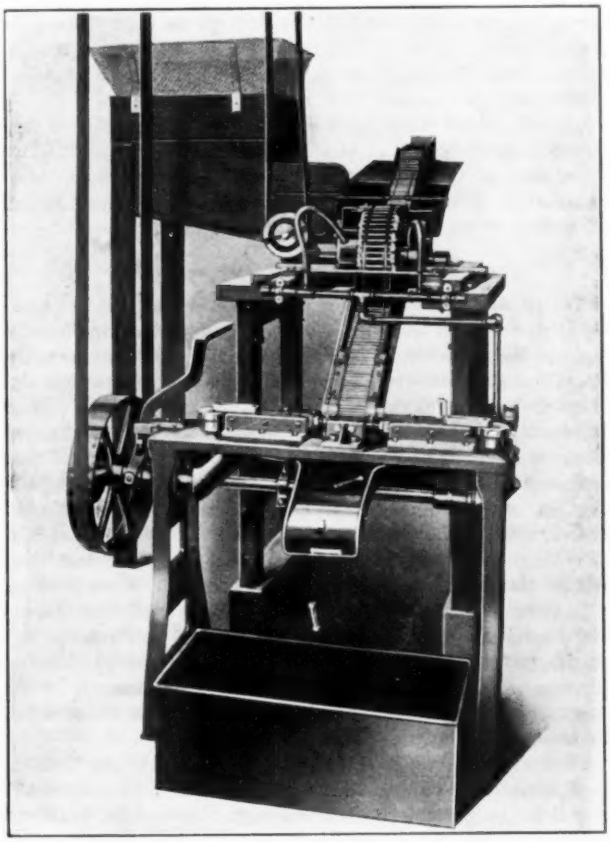

Fig. 2 Combination Annealing and Expanding Machine

(In this machine, the ends of the tubes are annealed and then expanded into a hexagonal form. At the same time the tubes are dimpled or indented.)

The foregoing represents the fundamental principles involved

in the manufacture of thin-walled copper tubes. While this method is styled cold extrusion, it has been shown that there is no such thing as true cold extrusion since plasticity of the copper, and consequently its extrusion, cannot be obtained without heat. The difference between the method above described and that discovered 130 years ago is that in one case the energy of the press is transmitted into terms of heat at the work instead of supplying the requisite heat by external means.

### Application

Once extruded, these tubes are sawed to the desired length, are given a hexagonal shape on the ends as shown in Fig. 2, and are finally tested individually at 35 lb. air pressure before passing on to be assembled into the object for which they are specified.

Primarily, these tubes serve an ideal purpose in almost all types of heat exchangers. The most common types of heat exchangers are radiators, whether of the type used in automobiles or in domestic heating. In the first, the water traveling through the system absorbs heat from the cylinder jackets, which is in turn dissipated to the surrounding atmosphere when passing through the radiator. In the second case, steam condensed within the radiator delivers its latent heat to the radiator, from which it is in turn radiated and dissipated to the outer air.

Returning to the tubes, the wall is very thin (0.003 to 0.006 inch), consequently any difference in temperature between the two sides of the tube tends toward rapid equalization. In other words, the rate of heat conductivity through the walls of the tube is rapid on account of the fact that the rate of heat transmission is a function of the thickness and this, of course, is at a minimum in tubes of this thinness.

Secondly, these tubes are made of copper, and copper is surpassed only by silver in the conduction of heat. With this explanation of the fitness of thin-walled copper tubes as ideal transmitters of heat, we pass on to a few practical illustrations of different types of heat-exchanging apparatus.

### Radiators for Airplane and Automobile Engines

Shortly after the termination of the World War, the Engineering Department of the U. S. Air Service made a comprehensive study of the then existing types of radiators used to dissipate the excess heat of airplane engines. During the course of their study, which included radiators in use on European planes as well as American, it was ascertained that most of the European radiators were made up of a multiplicity of individual tubes and that these radiators seemed to be efficient, were remarkably free from troubles, and were readily repaired when accidents occurred. At that time, the British Government had established a standard tube diameter of ten millimeters and the French Government had set the standard at seven millimeters. The tubes used by both these Governments were made of brass and were drawn. The English, however, were using a tube 6 in. long or approximately 15 calibers (the ratio of the length to the internal diameter). The French used a tube approximately 5 in. long or 12 calibers, which represented the practical manufacturing limit in the drawing of such a slender tube.

Further investigations and tests by the United States Government brought out the fact that if tubes from 30 to 35 calibers and 8 to 9 in. long could be obtained, higher efficiencies would be reached. It was then determined that the most practical method of manufacturing tubes of this description was the extrusion process and it is significant that from that day to this, these tubes have been standard with the United States Government on their water-cooled planes. The tubes most commonly used have a wall thickness of 0.006 in., are close to 7 millimeters in diameter, and ordinarily have a finished length of 9 in. Each tube weighs 107 grains or $^1/_4$ of an ounce. Each end of the tube is expanded into a hexagonal outline so that many are packed together, the ends of each tube nest perfectly against their neighbors, and when the packed assembly is dipped in solder to seal the hexagonal faces the result is that each tube is firmly attached on six sides, giving the maximum of strength and yet presenting as large an amount as possible of open space or free area for the passage of air. With very few exceptions, all of the tubes used for airplane radiators have a smooth body, as the use of air baffles or other obstructions is detrimental.

Besides the tubes with a plain or smooth body, as just described, there are also made other types which have a series of dents or air baffles on their bodies and which project into the air stream. These baffles serve the purpose of deflecting the air in its passage through the tube, imparting to the air a highly turbulent effect and causing it to scour the inside walls, thereby breaking up the air film normally adhering to the walls of the tube and tending to impair the transmission of heat from the tube to the air. This scouring effect is necessary and desirable when dealing with air speeds commonly encountered in automobile practice, but when the air velocities begin to mount over 7000 f.p.m., the very energy of this air is sufficient to break up the air film just mentioned and any baffling of the tube increases the head resistance of the radiator and decreases the speed of the plane without proportionately increasing the heat dissipating capacity of the radiator.

### Condensers

These tubes in shorter lengths are also coming into prominent use as condensers for automatic refrigerators using any of the hydrocarbons or $SO_2$ as a refrigerant. As is well known, the cycle of all compression types of refrigerating machines is the compression of the gas, condensation, and final expansion. After the gas has been compressed it is obvious that there must be removed from it, in order to effect condensation, the same amount of heat which it absorbed during the expansion cycle. It is for the purpose of removing this heat that condensers are made using these tubes as a matrix.

### Blast Heaters

Extruded tubes are coming into very prominent use in the manufacture of blast heaters or radiators. This type of radiator is to be distinguished from the well-known household type in that the stream of air is forcibly directed through the air spaces of the tubes, is thereby heated by the latent heat of the steam condensed within the tubes, and by the very movement of the air itself is diffused into the room in which it is placed. This type of radiator has effects entirely different from the ordinary direct radiator with which everyone is familiar and which heats the surrounding air by convection and radiation only.

The blast system of heating has many advantages, chief among which are the very short warming-up periods due to the almost instantaneous diffusion of heat, and the high efficiencies in heat transmission obtained with them. The writer recalls having seen an installation of such heaters mounted in a building 52 feet above the floor level in a monitor roof and yet the ground level was entirely comfortable, was free from drafts, and the temperature in all parts of the room was very uniform. Such movements of air over long distances can only be possible by heaters offering the minimum amount of resistance to air flow, and this resistance is kept at the minimum point by the construction and assembly of the tubes themselves. This type of blast heater is now in general use for heating industrial buildings, school rooms, offices, garages, or in fact in any place where an appreciable amount of heated air is to be delivered, and the writer believes that in the near future it will be possible to heat our homes by some similar type of radiation.

# Ball-Bearing Machine-Tool Spindles

By THOMAS BARISH,[1] JAMESTOWN, N. Y.

*This paper is a review of the three types of ball-bearing machine-tool spindles now in use, showing how rigidity is obtained in each type and what results are secured. There is also a historical review of the first type, which was originally put into service over ten years ago and has since received minor improvements. The three main groups are:*

(*a*) *Two-bearing, manually adjusted spindles*

(*b*) *Automatically spring-adjusted spindles*

(*c*) *Three-bearing spindles, adjustable and non-adjustable.*

*Comparisons are made between the various types for their rigidity, and some deflection curves and actual measurements of rigidity are quoted.*

## I—TWO-BEARING, MANUALLY ADJUSTED SPINDLES

THE first notably successful ball-bearing heavy-duty machine-tool spindles were built in 1917. These machines were all of the two-bearing, manually adjusted type using one angular-contact or radio-thrust bearing at each end, the two bearings being adjusted with initial thrust applied by a nut on the shaft in back of the smaller bearing. Fig. 1 is a typical example showing the Hart-Parr shell lathes built in 1917 for turning 16-in. shells.

### Initial Load and Deflection

These first machines showed that the ball bearings could be more rigid than plain bearings, but to do so they must be pulled very tight: the ball bearings must have a relatively large initial load. After a few experiments, the initial load was set at approximately 10,000 lb. thrust, about as much as the bearings would stand without impairing their life.

The initial load was not accurately measured because a wide variation was permissible—anything from 8,000 to 12,000 lb. proved satisfactory. The load was controlled by the simple method of pulling the adjusting nut as tight as possible with a six- or eight-foot pipe length on the end of the wrench.

Fig. 2 shows the axial-deflection curves for the bearings used in these first machines. These bearings of ten years ago show larger deflections than the more recent bearings with closer race curvatures (Fig. 4).

Both the large bearing at the front and the small bearing at the rear were of the radio-thrust or angular-contact type. In the first machine both bearings were RT 100 per cent types. In the later designs the smaller bearing at the rear is an RT 200 per cent type with greater contact angle and correspondingly greater thrust capacity, while the large bearing next to the work remains an RT 100 per cent type with a smaller contact angle to give greater rigidity in a radial direction.

The rigidity obtained by the large initial load can be determined from the deflection curves of Fig. 2. Consider first the effect of large thrust loads from an end-facing or boring operation.

TABLE 1 AXIAL DEFLECTION UNDER THRUST LOAD IN BALL-BEARING SPINDLE OF FIG. 1

| | | | |
|---|---|---|---|
| Thrust load from work assumed, lb. | 1,000 | 5,000 | 10,000 |
| Load on large bearing increases from 10,000 to | 10,500 | 12,500 | 15,500 |
| Load on small bearing decreases from 10,000 to | 9,500 | 7,500 | 5,500 |
| Difference equals load from work | 1,000 | 5,000 | 10,000 |
| Corresponding axial deflection (from curve) in. | 0.0002 | 0.00085 | 0.00178 |

Contributed by the Machine Shop Practice Division and presented at the Spring Meeting, Pittsburgh, Pa., May 14 to 17, 1928, of The American Society of Mechanical Engineers.

### Design

These first machines showed that the spindle itself had to be stiffer when mounted on ball bearings, largely because the ball bearing approaches a point support, whereas the plain bearing offers support over a longer length of spindle. This calls for increased spindle diameters except where the original spindle is oversize.

On the other hand, the relatively narrow ball bearing can bring the main point of support much closer to the nose of the spindle and reduce the overhang of the work, a very important factor for heavy roughing cuts, for greater accuracy, and for large overhangs.

Furthermore, the narrow bearings permit a definite shortening of the spindle and the frame. The resultant saving in cost of frame and the elimination of hardening for shafts and scraping for bronzes or babbitts materially reduces the cost of the machine.

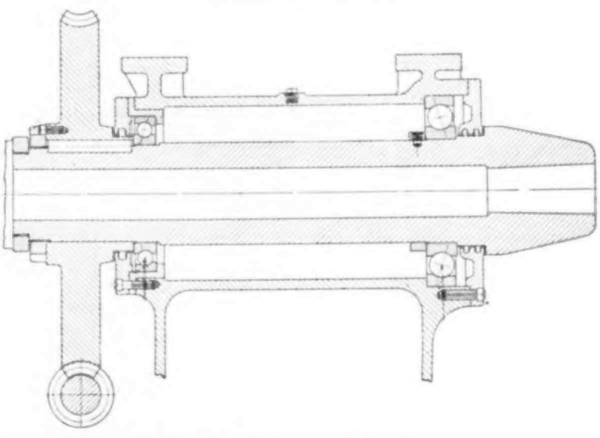

Fig. 1 Ball-Bearing Spindle of 16-In. Shell Lathe Built in 1917

(Typical example of first type of heavy-duty machine-tool spindle using two opposed angular-contact bearings.)

One manufacturer who regularly made both bronze-bearing and ball-bearing machines of a certain type reports a $400 lower cost of production for the ball-bearing machine.

This first type of ball-bearing spindle, the two-bearing opposed mounting, requires a rigid headstock, especially endwise. Otherwise the large initial loads pull the two end walls together. The very first experimental machines showed well over 0.010 in. movement under the initial load. The addition of several ribs and a thickening of the walls reduced this to much less than 0.005 in.

The ball bearings on the spindles of these first machines show a small saving in power. However, the power saving is of minor importance compared to the large increase in production that can be obtained. This is most noticeable under higher-speed roughing cuts. One authority explains the difference as folllows: A bronze-bushed lathe might not permit more than 0.015 in. feed because the flexible oil film will permit the cut to vary from 0.012 in. to 0.018 in., with resultant danger of chatter. A ball-bearing lathe with the same tools and cuts can use the full 0.018-in. feed and perhaps even 0.020 in. because of the greater steadiness. A specific comparison obtained on a machine of this type is given at the end of Part II of this paper.

The ball-bearing spindle is also useful for wide form-tool work,

For example, a ball-bearing spindle is cutting all the cooling ribs on the Wright Whirlwind airplane-motor cylinder. All the sixteen ribs on the steel forgings are cut in one operation with a multiple tool arrangement.

The increased steadiness also prolongs tool life and proves valuable for complicated and expensive tools and for difficult set-ups.

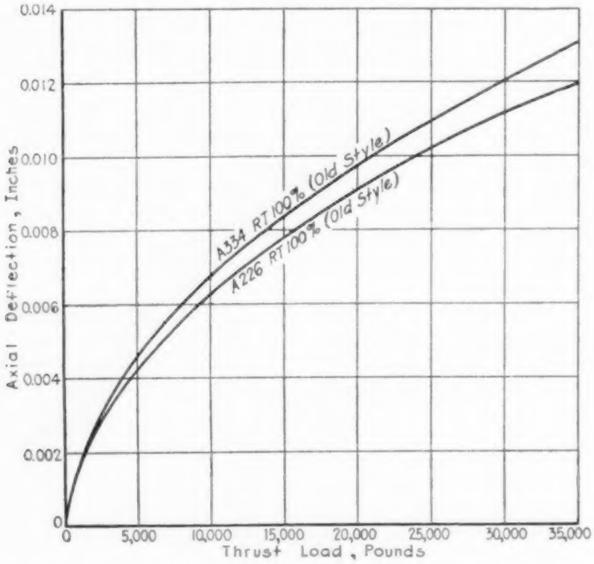

FIG. 2 AXIAL-DEFLECTION CURVES FOR LATHE SPINDLE SHOWN IN FIG. 1, DESIGN AND BEARINGS OF 1917

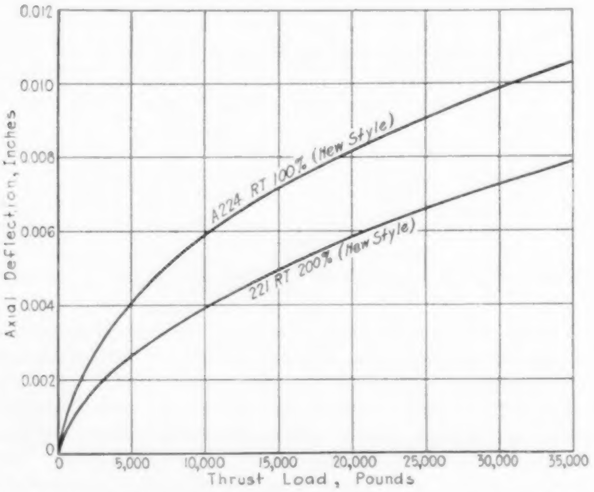

FIG. 3 AXIAL-DEFLECTION CURVES FOR MORE RECENT TWO-BEARING SPINDLE

[Similar to Fig. 1 but smaller (4 in. instead of 6 in.).]

The second important advantage of ball bearings was not realized until after the bearings were in use for some time. They require little attention for maintenance. There is a tendency for the bearings to "wear in," or perhaps it would be better to say "roll in," during the first 50 to 100 hours' operation. Then if kept clean they need no further attention for from two to six years, depending upon the severity of the service and the suitability of the mounting for the work.

The need for a readjustment after the "rolling-in" period can be avoided in all slow-speed and medium-speed spindles by setting the spindles up slightly tighter at the start.

## RECENT TWO-BEARING SPINDLES

The latest developments in two-bearing opposed mountings are arranged to meet the demand for heavier cuts and greater production by the use of even stiffer frames and spindles and certain modifications in the ball bearings for increasing the rigidity.

Fig. 3 shows the axial-deflection curves for bearings used within the last 3 or 4 years. These are smaller bearings than those of Fig. 1, but probably handle even heavier work. Note the much flatter deflection curve. These bearings use an initial load of about 4000 lb. The deflections are compared in Table 2, which is similar to Table 1.

TABLE 2 AXIAL DEFLECTIONS UNDER THRUST LOAD IN RECENT TWO-BEARING OPPOSED MOUNTINGS (RECENT CLOSE-CURVATURE BEARINGS)

| | | | |
|---|---|---|---|
| Thrust load from work assumed, lb. | 1000 | 4000 | 8000 |
| Load on large bearing increased from 4000 to | 4550 | 5750 | 8000 |
| Load on small bearing decreased from 4000 to | 3550 | 1750 | 0 |
| Difference equals load from work | 1000 | 4000 | 8000 |
| Corresponding axial deflection, in. | 0.00018 | 0.0008 | 0.0017 |

The effect of a radial load or a combined radial and thrust load is far more difficult to determine. The front bearing, because of its large initial thrust, will act under pure radial load somewhat like a radial bearing that is tightly fitted. To give some idea of the radial deflection, Fig. 4 (upper curve) shows the deflections for this same bearing if it were a radial bearing made with a line-to-line internal fit. Note how flat the curve becomes under heavy loads. The initial load moves the operating conditions up into the flat part of the curve. In other words, that part of the curve marked *AB* is moved down to the origin to the points marked *ab*.

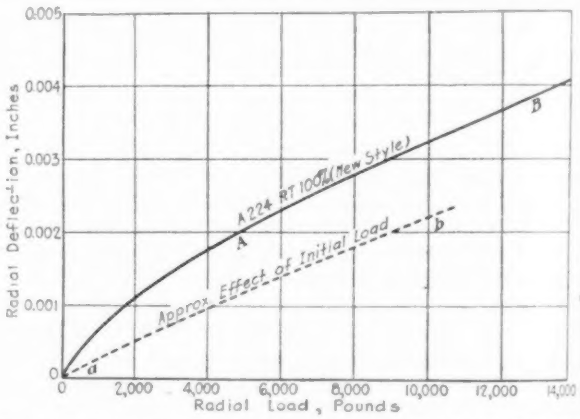

FIG. 4 RADIAL DEFLECTION (APPROXIMATE) FOR FRONT BEARINGS OF TWO-BEARING OPPOSED SPINDLE

(Same bearing as shown in Fig. 3. Note effect of large initial load in flattening curve.)

These small deflections compare favorably with those of the usual bronze bearings for a lathe of this size with their 0.002-in. to 0.005-in. initial looseness and their relatively flexible oil film.

In selecting the initial load of 4000 lb., the rigidity of the spindle was roughly checked under this selected load and again under an initial load about twice as large. In each case the spindle deflection was measured when adding a large radial load and then a large thrust load imposed by wedging a beam against the spindle nose. With 4000 lb. initial load the axial deflection was about 0.0008 in. and the radial deflection about 0.0009 in. Doubling the initial thrust load decreased these deflections to 0.0005 in. and 0.0006 in. This gives a clear conception of the extreme rigidity of these modern spindles.

The simple two-bearing opposed mounting adapts itself readily to large hollow spindles that are relatively short, for shaft diameters of 6 in. to 12 in. A number of such machines have been working successfully for several years peeling billets in

steel mills, a rather severe service because of the heavy cuts and the tough, uneven skin cuts.

## II—SPRING-ADJUSTED SPINDLES

Spring-adjusted ball-bearing spindle mountings have been used mostly for medium-speed and high-speed precision grinders. The bearing capacity is less at the higher speed and calls for more careful control of the initial load which can be obtained by springs. Also these spindles require finer or more frequent adjustments. The springs can be arranged exactly to control the initial load and to avoid entirely the need for readjustment.

Fig. 5 shows the type of spring-adjusted grinding spindle that has been in service in the Gurney ball-bearing plant for about 15 years for grinding ball-bearing race surfaces. The spring adjustment is fully automatic. That is its main advantage. There is no need for any readjustment during the life of the bearings.

The initial load in this machine was set at about 100 lb.; both bearings are of the RT 100 per cent type. The smaller contact angle means less radial clearance or looseness in the original bearing, and hence greater radial rigidity.

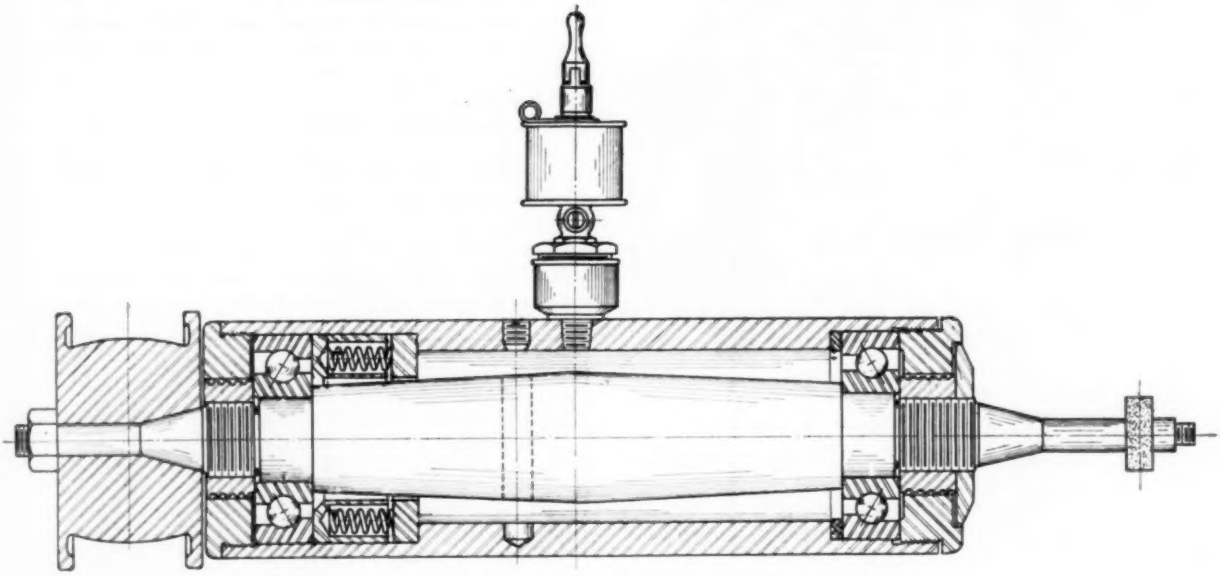

Fig. 5 Spring-Adjusted Spindle, Small High-Speed Grinder

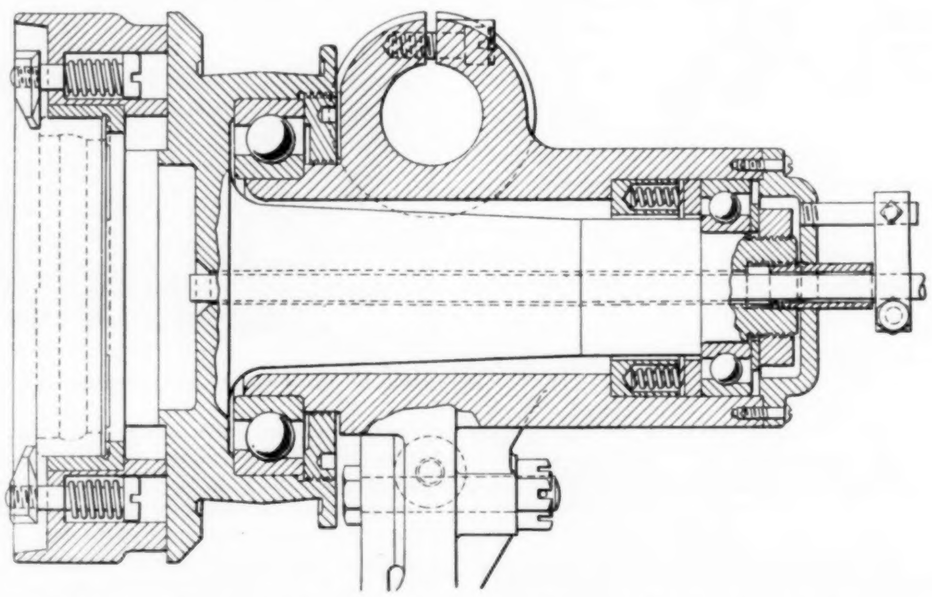

Fig. 6 Chuck Spindle or Work Head of Grinder Shown in Fig. 5. Spring Adjusted

We stop here to point out a limitation of the spring-adjusted ball-bearing spindle. A rapidly reversing thrust will cause the springs to deflect in one direction, very slightly, of course, but enough to affect quality of finish and accuracy in fine work. A similar effect occurs under large radial shock loads. The two angular-contact bearings tend to drop down into the bottom of the groove, and any slight yield of the spring permits this movement.

The automatically spring-adjusted spindle has proved itself desirable for certain types of work, viz.:

*a* For small high-speed grinders where the loads are rela-

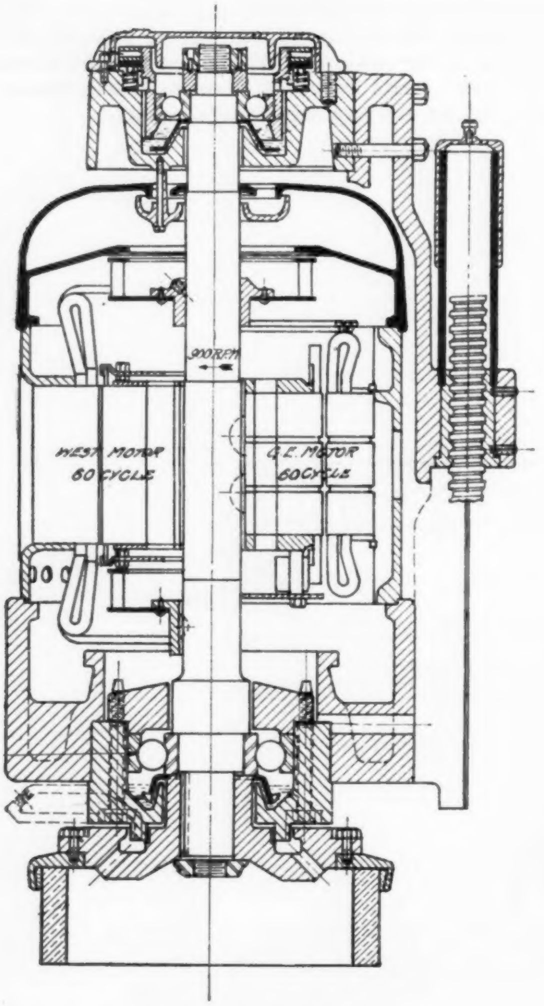

Fig. 7 Vertical Surface Grinder

(Spring-adjusted main-spindle angular-contact bearing at top loaded by spring to support weight of spindle and provide initial load.)

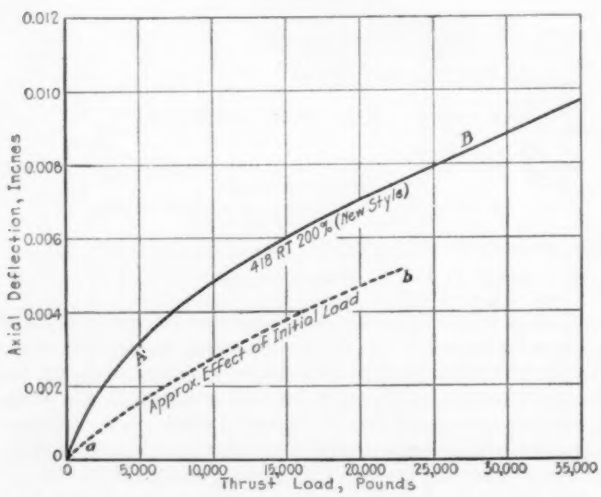

Fig. 9 Axial Deflection for Large Bearing at Lower End of Spindle Shown in Figs. 7 and 8

(Note effect of large initial load in flattening deflection curve.)

tively light and the spring load can be made large compared with the loads;

*b* For thrust loads of any size that are always in one direction. These may be combined with radial loads that are not large compared with the thrust load;

*c* For very steady loads (rare).

Fig. 5 is an example of the first class where the speeds are high and the loads relatively light. However, this design is not quite rigid enough under heavy grinding cuts, where the spindle or work is rapidly oscillated.

Fig. 6 shows another example where the loads are both radial and thrust, but relatively light. This is the work spindle or chuck spindle of the same ball-bearing grinding machines. Here the initial loads were set higher, the speed being lower and the load from the work mostly radial. Note how the springs are distributed and guided to apply the load uniformly

Figs. 7 and 8 show a well-known and highly successful application of a spring-adjusted spindle for heavy precision grinding

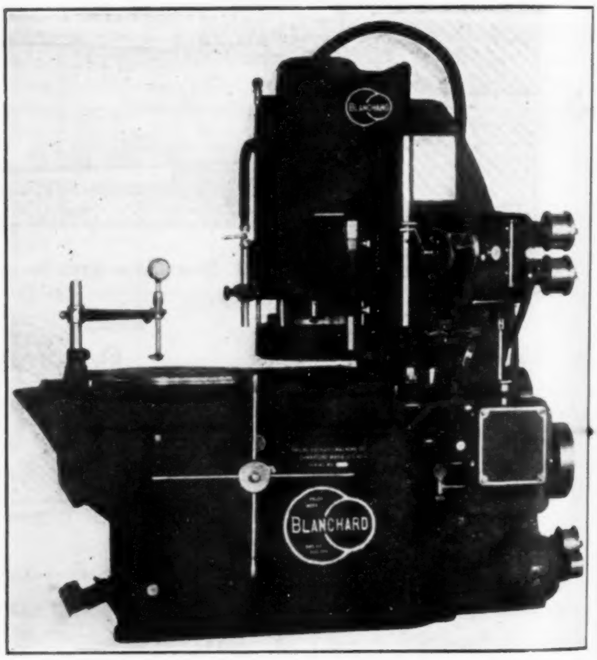

Fig. 8 Vertical Grinder Using Spindle Shown in Fig. 7

where the loads are almost all thrust or axial. This is a vertical surface grinder. The springs under the top bearing are set to carry all of the weight of the rotating parts and supply an additional large load for holding the bottom bearing tight.

Fig. 9 gives the deflection curve for the bottom bearing. The deflection of the top bearing does not matter because the springs follow up the upward spindle movement. Table 3 shows the effect of additional load from the work.

TABLE 3 SPINDLE DEFLECTION UNDER LARGE THRUST LOADS—SPRING-ADJUSTED SPINDLE

| | | | |
|---|---|---|---|
| Thrust from work, lb. | 500 | 1000 | 2000 |
| Bearing load increases from 1500 to | 2000 | 2500 | 3500 |
| Bearing deflection, in. | 0.00007 | 0.0003 | 0.0006 |

Note how this action differs from that of Tables 1 and 2. The load on the large bearing next to the work increases by the full amount of the added work load, whereas in Tables 1 and 2 part of the work load is carried by reducing the load on the smaller bearing at the other end of the spindle. Note the liberal bearing sizes to take care of this condition.

Figs. 10 and 11 show another very successful mounting for heavy loads that are mostly thrust but for an entirely different class of work. This machine is a special form of automatic used for turning nut blanks. The load from the work is practically all thrust, and is carried by the large angular-contact bearing up close to the work. The springs are carried inside of the nut next to the inner race of the small bearing. If this nut were pulled up tight the mounting would resemble a positively adjusted spindle.

This machine offers an opportunity to compare production results because the product, nut blanks, is standardized in size and material. The regular production obtained on the machine shown in Figs. 10 and 11 is 100 two-inch nut blanks per hour as compared with 23 per hour, the best possible for any existing plain-bearing machine of this type. Tool life is at least 10 per cent greater. Of course, these results are partly due to the peculiar tool design and set-up, but the machine manufacturer attributes a large part of the increased production to the use of ball bearings on the spindle.

Another unusual feature of this machine is the very narrow cut-off tool made possible by the endwise rigidity of the ball-bearing spindle. They are as thin as 0.062 in. in the smaller machines. This feature materially reduces the percentage of waste material for cut-off on the narrow, large-diameter nut blanks. Two cut-off tools are used on opposite sides to balance the tool pressures, and the cut-off tools do not go completely through the work. This arrangement combined with the relative steadiness of the ball-bearing spindle permits very thin cut-off tools.

The spring-adjusted spindle requires very careful selection of the correct bearing type. The contact angle for both bearings must be chosen according to the type of load—whether the thrust is predominant or the radial. The spring load also requires attention. Note that the front bearing next to the work should have a light press fit on the shaft not less than 0.0003 in., and a very close fit in the housing, approximately a push fit. Any looseness at these two points would be objectionable on account of its possible effect on the work.

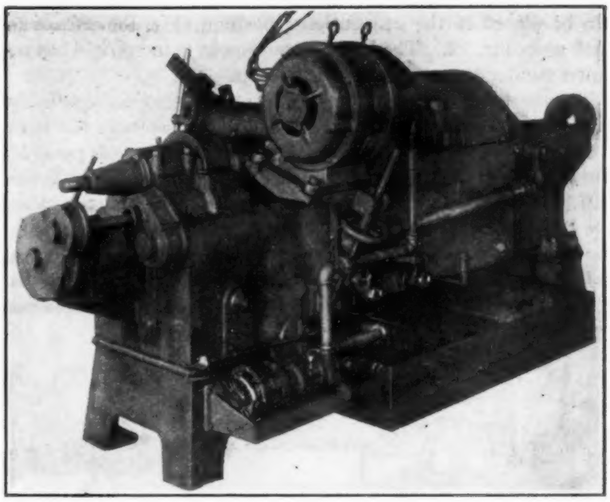

Fig. 11 Machine Using Spindle Shown in Fig. 10 Producing 100 Two-Inch Nut Blanks per Hour

## III—THREE-BEARING SPINDLES

Three-bearing machine-tool spindles (some have more than three) are all arranged to carry thrust load in both directions at the work end. One bearing carries the work thrust and a second bearing, also at the work end, carries the thrust in the opposite direction and applies the adjusting or tightening thrust.

Fig. 12 shows a non-adjustable three-bearing unit used mainly for small spindles and for mountings that do not require extremely careful setting of the initial load.

The two angular-contact or "radio"-thrust-type bearings at the nose come in pairs. They are ground by the bearing manufacturer so that the two outer rings can be clamped together and also the two inner rings, the result being a small initial load. The earliest form of these matched bearings is the Gurney Duplex, which has been widely used in other locations like worm drives to carry reversing shock-thrust loads. Note that these bearings

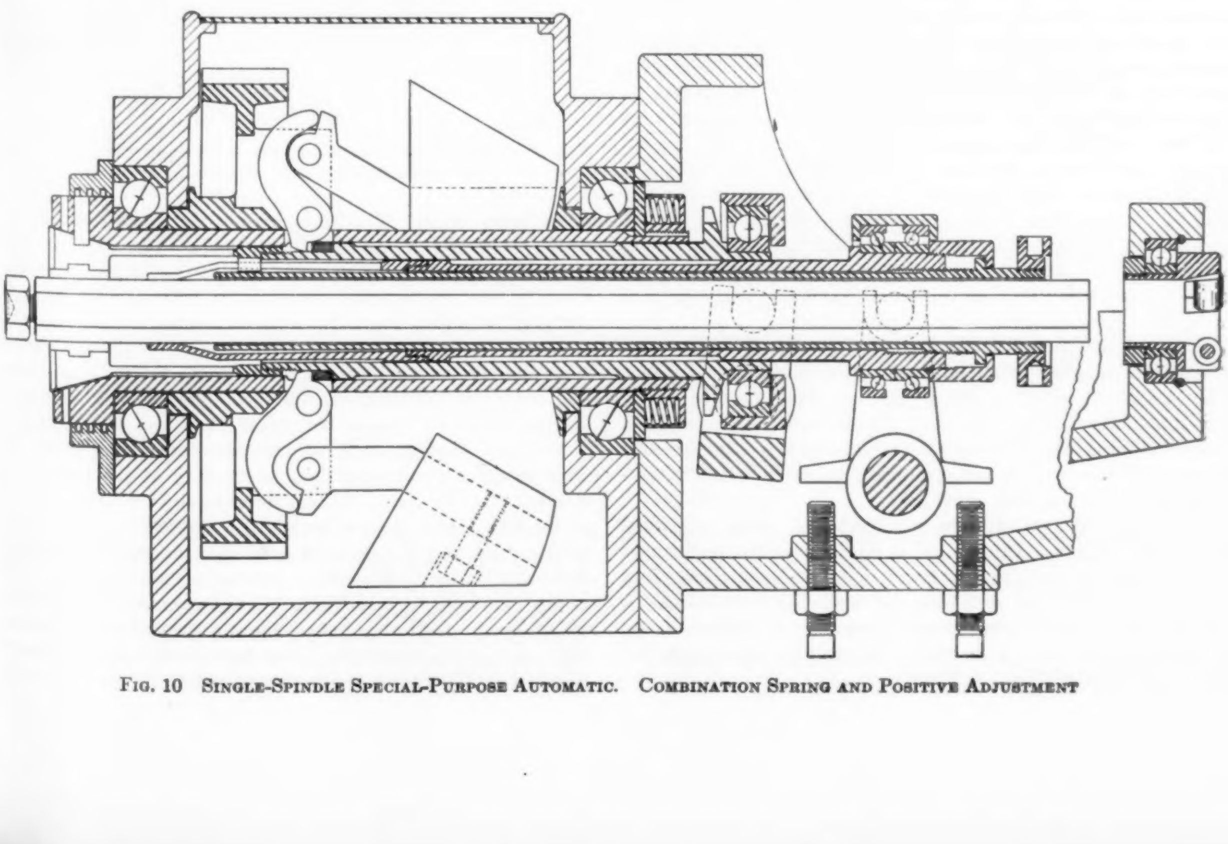

Fig. 10 Single-Spindle Special-Purpose Automatic. Combination Spring and Positive Adjustment

can be placed in the conventional position (Fig. 13) or back to back as in Fig. 12. The latter arrangement is more rigid but requires greater accuracy in aligning the spindle.

To produce extreme rigidity these Duplex-type bearings should have the maximum possible initial load. This calls for close cooperation between bearing manufacturer and user. If possible, the load should be varied somewhat for each individual application. Lower speeds call for larger initial loads. Furthermore, the initial load will be increased by even a light press fit on the shaft because the inner ring expands. Similarly slight errors in alignment or squareness will disturb the initial tightness. The duplex bearings are therefore commonly set a small amount

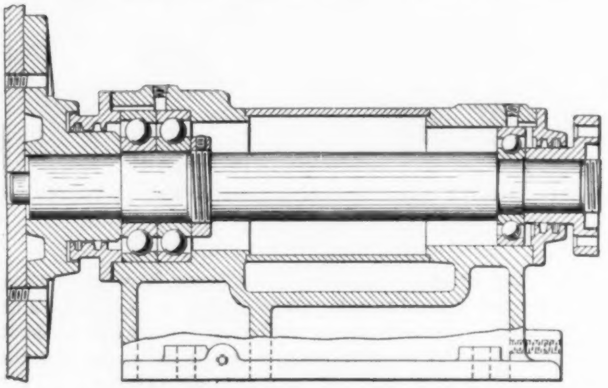

FIG. 12 SPINDLE OF LARGE HORIZONTAL DISK GRINDER USING OPPOSED PAIRED ANGULAR-CONTACT BEARINGS, NON-ADJUSTABLE

(The two bearings are back to back for rigidity.)

below the maximum possible tightness to avoid difficulty from these sources. The duplex type of mounting finds its greatest usefulness on spindles not requiring extreme rigidity—for example, the grinder spindle of Fig. 12.

### SEMI-ADJUSTABLE MOUNTINGS

This type of three-bearing mounting is also manufactured in semi-adjustable form, i.e., so that it can be adjusted when making the spindle, if necessary. They are not adjusted afterward, except perhaps when overhauling the machine. Fig. 14 shows a small high-speed vertical milling machine. The two halves of the Duplex bearing are separated by two sleeves, one between the inner rings and one between the outer rings. Both sleeves and all four bearing rings are clamped tight. The sleeve between the outer rings is split. To readjust, remove the nut holding the outer races and lower the spindle assembly about two inches until the split ring can be taken out. The split ring is then ground down in width from 0.001 in. to 0.002 in. and the unit reassembled. This arrangement is relatively simple and foolproof—yet quite rigid with all parts clamped.

A very similar mounting has been used extensively on the work spindle for bore grinders and on gear lapping and testing machines. The spacer between the outer races is omitted. The initial adjustment is made by positioning the end cover, which is bolted instead of threaded. To readjust the bearings it is only necessary to take off the end cover and machine off about 0.001 in. Sometimes laminated shims are provided.

The manufacturers of these machines test every individual spindle for rigidity. In one case a 400-lb. weight overhung 14 in. from the spindle nose must not produce radial deflections larger than 0.00025 in. at the spindle nose. In a second case a 750-lb. thrust must not produce more than 0.001 in. deflection, and a 750-lb. radial load 12 in. from the spindle nose must not give more than 0.00075 in. deflection.

### ADJUSTABLE THREE-BEARING SPINDLES

This same design of Fig. 14 can be made fully adjustable by omitting the spacer between the outer rings. The threaded end cover then becomes an adjusting nut. However, this arrangement is rarely used.

Fig. 15 shows a common three-bearing adjustable mounting as installed on a multiple-spindle automatic. The bearings are placed so the one nearest the nose takes the work thrust. The spacer between the outer rings is clamped solid. There is no spacer between the inner rings, and adjustment is provided by moving the inner ring of the inside bearing by means of the nut. This inner ring must be free to move on the shaft, but the front bearing, which takes most of the load, is tight on the shaft.

The initial load is easily controlled. For the machine shown in Fig. 16 it was set at 1200 to 1500 lb. (3-in. spindle). The pitch of the thread was selected so that a man pulling as hard as possible on an ordinary 8-in. to 10-in. wrench would exert the correct endwise force and produce the desired initial thrust.

Fig. 16 shows how this design is applied to large spindles, in this case a single-spindle automatic (about 6 in. shaft size at main bearing). Both inner races of the front bearings are clamped by a nut. The large bearing is fairly tight in the housing. The smaller bearing applies the tightening thrust through the sleeve around the outer race and the large nut.

The most important single feature in all of these ball-bearing machine-tool spindle mountings is the large initial load that produces the rigidity. The accuracy of the ball bearing permits

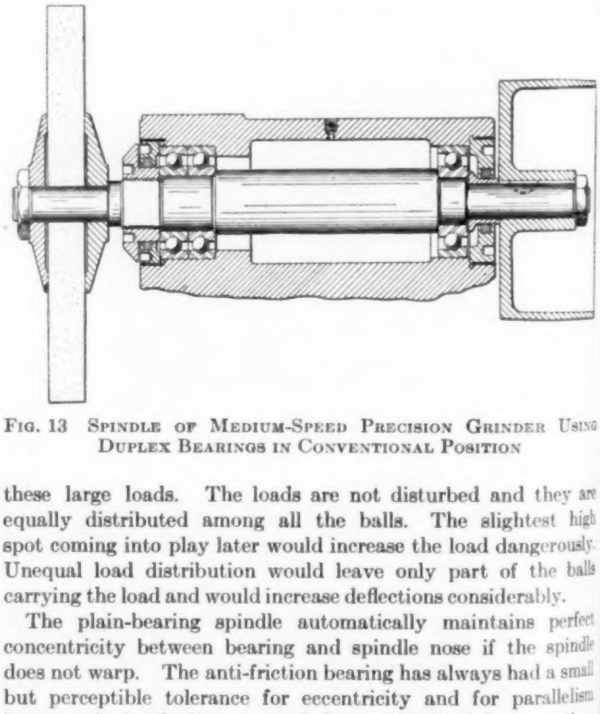

FIG. 13 SPINDLE OF MEDIUM-SPEED PRECISION GRINDER USING DUPLEX BEARINGS IN CONVENTIONAL POSITION

these large loads. The loads are not disturbed and they are equally distributed among all the balls. The slightest high spot coming into play later would increase the load dangerously. Unequal load distribution would leave only part of the balls carrying the load and would increase deflections considerably.

The plain-bearing spindle automatically maintains perfect concentricity between bearing and spindle nose if the spindle does not warp. The anti-friction bearing has always had a small but perceptible tolerance for eccentricity and for parallelism between the inside diameter and the race track of the inner ring. This produces a corresponding eccentricity at the nose of the spindle. In the past the small eccentricities were removed on the finer precision tools by taking a light finishing cut on the spindle nose after it was mounted in its own bearings. To meet this condition more efficiently, it has become necessary to develop a new grinding method for ball-bearing inner races that now yields almost absolutely true running surfaces for the bore and race track of the inner ring. The first lot of bearings made by this new method (3-in. bore) showed about 15 per cent of the

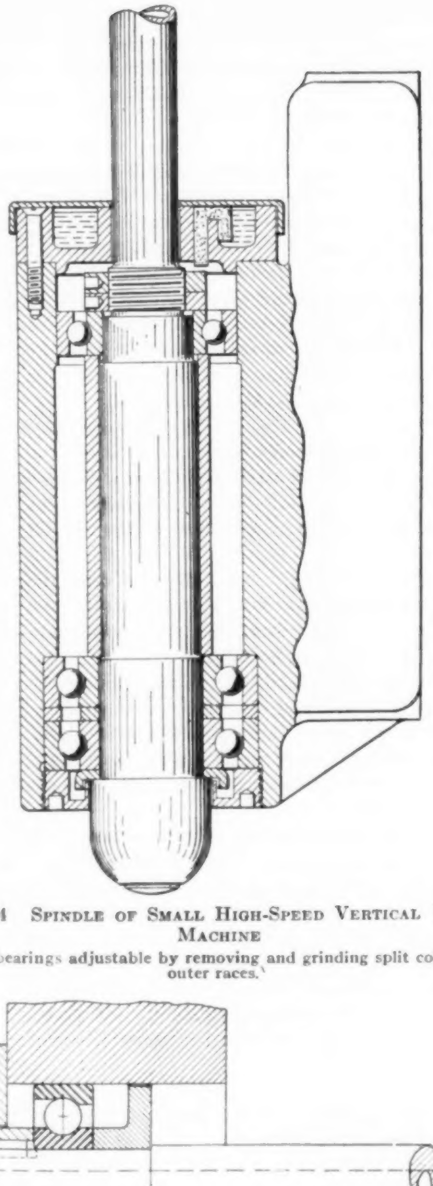

FIG. 14 SPINDLE OF SMALL HIGH-SPEED VERTICAL MILLING MACHINE
(Duplex bearings adjustable by removing and grinding split collar between outer races.)

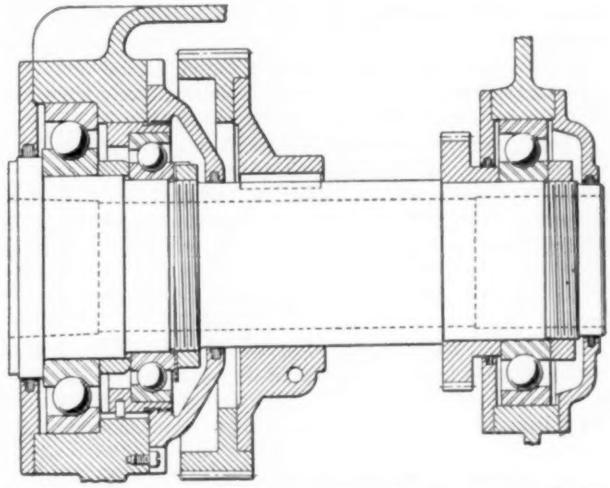

FIG. 16 THREE-BEARING FULLY ADJUSTABLE MOUNTING ON LARGE SLOW-SPEED AUTOMATIC SPINDLE

to take out radial play. These bearings can even be made so the balls are squeezed from 0.0001 in. to 0.0004 in. in assembling the bearing. The one bearing is more than ample for the great majority of designs because the bearing is so far from the work.

In a few rare cases where the overhang is large or where the spindle carries heavy load near both ends, it becomes necessary to mount two opposed bearings at both ends of the spindle. One end must float axially so the pair of bearings are either held in a floating sleeve or a pair of Duplex bearings are mounted back to back. This makes a total of four bearings per spindle.

A few spindles have been built using more than four bearings for greater capacity and also for greater rigidity obtained by the use of a larger number of balls or points of support. However, this arrangement introduces difficult problems of alignment, eccentricities, and load distribution. It is better to obtain the capacity by using fewer bearings, each having a larger capacity. These multi-bearing spindles usually fall within the class of semi-adjustable or non-adjustable three-bearing spindles.

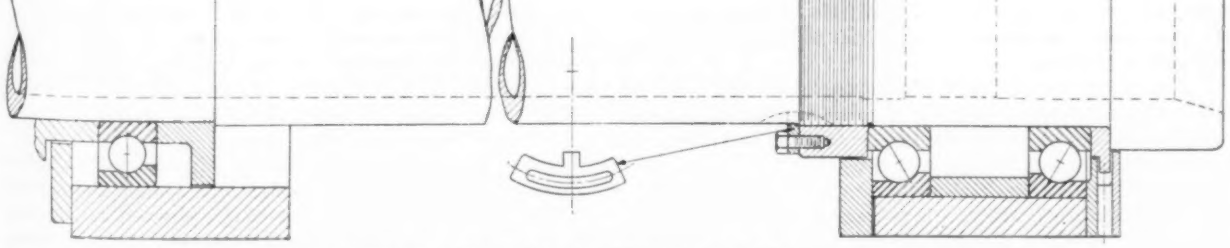

FIG. 15 FULLY ADJUSTABLE THREE-BEARING MOUNTING ON MULTIPLE-SPINDLE AUTOMATIC
(1200 to 1500 lb. initial load.)

bearings with 0.00002 in. maximum eccentricity, and 85 per cent showed no readable movement on a ten-thousandth indicator.

In all of these three-bearing mountings, the far end of the spindle is supported by a bearing that must float endwise in the housing to take care of shaft and housing expansions. The simplest arrangement is a single bearing closely fitted internally,

## CONCLUSIONS

Properly mounted ball-bearing machine-tool spindles have proved unusually rigid. Their main advantages result from this

**increased rigidity and from their ability to maintain their adjustment and accuracy.**

**Rigidity has been obtained by the use of angular-contact or radio-thrust type bearings assembled with relatively large and carefully controlled initial loads to keep them tight.**

**Three general types of mounting design have been developed as outlined above. It is important to select the right type of mounting and the correct bearing size and type to suit the load and service requirements. Sufficient experience is now available to permit intelligent selection.**

## Discussion

F. E. Cardullo.[2] It should prove valuable to have a word from the author as to the relation of the forces in actual practice to the ratings of the bearing. What factors of safety over the rated loads as given in the tables of the manufacturers are employed?

The Author. That is a difficult question and one that requires clarifying in general. Most of the output of the ball-bearing industry is used in the automobile and for that reason, its ratings are based upon automobile service as follows. A 50,000 to 100,000-mile machine with an average speed of 30 miles an hour means 2000 to 4000 hours life and most of the time under less than half the load. The ratings are therefore approximately equal to 1000 hours continuous operation under full load. When the load is cut in half the life increases approximately ten times.

On machine tools, the load varies over a very wide range but we must consider the initial load first. Take, for example, the common size No. A-224. This bearing has a thrust capacity at 300 r.p.m. of about 19,000 lb. We use an initial load of 4000 to 5000 lb. To this we must add about 1000 to 2000 lb. for the *average* load. This will give a safety factor of $3^1/_2$ to 4 with an estimated life of 50,000 to 100,000 hours of actual operation.

The maximum load is determined by the actual rating and can therefore reach well over 18,000 lb.

F. E. Cardullo. In Fig. 13 where a grinder spindle with opposed bearings is shown, these two bearings fitted into the bores and set up with initial tension presumably show no deflection except the elastic deflection of the material. However, on the tail end of the spindle at the pulley, a bearing with no initial tension is shown. How is the radial play at this point removed?

The Author. It is quite important to remove the radial play at the tail end of the spindle. In this case, it is done by providing an initial load within the bearing itself. The balls are made slightly oversize and forced into the bearing. The amount of oversize will vary from 0.0001 to 0.0004 in different cases. This provides the same type of initial load as is obtained at the front pair of bearings.

It may also be done by using a set of duplex bearings back to back when the two inner races are clamped together and initial thrust load is set up within the pair of bearings and then the outer races can float endwise to take care of axial play.

F. E. Cardullo. Fig. 16 shows two oppositely disposed bearings of different sizes, which, it is presumed, are to take care of thrust load. Does not the larger bearing have the lesser strain?

The Author. The larger bearing does have the lesser strain but the larger bearing takes almost all of the load from the work, whereas the small bearing is relieved when thrust is applied from the work. Therefore, it is correct to apply an initial load on the small bearing which is a larger proportion of its total capacity. The small bearing serves only to apply the large initial load. It takes a relatively small proportion of the radial load.

[2] Chief Engineer, G. A. Gray Co., Cincinnati, Ohio. Mem. A.S.M.E.

F. E. Cardullo. In Fig. 14 two bearings of the same size are shown drawn together, the lower one taking the thrust of the drill. Are these two bearings fitted differently so the lower one will take a greater proportion of the raidal load in order to equalize the service on the two bearings?

The Author. The thrust is all taken on the upper bearing of this pair. Pure radial load is divided. A combined load is taken entirely on the upper bearing. The two bearings are exactly identical and no attempt is made to provide a better distribution of the work. The additional economy which would be provided by such a method is not worthwhile.

F. E. Cardullo. Would there by any object in giving the lower bearing a 200 per cent "radio"-thrust matching and the upper one a 100 per cent "radio"-thrust matching?

The Author. This does not prove worthwhile except in the largest spindles like that shown in Fig. 16.

F. E. Cardullo. In Fig. 15, why are the two bearings on the right-hand side so widely separated?

The Author. This is a relatively long and hollow spindle of comparatively thin section. The two bearings on the right-hand end are spread apart to give rigidity to the spindle.

Walter H. Trask, Jr.[3] It would be of value to know if the spindle is treated as a beam fixed at both ends or freely supported and also how much larger must the spindle using ball bearings be than one employing plain bearings?

The Author. The usual ball-bearing support is more nearly analogous to a beam freely supported on the ends. The single-row ball bearing is almost always equivalent to this. However, the double bearing construction used at one end and sometimes both ends on a machine-tool spindle is much more nearly equivalent to a fixed support.

It is true that a ball bearing requires a heavier spindle than a plain bearing, perhaps 10 to 20 per cent larger. However, in most cases, no increase is required because the plain-bearing spindles are made much heavier than necessary. In other words, the minimum size of spindle that can be used with ball bearings should be somewhat larger than the minimum size spindle that can be used with plain bearings.

Note also, that the ball-bearing spindle can be much shorter than the plain-bearing spindle and therefore becomes more rigid in proportion.

Horace B. Schell.[4] Is the bearing shown on the right-hand end of Fig. 16 of the magneto type or open type with the outer race apparently free to float lengthwise in the housing?

The Author. This is not a magento-type bearing. The figure is slightly deceiving. This is the Gurney radial-type bearing where the outer race has a deep groove on one side and a relatively shallow but very definite shoulder on the opposite side. This makes it able to take some thrust in both directions and the outer race is definitely located on the bearing.

Wilson P. Hunt.[5] A particularly difficult problem for the writer's company is to place bearings on extremely close centers with vertical adjustment. In Fig. 16 it is assumed that the head bearing takes all the thrust both ways, and the tail bearing floats to compensate for shaft expansion. Comment on the adjustable bearing should prove valuable.

The Author. If the bearings are required to be close together axially, that is, on a relatively short spindle, it is advisable to use

[3] Mechanical Engineer, Salt Lake Hardware Co., Salt Lake City, Utah. Mem. A.S.M.E.

[4] M. D. Knowlton Co., Rochester, N. Y.

[5] President and Manager, Moline Tool Company, Moline, Ill. Mem. A.S.M.E.

a design like Fig. 1. For example, we mention a billet-peeling machine where bearings are used on a large-diameter spindle of very short length. There are two bearings, one at each end, adjusted against each other as in Fig. 1. There is a rotary tool inside the spindle taking heavy and very rough cut off the outside of billets.

If it is a question of small diameters, we refer to Fig. 15, a multiple-spindle automatic where diameters must be kept down. A three-bearing mounting is then desirable.

The most successful method for obtaining adjustment is to mount the whole spindle housing on a form of way and adjust on the ways. We refer to Fig. 7 which does the same thing to very close tolerances and likewise to Fig. 6. In both of these cases the adjustment is made within thousandths.

F. M. Brauer.[1] Do I understand that as many balls as possible are crowded in without a separator?

The Author. It is 15 to 20 years since bearing manufacturers have realized the absolute necessity of a separator. Bearings without separators are only being used in one or two very special cases. The angular-contact bearing as used in machine tools has particular need for a separator and provides one of the severest separator services. Under combined load, the contact angle of the ball on the races is not constant. It is smaller at the point where the maximum radial load is carried. This means that the ball rides on the inner race on a skewed path, causing a definite variation in ball speed. The separator must take care of this variation in ball speed.

# A Study of Tin-Base Bearing Metals

By O. W. ELLIS[1] and G. B. KARELITZ,[2] EAST PITTSBURGH, PA.

*This study represents the first part of an investigation of babbitts. It comprises the results of metallographic and mechanical tests on a series of tin-antimony-copper alloys containing up to 10 per cent of antimony and 8 per cent of copper. Relationships between the composition, microstructure, hardness, and compressive strength of these alloys are given, and the influences of elevated temperatures and of lead upon these properties are recorded.*

THIS paper concerns itself with an investigation of alloys of tin, antimony, and copper, some of which are used in engineering as bearing metals. This investigation was undertaken with the object of arriving at a logical method of determining which alloys of this system might best serve as bearing metals under any given condition. The present paper covers such work as has so far been accomplished, and shows the relationships which exist between the mechanical properties and the constitution of the alloys of this system of high tin content.

The tin-antimony-copper system has been the subject of considerable investigation, but, apart from a very complete study of the microstructure of the alloys of high tin content by Campbell (Proc. Am. Soc. Test. Mat., 1913, 13, 630) and a somewhat superficial survey of a more extended field of the ternary equilibrium figure by Bonsack (*Zeit. für Metallkunde*, 1927, 19, 109), the results of no systematic inquiry into that portion of the system which includes the bearing metals in more common use have been published.

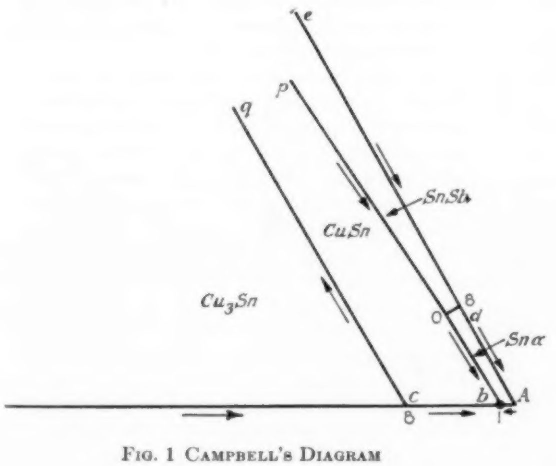

Fig. 1 Campbell's Diagram

To Smith and Humphries (*Jl. Inst. Met.*, 1911, 5, 194), Thompson and Orme (ibid., 1919, 22, 203), Fry and Rosenhain (ibid., 1919, 22, 219), Mahin and Broeker (Proc. Indiana Acad. Sci., 1919, p. 9) and Hudson and Darley (*Jl. Inst. Met.*, 1920, 24, 361) we are indebted for reports on the constitution, structure, and properties of individual alloys of this system, and it may be noted that the authors' conclusions agree in the main with such as are referred to in these and other papers of lesser importance.

### The Tin-Antimony-Copper System

Campbell, in the paper referred to, presented a tentative diagram for the tin end of the system, the main features of which are reproduced in Fig. 1.

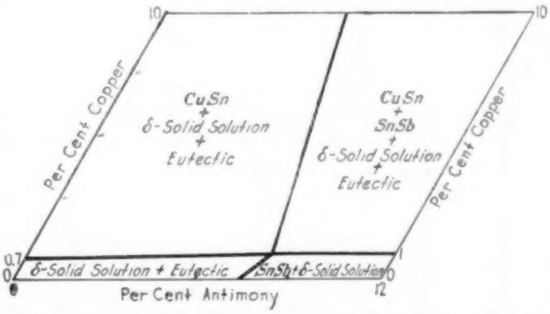

Fig. 2 Structural Characteristics of Tin-Rich Alloys of the Tin-Antimony-Copper System

He divided the alloys into four main groups:

1 Those whose composition fell within the area to the left of the line *qc*, from which $Cu_3Sn$ first separated on freezing
2 Those whose composition fell within the area *pobcq*, from which needles of CuSn first separated on freezing
3 Those whose composition fell within the area *pode*, from which cubes of SnSb first separated on freezing
4 Those whose composition fell within the area *bodA*, whose structure consisted of dendrites or grains of αSn set in the pseudo-eutectic which froze along *ob*.

The authors' plot of this corner of the ternary equilibrium diagram is shown in Fig. 2, which will be seen to differ but slightly from that due to Campbell. It should be noted that the authors have investigated a narrower field.

Fig. 3 Mold Used in Casting Alloys

### General Procedure Employed in Investigation

In arriving at the conclusions embodied in Fig. 2, the authors have been guided by certain of the physical and structural characteristics of a series of alloys covering the entire field of the diagram (Fig. 2).

Two series of 25 alloys each were cast under the conditions referred to later. These alloys were of the compositions quoted in Table 1.[3] They were cast in a mold

| 13 | 92 | 6 | 2 | 6.54 | 2.18 | 6.15 | 2.14 |
| 14 | 90 | 6 | 4 | 6.15 | 3.90 | 6.05 | 4.32 |
| 15 | 86 | 6 | 8 | 6.12 | 8.42 | 6.36 | 7.38 |
| 16 | 91.5 | 8 | 0.5 | 8.52 | 0.53 | 8.42 | 0.59 |
| 17 | 91 | 8 | 1 | 7.91 | 1.04 | 8.04 | 1.08 |
| 18 | 90 | 8 | 2 | 8.04 | 2.09 | 8.24 | 2.15 |
| 19 | 88 | 8 | 4 | 8.22 | 3.91 | 8.07 | 4.32 |
| 20 | 84 | 8 | 8 | 8.31 | 7.79 | 8.38 | 7.66 |
| 21 | 89.5 | 10 | 0.5 | 10.17 | 0.53 | 11.01 | 0.67 |
| 22 | 89 | 10 | 1 | 10.05 | 1.06 | 10.23 | 1.09 |
| 23 | 88 | 10 | 2 | 10.11 | 2.08 | 10.18 | 2.15 |
| 24 | 86 | 10 | 4 | 9.86 | 4.03 | 10.16 | 3.72 |
| 25 | 82 | 10 | 8 | 9.71 | 7.72 | 10.18 | 7.03 |

The top of the mold was flared with the object of concentrating any pipe that might form in the top of the casting. A photograph of the mold, which could be separated into two similar halves, is reproduced in Fig. 3. The two halves could be held together by means of a ring, which fitted the outside of the mold snugly.

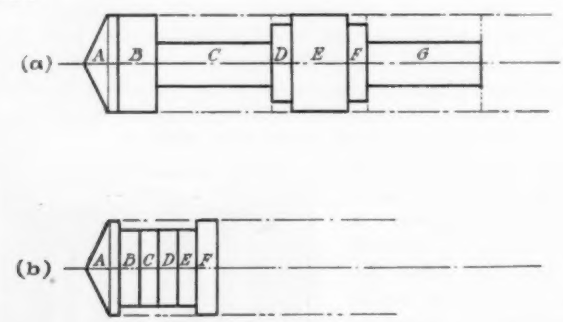

FIG. 4 CUTTING DIAGRAMS FOR TEST BARS

(*a*) A—For microstudy; B—$^1/_2$ in. thick for Brinell test; C and G—$1^1/_2$ in. long × 0.564 in. diam. for compression tests; D and F—1 in. diam. × 0.250 in. thick; E—$^3/_4$ in. thick for hardness tests.
(*b*) B, C, D, and E—1 in. diam. × 0.250 in. thick; F—for microstudy.

The mold was heated to 100 deg. cent. prior to casting. The pouring temperature used was 400 deg. cent.

The castings of the first series were poured into the mold direct from a graphite crucible. From these castings samples were turned for hardness and compression tests, and specimens were taken for chemical, microscopic, thermal, and electrical investigation. The approximate positions in the castings from which the various samples were removed are shown in Fig. 4(*a*).

The castings of the second series were run from a bottom-pouring crucible of steel which was heated electrically and from which the alloys were allowed to flow when at a temperature of 400 deg. cent. The procedure adopted in all cases was to heat the alloy to 425 deg. cent., then to stir the melt thoroughly, and finally to allow it to cool to 400 deg. cent. before tapping; the heating circuit was broken when the pyrometer registered a temperature of 425 deg. cent. The tapping hole in the crucible was $^1/_4$ in. in diameter.

From the castings of the second group samples for analysis, micro-examination, and hardness testing were taken from the points indicated in Fig. 4(*b*).

No trouble was experienced in pouring any of the alloys except those of high copper content. In the case of certain of these alloys, Nos. 5, 10, and 15 in particular, a portion of the melt always remained in the bottom-pouring crucible. Analysis of the material entrapped showed it to be higher in copper content

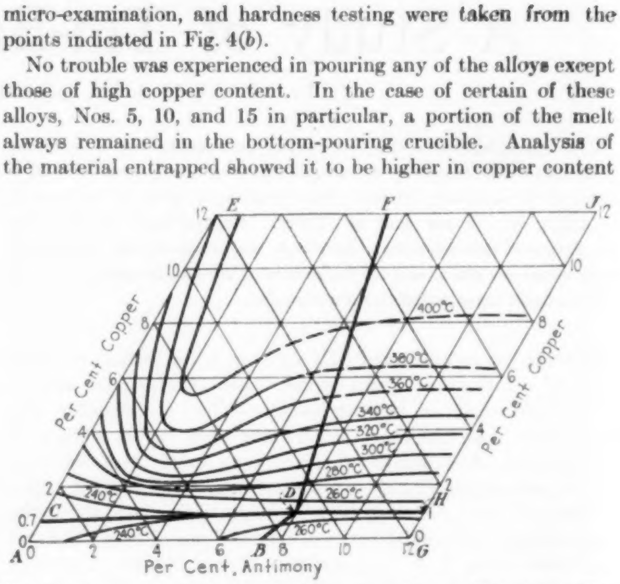

FIG. 5 CONTOURS OF LIQUIDUS SURFACE OF SPACE MODEL FOR TIN CORNER OF SYSTEM

than that which left the crucible to form the castings. A comparison of the microstructure of the two portions of the melt confirmed this. That portion which remained in the crucible, of which Fig. 16 typifies the structure, was characterized by many large crystals of CuSn and a paucity of the tin-rich matrix; the portion which flowed from the crucible into the mold (Fig. 17) contained but few of the coarse crystals of CuSn, and exhibited an almost normal proportion of solid solution.

This effect was more pronounced in the case of alloy No. 10, of which Figs. 16 and 17 are photomicrographs, than in that of the others. An experiment was made in which this alloy was heated to 425 deg. cent. and then tapped from the crucible, but even in this case a part of the apparently liquid mass was retained in the crucible. The amount entrapped was, however, less than that which was held in the crucible at 400 deg. cent.

The reason for this phenomenon was readily explained when the thermal and resistivity curves for these alloys were completed. It then became clear that these alloys, Nos. 5, 10, and 15, were, at 400 deg. cent., below the point at which separation of CuSn from the melt begins on slow cooling, as will be appreciated on reference to Fig. 5, wherein are shown the contours of the liquidus surface—or the surface of temperatures at which CuSn first crystallizes out of the melt—of the space model for the tin corner of this system. The material in the crucible at 400 deg. cent. in the case of these alloys consisted, therefore, of two phases—(1) liquid, which passed through the $^1/_4$-in. tap hole with but little, if any, difficulty, and (2) solid-crystals of CuSn, which settled and collected on the bottom of the crucible as tapping proceeded and of which only such as were in the immediate vicinity of the tap hole during pouring passed through into the mold. These crystals retained a certain amount of liquid, but the amount so prevented from issuing from the mold was relatively small.

In the case of the alloys melted in the graphite crucible and poured at 400 deg. cent. direct into the mold, no large crystals of CuSn were found in the microstructure. The absence of such large crystals is probably due to the fact that opportunity for growth was not given to the CuSn which coexisted with the tin-rich phase at the pouring temperature. When the time occupied by the alloy at temperatures just below the liquidus is prolonged, as was the case with the second series of alloys, excessive growth of CuSn may occur; what the effects upon the mechanical

properties of the material are, however, is unknown. A phenomenon similar to this, in which SnSb played the major role, has been described by Gallagher (*Jl. Phys. Chem.*, 1906, 10, 93) and by Mahin and Broeker (loc. cit.). The fact that such crystal growth can occur at temperatures below the liquidus, the melt being apparently free from the solid phase, is one that should not be overlooked in practice.

### Cooling Curves

Cooling curves were taken of all the alloys of the first series. The changes in electrical resistivity which occurred on slow cooling were also observed. Absolute measurements were not attempted, attention being directed solely to the temperatures at which alterations in resistivity occurred.

It was found that the temperature at which the precipitation of CuSn first occurred on cooling (the liquidus) was subject to considerable variation. It was difficult to prevent supercooling. It was possible, however, to get consistent results, and a close check was obtained between the thermal and electrical values for the liquidi, save in the case of the alloys of maximum copper content, where some dicrepancies arose. Curves typical of those obtained are shown in Fig. 6.

The liquidus values were used in the preparation of Fig. 5, to which attention has already been directed. In this figure the dotted contour lines refer to such portions of the surface of the space model of the system as may require revision on further investigation.

It has been of interest in this connection to compare the authors' results with those of other workers in this field. Thompson (loc. cit.), for example, has quoted 366 deg. cent. as the liquidus of an alloy containing 8.76 per cent of antimony and 4.51 per cent of copper. For an alloy of almost identical analysis Fry and Rosenhain (loc. cit.) have given the temperature 306 deg. cent. for the liquidus. The authors estimate the liquidus of this alloy to be 345 deg. cent., and it appears from this that Thompson's criticism (q.v.) of Fry and Rosenhain's result was justified.

Other values which may be compared are as follows:

| Antimony per cent | Copper per cent | Liquidus—According to authority | Liquidus—According to authors |
|---|---|---|---|
| 4.70 | 1.00 | 235 (*a*) | 243 |
| 8.36 | 3.35 | 320 (*b*) | 318 |
| 8.7 | 2.3 | 252 (*b*) | 265 |

(*a*) Thompson (loc. cit.); (*b*) Hudson & Darley (loc. cit.)

It is felt that the agreement here obtained is very satisfactory, in view of the difficulties which arise due to supercooling.

The authors have found that the solidus—the temperature at which the alloys become completely solid—for all the alloys of this section of the tin-antimony-copper system is 225 deg. cent. the eutectic temperature of the copper-tin system—and that in such alloys as contain SnSb as a separate microconstituent, SnSb begins to crystallize on cooling at an average temperature of 248 deg. cent.

### Microstructure

The microstructure of these alloys as cast is shown in Figs. 7 to 33.

The alloys may be arranged in four groups, according to their microstructure:

*Group 1.* Those alloys which, as cast, are characterized by a hypoeutectic structure comprising the copper-bearing δ-solid solution of the tin-antimony system and the eutectic of the copper-tin system. Figs. 7 (alloy 1), 12 (alloy 6), and 18 (alloy 11) are typical structures of cast alloys of this group. Prolonged annealing of these alloys at 150 deg. cent. effaces this structure and leaves the alloy as a homogeneous δ-solid solution supporting crystallites of CuSn (Fig. 34—alloy 11).

*Group 2.* Those alloys which, as cast, comprise the two microconstituents primary CuSn, δ-solid solution and copper-tin eutectic (Figs. 8, 9, 10, 11, 13, 14, 15, 16, 19, 20, 21, and 22). The proportion of the copper-tin eutectic in these alloys, as in those of group 1, becomes less as the content of antimony increases—cf. Figs. 8, 13, and 19. In these the dark areas represent the eutectic, the light areas the solid solution, and the white needles the primary intermetallic compound, CuSn.

*Group 3.* Those alloys which, as cast, comprise the two microconstituents primary SnSb and δ-solid solution (Figs. 23 and 29). These alloys show no eutectic in their structure, although they do not become completely solid until the eutectic temperature of the copper-tin system has been reached.

*Group 4.* Those alloys which, as cast, comprise the four microconstituents primary CuSn, secondary SnSb, δ-solid solution, and, in some cases, eutectic (Figs. 24, 25, 27, 28, 30, 31, 32, and 33).

These four groups lie within the areas outlined in Fig. 5. Group 1 occupies the area *ABDC*, group 2 the area *CDFE*, group 3 the area *BGHD* and group 4 the area *DHJF*. It will be noted that these four groups differ from those referred to by Campbell,

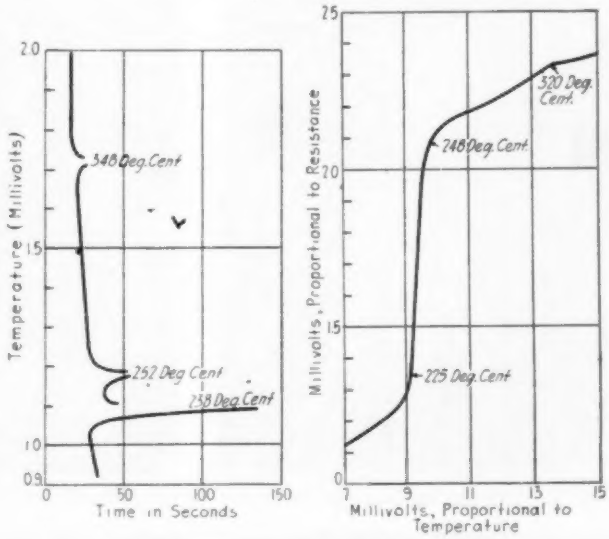

Fig. 6 Typical Cooling Curves

who, however, classified his alloys in accordance with the constituent that first separated from the melt on freezing.

Rapid cooling has the effect of suppressing the crystallization of SnSb at 248 deg. cent. in antimony-rich alloys in the neighborhood of the boundaries *BD* and *DF*. It is therefore possible to obtain a structure free from cubes of SnSb even in such an alloy as No. 18, if the same be cooled from the liquid state at a sufficient rate. This effect in alloy No. 18 is brought out in Figs. 25 and 26, the former representing the average structure toward the center of the ingot, the latter the average structure near the edge. It is possible that this effect might be of some importance in its bearing upon the anti-frictional behavior of the alloys lying near the boundaries *BD* and *DF*, and it may be well to emphasize the fact that the further removed an alloy is from these boundaries the less likely is the normal crystallization of SnSb to be prevented.

The rate of cooling these alloys is, of course, important in its effect on the size of the cubes of SnSb, as has been shown by many observers. The possibility of suppressing the precipitation of

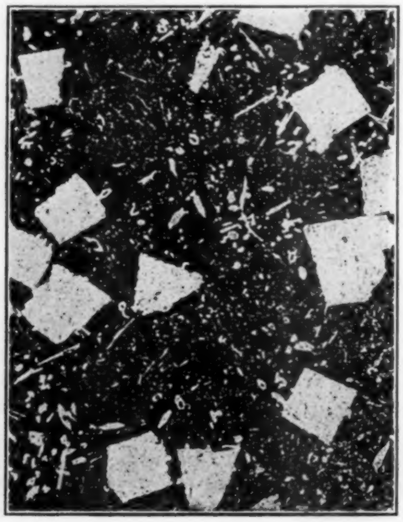

FIG. 32 ALLOY No. 24. 150X

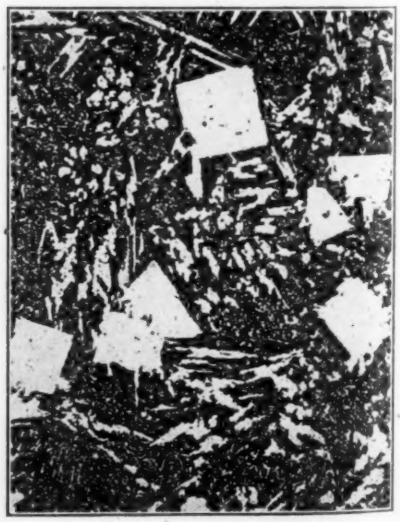

FIG. 33 ALLOY No. 25. 150X

these cubes does not, however, appear to have been referred to in the literature.

Another phenomenon deserving of note is the size of the SnSb cubes in the high-copper alloys as compared with that of the cubes in the low-copper alloys. This is well exemplified in the photomicrographs. If, for example, Figs. 23, 24, and 25 be compared with Figs. 26 and 27, the greater size of the cubes in the high-copper alloys will be appreciated. A comparison for the same purpose may be made between Figs. 29 and 30 and Figs. 31, 32, and 33. In the authors' opinion the difference in crystal size may be accounted for by assuming that the presence of primary CuSn facilitates the precipitation of SnSb and, as a result, a few large cubes are formed where, in the absence of the inoculating medium CuSn, a greater number of small cubes would be precipitated. The presence of needles of CuSn within the cubes of SnSb is a common occurrence in the alloys of high copper content, an occurrence which has been noted by former workers in this field.

### Hardness

Fig. 4(*a*) shows the location of the test pieces cut for investigation of the physical properties of the alloys from the first group of the series. The samples for hardness test were $^3/_4$ in. thick; their diameters were the full diameters of the ingots, that is, 1.25 in., approximately. The hardness was determined on a Brinell machine, a 10-mm. steel ball with a 500-kg. load being used, except when the metal was very soft, in which case a load of 350 kg. was applied to the ball. The load was invariably kept on for a period of 30 sec. for all tests.

Table 2 gives the Brinell hardness of the alloys at room temperature.

TABLE 2 BRINELL HARDNESS OF ALLOYS INVESTIGATED AT ROOM TEMPERATURE[1]

| Antimony, per cent | | Copper, per cent $^1/_2$ | 1 | 2 | 4 | 8 |
|---|---|---|---|---|---|---|
| | Alloy No...... | 1 | 2 | 3 | 4 | 5 |
| 2 | Hardness *a*..... | 9.5 | 11.3 | 12.3 | 13.0 | 15.3 |
| | *b*..... | 9.4 | 11.5 | 11.6 | 13.6 | 17.8 |
| | Alloy No...... | 6 | 7 | 8 | 9 | 10 |
| 4 | Hardness *a*..... | 12.1 | 14.7 | 15.0 | 16.7 | 20.8 |
| | *b*..... | 12.5 | 13.6 | 14.9 | 16.3 | 21.3 |
| | Alloy No...... | 11 | 12 | 13 | 14 | 15 |
| 6 | Hardness *a*..... | 14.6 | 17.0 | 19.2 | 19.5 | 26.6 |
| | *b*..... | 15.6 | 17.2 | 19.3 | 21.4 | 26.5 |
| | Alloy No...... | 16 | 17 | 18 | 19 | 20 |
| 8 | Hardness *a*..... | 18.6 | 19.9 | 21.7 | 21.9 | 26.1 |
| | *b*..... | 19.1 | 19.9 | 20.8 | 23.3 | 27.1 |
| 10 | Alloy No...... | 21 | 22 | 23 | 24 | 25 |
| | Hardness *a*..... | 18.7 | 20.8 | 20.8 | 22.6 | 30.4 |
| | *b*..... | 20.1 | 20.9 | 20.8 | 23.8 | 30.5 |

[1] The room temperature during these tests was 21.5 deg. cent. for set *a*, and 26 deg. cent. for set *b*.

Values marked *a* were obtained on the E test pieces [Fig. 4(*a*)]; those marked *b* were check tests determined on the B pieces [Fig. 4(*a*)]. The observations on the E and B pieces agreed within the limits of experimental error.

A three-dimensional figure of the hardness at room temperature as a function of the copper and antimony content is given in Fig. 34, while in Fig. 35 these data are presented in a diagram of lines of equal hardness (isoscleric diagram). Both diagrams are based on the measurements of hardness of the first group. The regions of the four different types of microstructure are shown by dotted or heavy lines.

It will be noted from the general character of the curves that addition of antimony beyond the line of separation of tin-antimony crystals (approximately 7.5 per cent antimony) increases the hardness but slightly, at least in the field covered by the authors' investigation. The hardness of the Straits tin which was used as the basis of the authors' alloys was found to be 5.0.

The data obtained by the authors may be compared (Table 3) with those given in other papers. J. R. Freeman, Jr., and R. W. Woodward in Technologic Paper No. 188 of the Bureau of Standards, and J. R. Freeman, Jr., in the Proceedings of the American

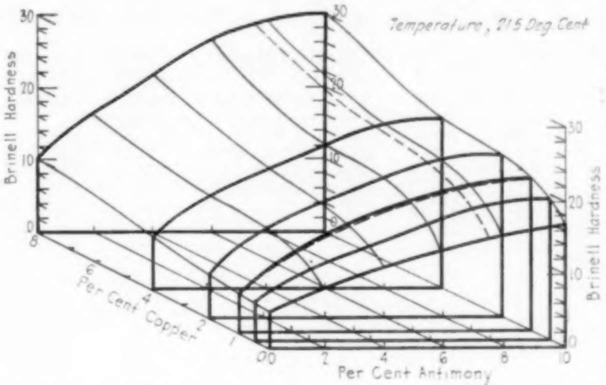

Fig. 34 Three-Dimensional Figure of Hardness at Room Temperature as a Function of the Copper and Antimony Content

Society for Testing Materials, vol. 22, 1922, p. 207, give Brinell hardness numbers for alloys which lie within the range of the authors' experiments.

TABLE 3 BRINELL HARDNESS NUMBERS OF ALLOYS GIVEN IN OTHER PAPERS

| No. of alloy | Copper, per cent | Antimony, per cent | Hardness as given | Authors' data by interpolation |
|---|---|---|---|---|
| A.S.T.M. No. 1 | 4.56 | 4.52 | 17.2 | 18.5 |
| A.S.T.M. No. 2 | 3.51 | 7.57 | 24.3 | 22.8 |
| S.A.E. No. 11 | 5.65 | 6.90 | 22.3 | 22.5 |

This appears to be a satisfactory agreement.

### Hardness at Elevated Temperatures

In order to determine the softening action of elevated temperatures on the alloys, a small electric furnace was built (Fig. 36)

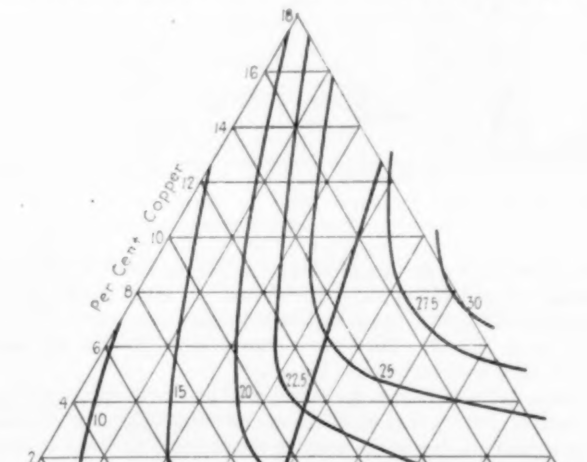

Fig. 3 Isoscleric Diagram for Varying Copper-Antimony Proportions

of a size small enough for it to rest on the anvil of the Brinell testing machine. The samples were placed in a glycerine bath, the temperature of which could be regulated by changing the current in the heating element. The bath was equipped with a stirrer and thermometer.

The Brinell numbers for temperatures ranging from 1 deg. cent. (melting ice and water in the bath of the furnace) to 125 deg. cent. were determined and are given in Table 4. The numbers printed in italics were obtained with a load of 350 kg. on the 10-mm. ball, the material being too soft for the use of a 500-kg. load. Figs. 37–41 and 42–46 show the hardness plotted against

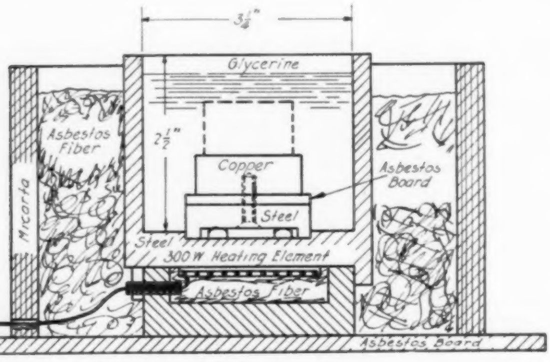

FIG. 36 ELECTRIC FURNACE USED IN DETERMINING SOFTENING ACTION OF ELEVATED TEMPERATURES

temperature for groups of alloys containing equal amounts of antimony and of copper, respectively. A space model of the hardness of the 25 alloys at various temperatures was prepared and is show in Fig. 47. The surface corresponding to 21.5 deg. cent. is the same as that shown in Fig. 34.

Since babbitt linings are often working at temperatures between 70 and 90 deg. cent. the considerable difference between the Brinell number at the working temperature and that at room temperature is very important. It seems advisable to specify hardness of the bearing metal both at room and at elevated temperatures.

## COMPRESSION TESTS

Two compression test pieces were cut from each ingot of the first group of alloys. These are denoted as C and G; by comparing the compression test data for these two samples, taken from the upper and lower portions of the castings, respectively, it was possible to judge the uniformity of the material of the castings. The shape of the test pieces was based by the authors on the investigation of J. R. Freeman, Jr., and P. F. Brandt reported in a paper entitled "The Influence of the Ratio of Length to Diameter in the Compression Testing of Babbitt Metals," in Proc. A.S.T.M., vol. 23 (1923), part II, p. 150. This paper showed that the stress-deformation curves for these metals are the same when the ratio of the length to the diameter of the test piece lies between 3 to 1 and 1 to 1, and that the gage length may be either a part or the whole length of the test sample. In another paper by Mr. Freeman (Proc. A.S.T.M., vol. 22 (1922), part I, p. 207) it was demonstrated that the results of tests do not vary, for babbitt metals, when test pieces of 1-in. or $^1/_2$-in. diameter are used. The authors therefore adopted compression test pieces $1^1/_2$ in. long by 0.564 in. diameter, which gives a 0.25-sq. in. cross-sectional area.

The compression tests were made in an Amsler testing machine of 20,000 lb. maximum capacity. The test piece was compressed between two hardened polished steel plates. An initial load of 50 lb. was applied to take up slack motion in the set-up, and the load was increased gradually at a rate of 100 lb. per min. for all the alloys. The tests were continued till a compression of 0.375 in. or 0.250 in. per inch length of the test piece was attained; the corresponding load was considered as the "ultimate load." An autographic record of the stress-deformation curve was taken on the machine, and accurate readings of the deformation were taken by means of dial gages showing the motion of the plunger of the Amsler machine. Readings were taken at every 50 lb. till 600 lb. load was reached, and subsequently at every 100 lb.

Fig. 48 shows the stresses plotted against deflections for the initial part of the compression of the samples cut from the ingot of alloy No. 9. The upward bend at the lower end of the curves is probably caused by the elasticity of the parts of the Amsler machine. The stresses 3100 and 2690 lb. per sq. in. were taken to be the proportional limits of the two samples. It should be noted that the alloys have no proportional limit in the strict sense of the word, since the point where the curve deviates from a straight line will differ, depending on the scale to which the deflections are plotted. All test data were plotted to the same scale as in Fig. 48, and either the apparent end of the straight-line portion or the point of maximum slope of the curve in case no such line existed, was called by the authors the "proportional limit." Determinations were also made of arbitrarily chosen yield points of these alloys, these yield points being taken as the stresses corresponding to the points of intersection of the initial straight portions of the load-compression curves and the tangents

to these curves at the points corresponding to 0.375 in. compression. Determinations of the proportional limits and yield points of these alloys cannot be made with the same degree of accuracy as can those of the ultimate strength, which is measured directly on the dial gage of the machine; nevertheless these values obtained from the load-compression diagram for these alloys are given in Table 5. These values represent the characteristics of these alloys at room temperatures ranging from 21 to 26 deg. cent., the stresses quoted being the average of those obtained for the bottom and top test samples.

Copies of the autographic load-compression charts are given in Figs. 49 and 50. In Fig. 49 the curves are grouped according to the content of antimony, those for the samples taken from the bottom and top of the ingots being superimposed; the coincidence between the curves is very satisfactory. In Fig. 50 the

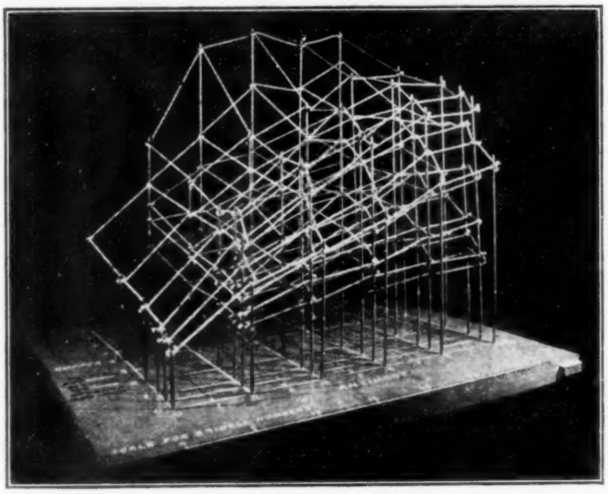

Fig. 47 Space Model of Hardness of the 25 Alloys at Various Temperatures

curves for the bottom pieces only are given; they are grouped according to the content of copper. A peculiar feature is noticeable when the two figures are compared: in Fig. 49 the curves in each group with equal amounts of antimony are fairly parallel, i.e., of equal slope, in the region of plastic deformation, while in Fig. 50 the curves for alloys with the same amount of copper, but different contents of antimony are divergent, the slopes increasing with increase in antimony content. This may be explained by the fact that the crystallites of CuSn are in the shape of small needles, while those of SnSb are in the form of comparatively large cubes. Although the needles add greatly to the initial strength of the metal, when internal slipping occurs the needles of CuSn are not so effective in preventing further flow as are the cubes of SnSb.

The babbitt may be aptly compared with a plastic clay in which are incorporated numerous small splinters and larger cubes of wood. When stress is applied to this clay, both the splinters and cubes help it to

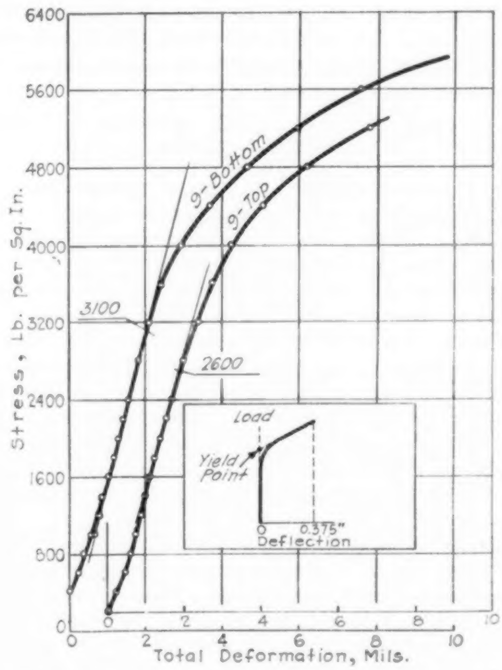

Fig. 48 Stresses Plotted Against Deflections for the Initial Stage of Compression of Samples Cut From Ingot of Alloy No. 9

resist deformation. At a certain stage of deformation, however, the splinters, which initially offered mutual support to one another and thus greatly influenced the strength of the mass as a whole, become disturbed, and, being thus disconnected and relatively small, fail to prevent effectively the further deformation of the clay. The larger cubes, however, due to their shape and size, still act as keys to inhibit slip.

The differing actions of copper and tin in the babbitt are also interestingly demonstrated in the photograph, Fig. 51, of the test pieces after 25 per cent compression. The surface of the test pieces with high copper content are rather smooth when compared with those of low copper content. The low-copper samples in all cases have the same superficial appearance as that of the Straits tin, which is shown on top of an uncompressed piece in Fig. 51. This may be explained by assuming that the interlocking needles of CuSn so break up the structure of the

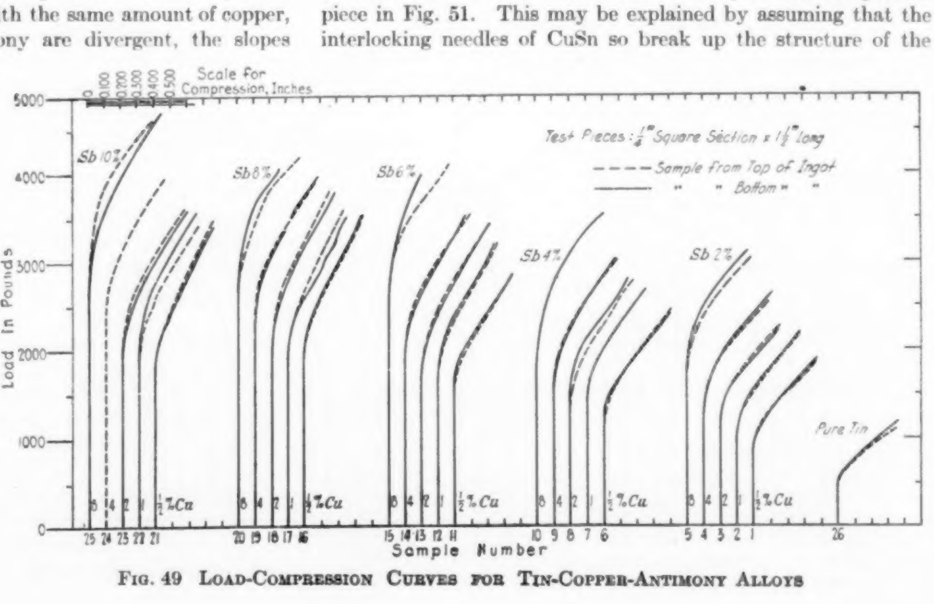

Fig. 49 Load-Compression Curves for Tin-Copper-Antimony Alloys

alloy that slip of relatively minute blocks only can occur, whereas in the absence of these needles movement of comparatively large sections of the metal can take place, resulting in a rough surface of the sample after compression.

### Relation Between Compressive Strength and Brinell Hardness

Since it is much quicker and easier to test a babbitt metal for Brinell hardness than for compressive strength, the relation between the two tests was investigated by the authors, and a satisfactory correlation of results was found.

Fig. 52 shows the relation between the ultimate strength of the alloys and their hardness, both at room temperature. The points fall on a definite curve, the deviation of the points being within the limits of experimental errors. The plotting of the proportional limits and the yield points against the Brinell hardness (Figs. 52 and 53) shows a certain relation, although the points are more scattered. This is natural, since the proportional limits and yield points are obtained by an arbitrary method. It seems reasonable to adopt the straight-line relation shown in Figs. 52 and 53.

It should be noted that the authors do not imply that there is any logical reason to expect a definite correlation between compressive strength and Brinell hardness, and the relations given are merely a convenient empirical way to derive the strength of babbitts from Brinell tests. This is especially important when the strength at elevated temperatures is sought, since, having the Brinell number the ultimate strength, proportional limit, and yield point may be found and the approximate stress-compression curve may be constructed.

The 12 standard white bearing metals of the A.S.T.M. were tested by J. R. Freeman, Jr. (loc. cit.), the hardness and ultimate strength of the metals at 20 deg. cent. and 100 deg. cent. being given. Table 6 gives a comparison between the ultimate strengths found by Mr. Freeman and the values obtained by scaling off from the curve in Fig. 52. It is worthy of note that a close agreement exists, not only between the two sets of values for the tin-antimony-copper alloys at 20 deg. cent., but for the lead-base alloys as well. The agreement is not so close in the case of the 100-deg. cent. values, but it may be observed that Freeman in his hardness tests used a 500-lb. load, and at a temperature of 100 deg. cent. such a load is excessive and readily leads to inaccurate readings.

### Influence of Small Admixtures of Lead

For two reasons it became clear that a study of the effect of lead on the microstructure and properties of certain of these alloys would be advisable. In the first place, the use of commercial tin containing lead and copper is not uncommon. In the second place, the tinning of bearing shells prior to babbitting generally involves the use of a tin-lead solder, and as a result contamination of the lining with lead is unavoidable.

To investigate the effect of lead upon the properties of typical tin-base bearing metals two groups of alloys were prepared of the following analyses:

| | Group 1 | | | |
|---|---|---|---|---|
| | Sb | Cu | Pb | Sn |
| *a* | 7.90 | 1.39 | 0.72 | diff. |
| *b* | 8.02 | 2.02 | 1.18 | |
| *c* | 7.93 | 2.00 | 1.81 | |
| *d* | 7.84 | 2.00 | 2.33 | |

| Group 2 | | | |
|---|---|---|---|
| Sb | Cu | Pb | Sn[1] |
| 8.65 | 8.336 | 0.82 | diff. |
| 7.93 | 8.18 | 2.69 | |

[1] Very small amounts of other impurities also.

Group 1 is a series of alloys having alloy No. 18 as a base, lead having been substituted for tin in this alloy.

Group 2 is a series of alloys

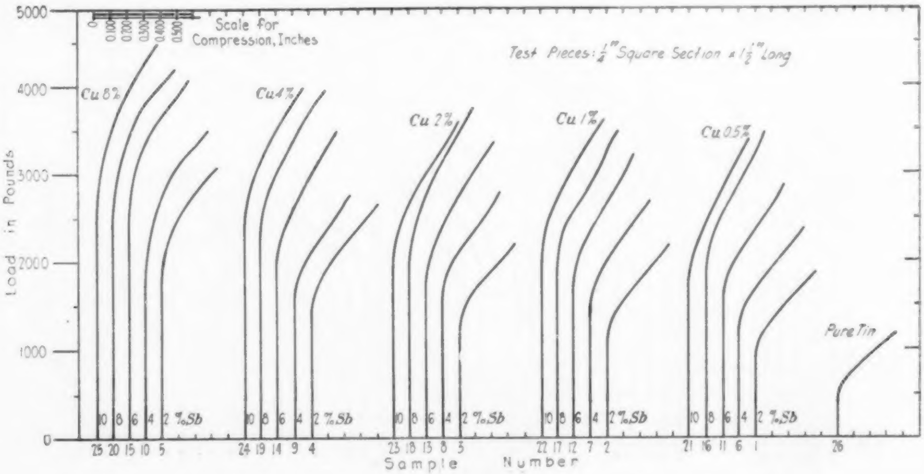

Fig. 50 Load-Compression Curves for Tin-Copper-Antimony Alloys

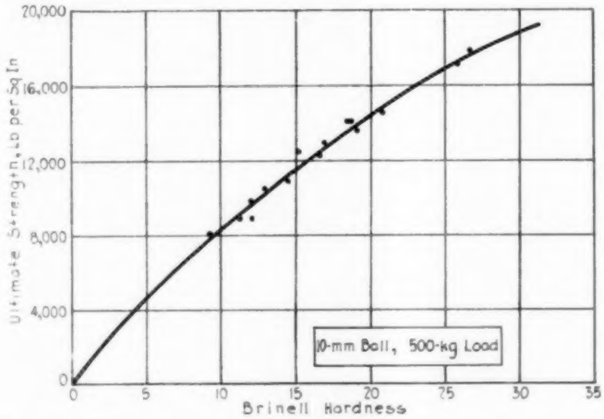

Fig. 52 Relation Between Ultimate Strength and Hardness of Alloys at Room Temperature

having alloy No. 20 as a base, lead again having been substituted for tin.

These were examined microscopically and hardness and compression tests were made. The effect of temperature on hardness was also studied. The cooling curves of these alloys exhibited a deflection at 181 deg. cent. in addition to those noted in the lead-free mixtures. This, no doubt, was due to the presence of traces of the eutectic of the lead-tin system. Such an evolution of heat has been referred to by Cowan (Institute of Metals—Advance Copy No. 451—subject to revision), who has shown also that the presence of lead in these alloys results in the formation of minute shrinkage cavities due to the freezing out of the lead tin eutectic at 181 deg. cent.

Photomicrographs of alloys *b* and *c* of Group 1 are shown in Figs. 55 and 56. These may be compared with Fig. 25, which shows the structure of lead-free alloy of about the same composition. It appears from these photographs that the substitution of lead for tin in alloys of low copper content has the effect of causing the CuSn needles to crystallize in a massive form. It has the further effect of pushing the lines *BD* and *DF* of the ternary equilibrium diagram away from the tin corner of the system. This effect is made evident by the almost complete absence of cubes of SnSb from the structure of alloy *d*.

It is not improbable that the deleterious effect of lead upon the malleability and shock-resisting qualities of certain of these alloys, which have been frequently referred to in the literature, is due to the manner in which the CuSn crystals separate from the melt. The authors, however, have no conclusive argument at the moment either for or against the evidence which has appeared in regard to the effect of lead on the brittleness of these metals.

Typical structures of alloys *a* and *b* of group 2 are shown in Figs. 57 and 58. In these alloys the coarsening effect of lead upon the CuSn constituent is not so marked, but the tendency of lead to extend the area of the δ-field of the diagram is clearly shown by the lesser number of cubes per unit volume of alloy—compare Figs. 58 and 28.

The strength of the alloys of group 1 was investigated in the same manner as described before. Fig. 59 shows the stress-deformation curves for the test samples taken from the lower portion of the ingots. The strength of the alloy increases from alloy No. 18 to alloys *a* and *b*, while further increase of lead content does not affect the strength of the metal. The same effect is demonstrated in a Brinell hardness chart in Fig. 60. The Brinell number increases with the addition of lead up to 1 per cent. After this point the hardness curve flattens out.

It is interesting to note that at elevated temperatures the effect of lead content gradually decreases, the effect at 125 deg. cent. becoming negligible.

The same characteristics of the effect of lead on the strength of a tin-copper-antimony alloy are evident from the hardness data obtained with the alloys of group 2, shown in Fig. 61.

These data accord with the observations of J. R. Freeman, Jr., and R. W. Woodward (loc. cit.), who tested a 3.5Cu-7.6Sb-88.9Sn alloy with admixtures of lead up to 5 per cent. It is the authors' opinion that, since the practice of tinning shells with solder prior to pouring the lining introduces a small amount of lead into it, the babbitt used should be as free from lead as is commercially reasonable.

## Influence of Impurities on Tin

In view of the known effect of lead upon the mechanical properties of these alloys it is of importance to consider the analysis of the tin which forms their basis. Straits tin, for example, is relatively free from lead; commercial tin—"99 per cent"—contains

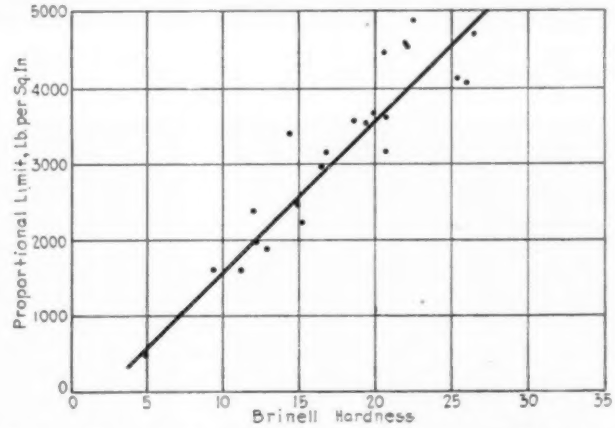

Fig. 53 Relation Between Proportional Limit and Hardness of Alloys at Room Temperature

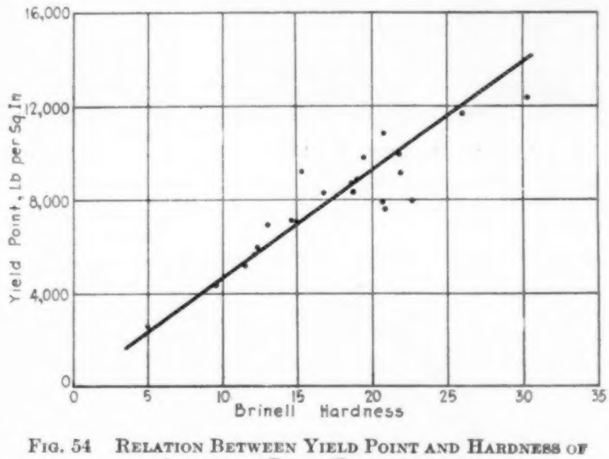

Fig. 54 Relation Between Yield Point and Hardness of Alloys at Room Temperature

up to about 1.0 per cent of lead. Typical analyses of these varieties are quoted below.

| | Straits | 99 per cent |
|---|---|---|
| Tin | 99.95 | 98.99 |
| Lead | 0.032 | 0.78 |
| Copper | 0.005 | 0.12 |
| Iron | 0.010 | 0.02 |
| Bismuth | 0.010 | 0.024 |
| Zinc | traces | traces |

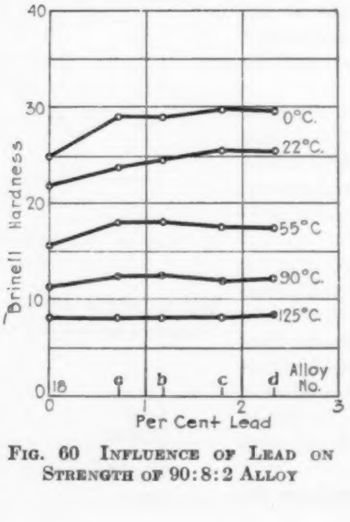

FIG. 60 INFLUENCE OF LEAD ON STRENGTH OF 90:8:2 ALLOY

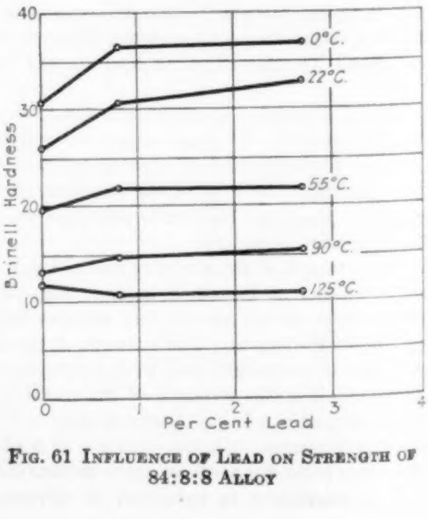

FIG. 61 INFLUENCE OF LEAD ON STRENGTH OF 84:8:8 ALLOY

The microstructure of samples taken from standard castings (mold in Fig. 3) made from these two brands of tin are shown in Figs. 62 and 63, which bring out the remarkable difference between the two materials in their reaction to similar treatments with the same etching reagent—undiluted ferric chloride. The white constituent which appears in Fig. 63 is doubtless CuSn.

The Brinell hardness of Straits tin was found to be 5.0, that of 99 per cent tin, 10.3.

Two alloys were made up of the same constituents and were cast under identical conditions. In one, Straits tin formed the base; in the other, 99 per cent tin; otherwise the alloys were exactly similar. No analyses were made, as the authors were interested only in comparing the properties of similar charges

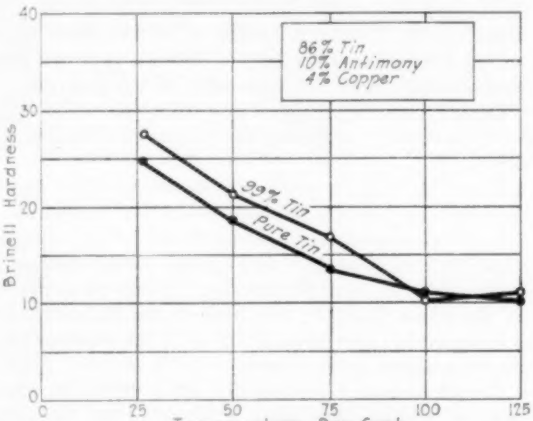

Fig. 64 Relation Between Temperature and Hardness for 86:10:4 Alloy Made With Tins of Different Analysis

with different basic metals. The results of hardness tests made at various temperatures on the castings obtained, which were of the following approximate analysis, tin, 86 per cent, antimony, 10 per cent, and copper, 4 per cent, are shown in Fig. 64.

### Conclusions

The authors have found that a systematic relationship exists between the mechanical properties of the tin-antimony-copper alloys of high tin content and their percentages of antimony and copper. The phase boundaries of the system were determined as a result of a complete metallographic study. A ternary diagram of the system is given.

A definite relationship has been shown to exist between the Brinell hardness numbers and the compression strengths of these alloys. The hardness numbers, therefore, satisfactorily express the mechanical properties of babbitts.

The strength of these alloys does not increase appreciably with antimony content above the point of appearance of the SnSb cubes. Addition of copper increases the strength of these alloys, but the rate of increase of strength falls off on the appearance of CuSn needles. This last effect is most pronounced when the alloys are tested at high temperatures. On this account it does not appear rational to use high copper contents in babbitts that are to work at temperatures in excess of 75 deg. cent.

Babbitts of high copper content must be poured at higher temperatures than those of low copper content, since the separation of CuSn on cooling occurs at rapidly increasing temperatures with increase in copper content.

The strength of these alloys falls off appreciably with increase in temperature within the working range of babbitts in bearings.

Lead has an important effect upon the microstructure of these alloys. It increases the mechanical strength of babbitts when added in quantities up to 1 per cent. Further additions have no strengthening effect whatever and at high temperatures this effect is entirely lost, no matter what the content of lead. The microstructural changes occasioned by lead tend to confirm the current opinions regarding its embrittling action.

## Discussion

R. L. Templin.[4] The writer does not believe that there is such a thing as zero Brinell hardness, either in theory or otherwise. There is, however, a minimum value that obtains when the diameter of the impression equals the diameter of the steel balls. This minimum value is a finite one, being 3.18 on the basis of using a 10-mm. diameter ball under a 500-kg. load. Therefore any curve that portends to show a relationship between Brinell hardness and tensile strength ought to take this fact into account in its equation as is usually done in an equation showing the relationship between the Brinell hardness and tensile strength of steel. Quite frequently the Brinell hardness can be multiplied by a constant to get an approximate value of the ultimate tensile strength of a metal, but strictly speaking this is not correct. For instance, the Brinell hardness multiplied by 550 gives an approximate tensile strength of most of the known wrought alloys of aluminum. More satisfactory results are obtained, however, f the known tensile strength of the material is divided by 550 in order to obtain a Brinell value of reasonable accuracy.

The authors state that in obtaining the Brinell hardness values the load was applied for thirty seconds. It has been found in the case of magnesium, for instance, that a satisfactory Brinell hardness value cannot be obtained unless the load is applied for an appreciably longer period, from $1^1/_2$ to 3 minutes.

A rule sometimes given for Brinell hardness test indicates that as long as the depth of the impression does not exceed one-third the thickness of the specimen, the thickness of the material will not affect the hardness. The writer, however, has not been able to check this rule in the case of the non-ferrous metals although he has performed the following experiment a number of times: A specimen of wrought aluminum alloy about one-half inch thick is first carefully given a Brinell test to check the uniformity of the material, then the specimen is planed off on one side so that it tapers from the full thickness at one end to a knife edge at the other end. Brinell hardness tests are then made on the unplaned surface at definite intervals until a point is reached where the readings become constant, that is, where the anvil effect or the specimen thickness ceases to change the hardness values. Our results show that if the depth of the impression does not exceed about one-thirtieth of the thickness of the specimen, the results are not affected by the thickness of the specimen.

With regard to the hardness tests on hard constituents existing in the form of large crystals in the material, we have found that in specimens containing large crystals as large as or larger than the Brinell ball used, so that it is possible to take readings on individual crystals, there seems to be very little difference in the Brinell values taken on the individual crystals or on the juncture of the crystals. This applies, of course, to aluminum alloys. We do find, however, in the case of Brinell tests of coarse crystal aggregates, as the Brinell ball is applied to the specimen, that certain of the crystals appear to rise up in the material while others are depressed adjacent to the Brinell impression. This causes the edge of the Brinell impression to be very irregular indeed and the determination of the Brinell hardness is quite doubtful. Another factor that should be considered is the differential recovery of cold-worked metal as the load is removed from the Brinell ball. In such cases the Brinell impression instead of

[4] Chief Engineer of Tests, Aluminum Co. of America, Pittsburgh, Pa.

being spherical in shape frequently has a four-sided appearance; then depending upon whether the diameters are read across the corners or across the sides of the impression, variations in Brinell values of from 17 to 20 per cent may be observed.

W. R. Webster.[5] In practically all of the copper alloys, the curve relating tensile strength to percentage of reduction by cold-working is fairly straight, having a slope which varies with specific alloys.

If a Brinell-hardness curve of the same series is drawn, it will start with a greater pitch angle, but will gradually flatten out until after a while there is very little increase in the Brinell, whereas tensile strength goes up all the time. It would be interesting to know if this has been observed in the alloys mentioned in the paper.

P. W. Brace.[6] In connection with the structure of each of these alloys, we have finally the duplex structure in which we find both the antimony-tin cubes and the needles and the cubes. The writer would appreciate information as to which type of structure seems to be best from the standpoint of bearing performance. Listening to various discussions on bearing metals, one hears many different ideas as to what is the best bearing metal. Each person who discusses the subject seems to have his pet alloy which will do a certain duty better than any other one.

Here we have mentioned three very definite types of structure, and some comment on the subject at this time seems desirable.

A. L. Davis.[7] In tests made by Scovill Mfg. Co., the Brinell test has seemed to be a good indication of the strength. It is much more convenient than laborious compression tests, and seems to be quite satisfactory.

In testing various bronzes and "high-lead" bearing metals, we have found much of interest, which in practice we have tried to follow out by using the various alloys for bearings under rolls. We recently found that we do not necessarily have to have an exceedingly hard metal to carry a heavy load, providing the speed is not too great. Some of the "high-lead" metals that are ninety-six or seven per cent lead, hardened up by sodium or alkaline earths, seem to be excellent. The only qualification is that under certain conditions they tend to pick up grit and act as a lap. When in such position that grit does not get in, they make admirable bearings under very heavy loads.

R. W. Cadman.[8] It has been found that the introduction of aluminum into tin-base babbitt has a tendency to break up the crystal and eliminate the antimony in tin and copper crystals. The elimination of crystals in white bearing metals seems to be the most essential thing we can strive for, because after all, the test of a babbitt metal is how long it will last without oil. Most any babbitt metal will carry the load so long as it has the proper lubrication, but with large crystals heat is sure to result, and heat is the source of the bearing's destruction. In the writer's judgment, the needle structure of the babbitt metal is the ideal condition. A metal is never harder than its matrix; therefore, the Brinell value may appear high when one or more of the hard crystals is encountered, but will drop if the test is made at another spot. While Brinell test is wonderful and keeps one informed as to the hardness of the metal, the writer does not believe that it is quite as important as the ability to carry load.

[6] Research Engineer, Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa.

[7] Research Engineer, Scovill Mfg. Co., Waterbury, Conn. Mem. A.S.M.E.

[8] A. W. Cadman Mfg. Co., Pittsburgh, Pa.

### Authors' Closure

In reply to Mr. Webster's inquiry as to the effect of cold work on the hardness and strength of these alloys it can be said that work in this connection is included in our program.

Mr. Davis' remarks are most interesting, since the authors are at the moment investigating the properties of typical high-lead alloys.

In reply to Mr. Brace's question as to the optimum structure for these alloys, we are not in a position at the present time to make any recommendation as to a specific alloy. It is necessary for further tests to be made before we can decide which of this system of alloy is the most satisfactory. Reference to the third page of the paper, however, will indicate the authors' present feeling in regard to those alloys which lie in the neighborhood of the phase boundaries of the system.

Mr. Templin's point regarding Fig. 52 is worthy of remark. However, on the previous page it is stated by the authors that there was no logical reason "to expect a definite correlation between compressive strength and Brinell hardness," the curve being of an empirical character.

As to the reliability of the hardness tests, one of the authors made a series of hardness tests some three to four months before the other. A comparison between the two sets of figures given in Table 2 shows that the results obtained by two observers at totally different times, using the same conditions of testing, are very close indeed.

With respect to Mr. Cadman's remarks, the authors believe that his criticism of the Brinell test is not justified. The longest cubes encountered in the alloys investigated by the authors were not more than $^1/_{300}$ in. across the edges. The size of the impression produced in the Brinell test of this same alloy (i.e., number 25), was about $^1/_5$ in. In other words the diameter of the impression was 60 times greater than the edge of the largest crystal.

In some instances tests were made on a baby Brinell machine, using a $^1/_{16}$ in. ball and a $7^1/_2$-kg. load. Even in this case it was found that the difference in the hardness at four different points in each sample was quite inappreciable.

It would be of great interest to the authors to have quantitative data in regard to the effects of small and large crystals on the antifrictional qualities of bearing metals. A search for such data forms, of course, a part of the authors' program.

# The Design and Building of Jigs and Fixtures

## A Brief Description of the Methods Employed by the Western Electric Company in the Manufacture of Telephone Apparatus and Equipment

By F. P. HUTCHISON,[1] KEARNY, N. J.

WITH the general adoption of tools which will insure interchangeability of product and the increasing necessity for more economical manufacture, the efficient designing and building of jigs and fixtures is being emphasized more than ever before as one of the important factors to be considered. One of the industries to which this statement may well be applied is that of manufacturing telephone apparatus and equipment, especially when handled on a large-production basis as is done in the plants of the Western Electric Company, where over 13,000 separate and distinct kinds of apparatus are manufactured, in the assembly of which are used approximately 110,000 different parts made on an interchangeable basis from over 18,000 different sizes, shapes, and kinds of raw material. The manufacture of this product involves not only all the standard operations usually found in wood- and metal-working shops, but many special operations as well. It requires the use of many different designs and kinds of tools falling under the general classification of jigs and fixtures ranging in cost from a few dollars to over $5000, and in size from drill jigs and fixtures which are small enough to be carried in a man's vest pocket, to portable fixtures used for assembling and holding during arc welding, structural-steel frames approximately 11 ft. long and 4 ft. wide. However, the larger proportion cost less than $400, as generally speaking the majority of the parts manufactured are small in size when compared with those used in engines, generators, heavy machinery, etc.

The same general procedure is followed for the manufacture of jigs and fixtures as for other classes of tools, the work being divided into five steps or divisions, namely, planning, designing, ordering, tool making, and inspection, which will be considered in the order given.

### Planning

In order to meet the increasing demands of the telephone business, new and changed designs of apparatus and equipment are constantly being developed for the purpose of improving the quality and reducing the cost of telephone service, which means that manufacturing requirements are continually changing. These new and changed designs must be analyzed and the best available methods of manufacture determined consistent with the quantity of parts to be made and the accuracy required. This work is performed by planning engineers, who prepare the manufacturing analysis giving the sequence of operations, tools and machines to be used, speeds, quantity of materials required for unit output, and other manufacturing information. These engineers determine the new or changed tools, such as jigs and fixtures, which will be needed, make a preliminary estimate of the cost, and prepare the necessary requisitions for their designing and building.

Studies are also being carried on by groups of engineers with the object of reducing manufacturing costs. As a result of these investigations requisitions are very often originated for the designing and building of new jigs or fixtures or for improvements in present tools. It would appear that if the planning job were done properly at the time of the original analysis, there would be no need for further study. However, this does not always hold true, as methods, processes, and tools which have already been proved and which it is known will work well, must be specified as far as possible in order that the product may be produced by a given date and at near the estimated cost. Later, after manufacture is under way, it is possible to try out new ideas and improved methods and tools without holding up production. Also in many cases the quantity of a part manufactured increases sufficiently to warrant improved and more expensive tools, which would not have been justified on the lower schedules.

After the tool requisitions have been written up and properly approved for expenditure in accordance with the estimated cost, they are routed to the Tool and Gage Design Division.

### Designing

The Tool and Gage Design Organization is divided into sections according to the class of work handled; for example, there is one group which designs drill jigs and tapping fixtures, another arc-welding, milling, and assembly fixtures, a third screw-machine and heading tools, a fourth riveting, molding, and spot-welding fixtures, etc. This plan is not only of advantage from an organization and assignment-of-work standpoint, but tends to produce more efficient designs and lower design costs, especially considering the very large variety of tools involved.

In order to handle efficiently between six and eight thousand requisitions a year, approximately one-third of which are for jigs and fixtures, it is necessary that the completion dates for the design work necessary be determined and the jobs scheduled accordingly on the groups handling each particular class of work. This function is performed by the scheduling section, who maintain a balanced load against each design section's capacity. The requisitions or orders are assigned to the designers by the supervisor in charge of the group. After the drawings have been completed they are checked in detail by checkers, and for general design by the section and department chiefs, before being finally approved by the chief of the Design Division.

The actual time and expense for design work are recorded for each order and included as part of the total cost of the tools. For jigs and fixtures the design expense may vary from 5 per cent of the total cost to several times this figure, depending on the nature of the design, amount of development work necessary, number of tools being built, etc. Every effort is being made through standardization and other means to hold design costs to the lowest possible figure consistent with good practice. Very few ink tracings are now being made at the time of designing except in special cases or where it is probable that the drawing will be subjected to considerable handling, as, for instance, when a number of prints may be required at frequent intervals for reorders or maintenance purposes. The majority of the drawings are made only in pencil on pencil-cloth cut to five specified sizes ranging from $7^1/_2$ in. $\times$ $12^1/_2$ in. to $31^1/_2$ in. $\times$ $38^1/_2$ in. within border lines, and with the standard form printed, so that no ruling or lettering for this part of the drawing is necessary by the designer. If it is later found advisable to make an ink tracing, this can be done when required. Meanwhile any corrections or changes found necessary in the design can be made

[1] Chief of Tool Design, Manufacturing Objectives, and Labor Grading Division, Western Electric Co., Kearny Works. Jun. A.S.M.E.

Presented at a meeting of the Metropolitan Section of the A.S.M.E., Newark, N. J., March 28, 1928.

much easier and at less cost on the pencil drawing than if a tracing had to be changed. As between 1200 and 2000 drawings and sketches for jigs and fixtures are made yearly, there are now a large number of different designs on file, so that it is often possible to eliminate making a drawing for a new tool and specify that it shall be similar to another drawing with certain modifications. Where only one tool is to be made and the design is comparatively simple, instructions for making included on the order together with the drawing of the apparatus or piece part will often suffice. Approximately 12 per cent of the orders issued for new jigs and fixtures not previously designed are being handled satisfactorily on a not-drawn basis. In many cases a sketch or drawing showing only the drilling and milling layout and specifying standard parts is furnished.

Considerable progress has been made in the standardization of tool designs, and further studies of this nature are being carried on. Standard drawings have been made for various types of drill jigs and fixtures, as well as other tools, and details such as bushings, channels, latches, springs for plate jigs, gage pins, jig feet, clamping cams, etc. have been standardized and stocked where the quantities used are sufficient. Tool steels have been classified and assigned code numbers, except in the case of S.A.E. specification steels where the standard classification numbers are used. Trade names of steels are not shown on drawings except in special cases. The purposes for which the various steels are best suited have been determined by the Metallurgical Department, and a table with over 250 classifications of tools and parts has been prepared giving the code numbers of the proper steels to be used and the degree of hardness according to the Rockwell scale. S.A.E. 1020 steel is generally specified for jig and fixture parts made of machine steel, especially when case-hardened. Information is given on the drawing for each part as to the method, whether cyanide or pack hardening, and the specification number covering the process. In addition, if pack hardened, the depth of case, the treatment number, and the tempering temperature are shown.

A book of standard design practices has been compiled in loose-leaf form which is furnished each designer, and the following rules have been established in connection with its use:

1 The instructions and data included shall be followed as far as possible so that similarity will exist in the drawings made by different individuals, and designers are not to deviate from them without the consent of their supervisor.

2 Parts commonly known as standard tool parts, as well as such commercial articles as are kept in stock and ready for use, shall be incorporated in all designs whenever suitable whether the tool is new or to be changed.

3 Typical designs shown are to be followed as closely as possible whenever practical for the particular job on hand.

4 Economical production of equipment depends on the careful selection of parts and materials entering into the tool, and care should be taken to scan the data sheets as well as the stock lists for suitable parts and material before designing or using anything special.

Some of the important factors considered in designing drill jigs, and also tapping and milling fixtures where applicable, are:

1 Design of jig should be simple, light to handle, safe for the operator to use, and strong to withstand rough usage, so that accuracy is not destroyed.

2 Locating pins or blocks should where possible locate the part from the same points as in preceding operations, if any have been performed.

3 Clamps and methods of holding the work should be as few as possible consistent with rigidity and accuracy, and easy and quick to manipulate, so that loading and unloading time will be reduced to a minimum.

4 Provision should be made for chips and burrs so they can be easily cleaned out, particularly away from locating points.

5 Bushings should not be placed in movable parts, such as leaves, unless it is unavoidable.

6 The design should be such that all holes or as many as possible are drilled at one setting.

7 Wearing parts should be designed so that they may be repaired or replaced without reconstructing the entire jig or fixture.

8 Whenever possible and production requirements permit, the design should be such that a tool can be used for more than one part by means of interchangeable details.

Owing to the large variety of equipment and apparatus manufactured, many special designs of jigs and fixtures not required in the more or less standard or common manufacturing operations such as drilling, milling, tapping, etc. are necessary, which call for more than average designing ability. The assembly and adjustment of the apparatus require many different kinds of fixtures for locating and holding the piece parts in position in order to facilitate this work both on machines and by hand operations on the bench. Welding, both spot and arc, is an important operation requiring a large variety of fixtures, ranging in cost from less than $100 to several thousand dollars for the largest arc-welding fixtures previously referred to, which are used for welding dial-system frames made of channels, angles, and flat stock. These fixtures are mounted on trucks so that the details can be assembled by helpers and the fixtures moved into the welding booths for the welding operations. They must be designed so as to prevent distortion and maintain limits which are comparatively close for this class of work. Several of the drawings for these fixtures each cover as many as twenty-five large-size sheets. Many small parts are spot-welded in fixtures used in welding machines of the press type, and these are usually designed to assemble parts within close limits. In fact, in order to obtain the correct functioning of the apparatus or equipment and also to insure interchangeability in assembly, a large percentage of the piece parts must be made and put together with a considerable degree of accuracy, often within limits of less than 0.001 in. for some of the dimensions, and the tool designs must be made accordingly.

### Ordering

The Design Division forwards the tool requisition together with the necessary prints to the Tool Ordering Division. This organization checks the estimated cost and approvals, places orders for patterns, castings, or forgings, and standard commercial parts as required, and follows these orders to insure delivery to the tool room. They write up the final order giving the layout of the department to perform the work and operations to be performed by each, complete description of the tool, final estimated cost, and other manufacturing information. The order with prints attached is then forwarded to the shop with copies to the technical and accounting organizations interested.

### Toolmaking

Although in special cases and when production requirements have necessitated doing so, tools have been made in accordance with our drawings by tool manufacturers, the company has found it expedient and desirable as a general practice to build its own tools. Considering the high standards which are maintained and the accuracy usually required, a substantial advantage from both a quality and tool-service standpoint is gained by so doing. Approximately 600 toolmakers and machinists are normally employed in the actual making, changing, and repairing of tools, about 100 of whom are engaged on jig and fixture work. Specialization of work or division of labor in the toolroom has been

carried out to a high degree. The main groups are the milling-machine section, the grinding section, the lathe section, the gage, jig, and fixture bench-work section, and the punch-and-die bench-work section. These sections are further subdivided according to type of work handled, with specialists in each who do only that class of work, as, for example, there are men in the bench-work sections who work on the final fitting and assembly of drill jigs, others on assembly fixtures, etc.

When an order is received in the toolroom the necessary clerical work in connection with recording, scheduling, etc. is performed and the raw material and standard parts are drawn from stock. The material, including any forgings or castings, together with a work ticket is then routed to the proper sections for performing the various machining operations. The machined parts upon completion are forwarded for fitting to the bench-work section handling the particular class of work. Parts requiring hardening have this operation performed by specialists on this kind of work, using the most improved equipment and automatic temperature recording and control, after which they are returned to the bench-work section for the final fitting and assembly.

By this plan each operation is performed by a man skilled in that particular work, so that a minimum amount of time is necessary and increased efficiency and accuracy are obtained. Also since the skill required varies for the different operations, the proper grade of workman can be employed for each, thus resulting in a much lower labor cost than if a high-grade toolmaker, required for the bench work, performed all the operations and built the tool complete.

Practically all of the accurate work in connection with laying out and boring holes in jigs and fixtures is done on jig-boring machines and vertical millers equipped with verniers, and methods such as the size-block, disk, button, vernier caliper, height gage, etc. are seldom used. As in the case of other machine operations, this work is performed by specialists experienced on these machines, so that the highest quality and accuracy with the minimum amount of time required are obtained.

As previously mentioned, details such as drill bushings, latches, springs, gage pins, clamping cams, jig feet, etc. have been standardized and are made in quantities and stocked. In addition to jig and fixture details, parts for other types of tools and a large variety of small tools, including taps, dies, reamers, and milling cutters are made and handled on a stock basis. This work is performed by a separate toolmaking department set up for this purpose and a large part of it is done on a gang piece-work basis, the earnings being distributed weekly on a pro rata basis in a manner similar to regular production in the general manufacturing departments. Standard manufacturing layouts giving the operations to be performed, machines and tools used, etc. are issued for stock parts, the same as is done for apparatus and piece parts, although the amount of detail given on the layouts varies according to the nature and output requirements of the part. A plan such as this, which results in large economies, is of course practical only where the quantities to be made justify such a practice.

### Inspection

Upon completion, the jig or fixture is routed to the Tool Inspection Organization where it is inspected for workmanship, conformance with the drawing, and whether the part produced is satisfactory. In some cases it is necessary to make a test of the tool under operating conditions, commonly termed a "try out," in order to determine the accuracy, probable durability, safety, speed, ease of operation, and that it does not injure the product or disturb any previous adjustments. In this connection it might be mentioned that while the convenience of using the jig or fixture must not be overlooked as an item in facilitating production and preventing unnecessary fatigue, safety of the employee is a factor of paramount importance which is always given careful consideration.

Tool inspection in reality forms the connecting link between the manufacturing tools and the finished product. Good inspection requires not only the ability to interpret drawings and make accurate measurements, but some degree of technical knowledge as well and an appreciation of the economical and correct use of tools and gages. Tool-inspection work has also been developed and divided into more or less specialized units, with the resulting advantage of higher-grade work at less cost. To facilitate inspection operations and insure the required accuracy, precision measuring instruments and gages, such as Johanssen and Hoke gage blocks, dial indicator gages, optimeters, and contour-measuring projectors are used, although these are not required as much in connection with jigs and fixtures as for some of the other types of tools and gages made.

### Conclusion

To cover completely all the practices, methods, routine, etc. followed by the Western Electric Company in the design and building of the many different types of jigs and fixtures is beyond the scope of a short paper of this kind, and in the foregoing description an effort has been made merely to give, without the inclusion of too many details, a general picture of the way the work is handled. Although the present practices are satisfactorily meeting requirements at a reasonable cost, this does not necessarily mean that they are considered the best possible methods. As mentioned before, studies are being carried on and improvements and changes are constantly being made in an effort to further reduce costs and still maintain high standards of quality and accuracy.

# Maintenance of Machine Tools

## Procedure of the Singer Manufacturing Company in the Repair of Old Tools And the Purchase or Building of New Ones

By J. C. MATTERN,[1] ELIZABETHPORT, N. J.

IT IS THE author's purpose to describe the plan under which the firm he is employed by operates in the maintenance of its machine tools.

Maintenance of machine tools as treated in this paper will cover:

The repair of machine tools

The purchase of new machine tools

The building of new machine tools by the tool room or machine shop.

There is little room for discussion as to the final action in either the repair, building, or purchase of machine tools. When the decision has been reached, the obvious thing to do is to act. Where engineers will differ, however, is in regard to the procedure to employ. It will be well at this time to describe the various agencies that carry out the work of repairing, building, or purchasing of machine tools.

The mechanical-engineering department consists of a small body of men well trained in the machine requirements of the plant. Some of them in their activities cover the whole plant, while others confine themselves largely to certain departments. This department works with the designing department, or drafting room, as it is usually called.

Here again, while no hard-and-fast lines are drawn, each of the four chief designers specializes along certain lines in the design of special machine tools. It might be said in passing that the two organizations above described are quite flexible as regards the work they are at times called upon to do. A condition arises where the tools necessary to manufacture a new product are to be produced in the shortest possible time. Immediately practically all other work in process is stopped and both departments devote their entire time to the designing and drawing of the machines and tools needed. By so doing the work is soon put up to the tool room.

Working in conjunction with the mechanical-engineering and drafting departments is the central tool room, which is in reality a tool room as that term is generally understood, and also a machine shop. Its organization consists of a department manager, machine foremen, and assembly foremen.

These assembly or erecting foremen are men who are specialists in certain types of machines used in the manufacture of the company's product, and while as a rule they work on the machines in their line, nevertheless the same flexibility exists here as in the drafting room.

When the case arises where it is necessary to build the tools to manufacture a new product as quickly as it can possibly be done, these assembly foremen drop all work that can be sidetracked and build jigs, fixtures, or any type of machine tool needed.

The manufacturing plant is composed of many departments, each having its special line of parts to produce or assemble, and each department having its machine tools designed and built or purchased to produce its work at as low a cost as possible consistent with maintaining the high quality demanded by a heartless inspection department which is armed with as good a line of gages as the mind of man can devise.

[1] Equipment Engineer, Singer Manufacturing Company. Mem. A.S.M.E.

Presented at a meeting of the Philadelphia Section of the A.S.M.E., Philadelphia, Pa., November 22, 1927.

The department organization consists of department manager, equipment man, tool-room foremen, section foremen, and cutter setters. There are other members of the department family, but they have little if any relation to the subject of this paper.

### Repairing Machines

When to repair a machine rests mostly with the section foreman, the reason being that he is most directly responsible for production running parallel with the orders, and for the quality of the product turned out. All of his work is subject to rigid inspection, bad work being of course rejected, and a record of such "spoilt work" being kept by the cost department. In addition a loss percentage is set, above which he must not go.

Beyond the section foreman the equipment and department managers are also responsible for "spoilt work." These three men are therefore keenly interested in having their machine-tool equipment in good condition. Being responsible for production as well as quality, they are in the best position to determine when a machine should be repaired. They look into the stock on hand, determine how long the machine can be shut down, and ascertain whether they have another machine capable of doing the work in the department that can be substituted. In short, they review the situation as it affects this machine.

We have here keen personal interest—personal responsibility resting on men who understand the work to be performed, who are intimately acquainted with the machine that does the work. If they fail, this will be shown by either the quality or the cost of production. There is no central authority that keeps a record of the 15,000 or more machine tools in the plant as regards the number of times a machine is repaired and at what cost it was repaired. The exception to this is where a machine fails to stand up as it should and is constantly developing trouble, and when such is the case, the bookkeeper of the department in which the machine is located starts a record card showing the time and cost of each repair job. The case of this machine is taken up by either the department manager or equipment man with the mechanical-engineering department, who take means to correct the trouble by changing the design, substituting another machine or any action which in their judgment is best. But no action is taken without consulting the department organization.

It is within the scope of a member of the mechanical-engineering department to call to the attention of the department manager the condition of a machine and advise that it be repaired.

A decision having been reached by the department manager that a machine is to be repaired, an order is issued either on the department tool room or the central tool room, and this brings up the question of how and where the work is to be done.

If it is a minor repair the order is placed with the department tool room and none but the department organization, as a rule, takes any interest therein.

If the repair work is of any magnitude, or must be very quickly accomplished, it is sent to the central tool room where the department manager assigns it to the assembly foreman who specializes in that type of machine tool. If a machine of the type to be repaired can be purchased, the tool room estimates the amount of money necessary to cover the cost of repairing the old machine. The matter is then analyzed by the mechanical-engineering department and the manager of the department interested. If

the decision is to buy a new machine, a report is drawn up setting forth the facts in the case and asking for an appropriation of a sum necessary to purchase the new machine.

The cost of the new machine having in the meantime been obtained through the purchasing department on quotation, this report is submitted to the works manager for his approval. Action in accordance with his ruling is then taken.

One other phase of the question should be mentioned at this time, namely, that of improving the machine to be repaired as a means of reducing the cost of the part it produces. A suggestion to this end can emanate from the superintendent of works, the department owning the machine, or the mechanical-engineering department after the proposed improvement has been discussed by the organizations interested and approved by the head of the mechanical-engineering department and department manager; and if deemed of sufficient importance submitted to the superintendent and works manager, and if by them approved, the machine is rebuilt.

The reason for making the repairs in the central tool room as against doing the work in a special repair shop is that there are in the central tool room foremen who are in fact experts on the many different types of machines used to produce the plant's product, and a better result is obtained than would be in a repair shop where it would be impossible for the foreman and men who do the work to have the same degree of knowledge and experience.

### Purchasing or Building New Machines

New machines are installed for the following reasons:

*a* When an old machine has reached the point where it should be replaced by a new one

*b* When a new machine can be built or purchased and the saving in cost of production of the part or parts produced thereby will defray the cost of the new machine within a period of from three to four years

*c* When their purchase or construction is necessary because of an increase in production or a new product added to the line

*d* When in the cost of machines purchased for the tool department the estimated saving on work will pay for them within four years.

No old machine is scraped, no matter what its age, unless the new machine that would replace it can prove itself by showing a worth-while reduction in the manufacturing cost of the part produced.

The author can call to mind machines probably from 30 to 35 years old, performing simple drilling operations, located in a line where the operator serves a number of machines, and where the machine cost is such that no new machine up to this time has been thought of that would reduce the cost at all.

The suggestion to build or purchase a new machine having for its object the reduction of the cost of manufacture of a part or parts can emanate from any source whatsoever. The works manager or the superintendent may order an analysis because of the facts shown by the cost sheets. The department manager, section foreman, department equipment man, any workman if he has an idea, any member of the mechanical-engineering or drafting departments, is listened to and encouraged to make suggestions.

With very few exceptions all suggestions either to build or to purchase new machines ultimately come to the mechanical-engineering department, where the cost of the new machine is compared with the estimated saving in the production cost of the part or parts to be machined.

If the estimated saving over a period of three or four years equals the cost of the new machine the facts are entered on a form sheet designed for that purpose, setting forth the operations and prices paid therefor in one column. Another column shows the operations as it is proposed to perform them on the new machine and the price to be paid. A third column sets forth the saving in cost to be made, and a fourth either the amount of money needed to design and build the new machine or, if bought outside, the purchase price. At the bottom of the sheet is shown the length of time necessary to pay for the new machine. As mentioned before, the period set is from three to four years, provided no element except cost reduction is considered. Should it be a matter of safety, a machine may be altered, or a new one built or purchased, without the necessity of showing a reduction in cost of manufacture.

Where new machine tools are required for a new product added to the line, the following action is taken.

The new parts are assigned to the various departments by certain men of the organization. The operation lists are then written up by men trained in this procedure, who work closely with the department organization on the parts assigned to them. The author would like to emphasize the desirability of close co-operation between the department organization and the machanical-engineering department, the drafting department, and the central tool room, both in the designing and building and in the purchasing of new machine tools.

Upon completion of the operation sheets the mechanical-engineering department in conjunction with the drafting department and department organization maps out the types of machines to be built or purchased and settles on their cost. All of this is then submitted for approval to the works manager and superintendent of the works. If approved, usually a due date is given, and the work is assigned.

The central tool room does its own repairing when and how it pleases.

The purchase of new machine tools for the central tool room is also based on the ability of the contemplated new tool to show such an increase of work turned out over the old tool that it will pay for itself within the given three or four years. The reduction in cost is arrived at in the following manner. Drawings of from 10 to 12 jobs or samples of work to be done are sent to a firm building the machine tool under consideration, for time studies on the drawings or samples submitted. These time studies are checked against the best that can be done on the machine tool or tools to be supplanted.

There is considerable ground for discussion in this work of maintaining the machine tools of a manufacturing plant. Among many, the following questions are those that most frequently present themselves to the author:

Is the rule that a new machine must pay for itself in from three to four years all that is necessary? Should elements other than the element of safety of the operator enter in?

Should there be a central organization with records and an office force to keep track of the machines in use instead of leaving matters with that part of the organization that is directly in touch with the machines? Are there certain vital elements entering into the question that these men know nothing about?

Is it best to have a repair shop where all repairs are made and should this shop handle nothing but repairs?

# Maintenance in the Large Industrial Plant

## Details of System Employed in the Henry Disston & Sons Works, With Maintenance Costs Of Machinery Expressed as Percentages of Productive Labor and As Percentages of Book Value

By C. M. Thompson,[1] Philadelphia, Pa.

There are two systems of maintenance of property and equipment in an industrial plant. One is to allow machinery to run until a breakdown occurs and then order repairs, while the other system is based on periodic inspections and minor repairs in an attempt to forestall interruptions to production.

Which of these systems should be used is a matter to be decided by the management of the individual concern, but there are, however, certain pertinent factors which should be considered: namely,

1 Size of plant
2 General layout
3 Product manufactured
4 Source of power supply, and
5 Labor conditions.

Before discussing the subject in detail, it might be well briefly to outline the influence the above items exercise on the problem in which the author is particularly interested.

The plant of Henry Disston & Sons covers approximately 63 acres and contains 54 buildings with a total floor space, excluding the steel works, of about 530,000 sq. ft. (more than twice the area of the main span of the Delaware River Bridge), requiring a larger force than would be the case if the various departments were confined in a fewer number of buildings.

There are three main divisions in the factory, namely, steel works, saw works, and file works, each presenting varied maintenance problems. The saw and file works buildings are of the slow-burning mill-type construction of one and two stories, while those in the steel works are of typical steel-mill construction.

An idea of the many types of machinery installed in this plant can be gained from the following partial list of products manufactured: Steel, saws, files, knives, trowels, shears, squares, levels, screwdrivers, scrapers, as well as a large number of metal products, such as automobile clutch disks, etc.

The power supply at the present time is largely electric, although seven rolling mills in the steel works and three departments in the saw works are driven by reciprocating engines which are supplied from two stoker-fed boiler plants. There is a considerable amount of process steam used, the majority of which is for dry kilns and steam boxes in the lumber yard. The exhaust steam from the rolling-mill engines is delivered to the power house where three low-pressure turbo-generators supply about fifty per cent of the electric-power load. The remainder is supplied by the Philadelphia Electric Company.

Being situated in an industrial center such as Philadelphia, a plentiful supply of skilled labor is available at reasonable wages, which permits the employment of first-class mechanics in their respective trades. This is especially true in the Maintenance Department.

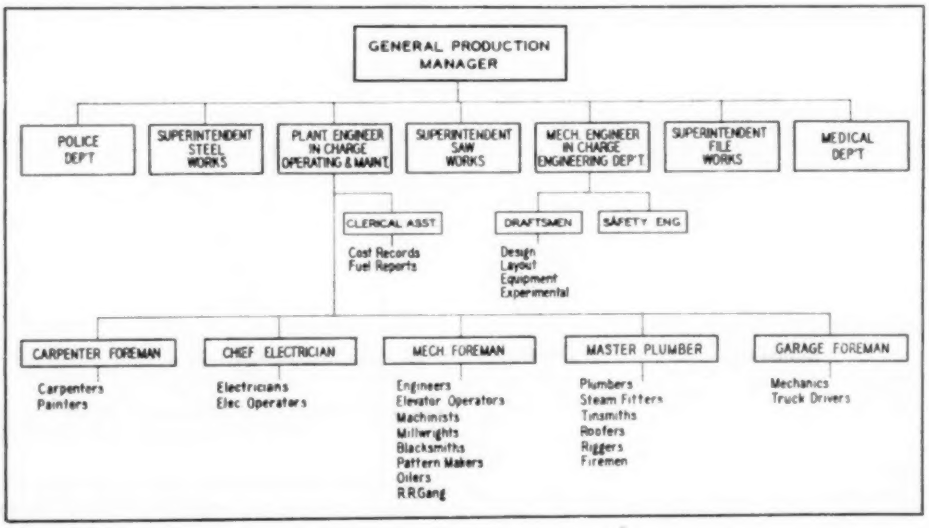

Fig. 1 Organization Chart Showing Various Divisions of Maintenance Department, Their Respective Duties, and Relation of Whole to Production and Engineering Departments

Fig. 1 is an organization chart showing the various divisions of the Maintenance Department, their respective duties, and the relation of the whole to the Production and Engineering Departments.

As customary, the Maintenance Department is responsible for the upkeep of buildings, grounds, equipment, and machinery and in addition the operation of the power supply. The department consists of a plant engineer in charge, an assistant whose duty is the supervision of the clerical work, such as costs, records, fuel reports, etc., and five subdivisions as shown in the organization chart.

The Mechanical Division is responsible for the upkeep of all

engines, lineshafting and main drive belts; elevators; railroad tracks and roads, cranes, etc. All engines are thoroughly inspected, including removal of cylinder heads, twice a year. An oiler is employed to care for all main lineshaft bearings and report any trouble with either shafting or belting. The oiling of machinery and countershafts is the responsibility of the individual departments. Weekly inspections of all cranes are made and reported on a special form shown in Fig. 2.

The Electrical Division's duties comprise the upkeep of all

electrical units, including the oiling and cleaning of all motors and generators, weekly inspection of cranes and the melting furnaces, and a daily inspection of the substation equipment and all large motors. The electrical inspector also changes all charts and collects them from the recording instruments. In addition to the large units, there are about 425 motors in operation, ranging in size from 1 to 75 hp. Two electricians are assigned to the cleaning of motors each week end, and by this procedure it takes about 5 months to complete a round. Every other Saturday the entire electrical force is assigned to the oiling of motors, each man having a specified group, thereby completing the job in about four hours. By this means the maintenance expense of motors is held to a minimum, as any apparent trouble such as bearing, loose pulleys, etc., is noticed before a shutdown is necessary. The total cost of oiling, cleaning, and repairing the entire motor installation averages $1.60 per hp. per year. Card records are kept of the data of each motor and its location, together with a complete record of the dates the motor was cleaned and any repairs made.

The cleaning and replacing of electric lamps is also the duty of this division. Lamps are cleaned about every six weeks, requiring one man's time for about two weeks to cover the factory. The cost of this cleaning amounts to about $400 per year. The replacement of defective or blown fuses is prohibited except by an electrician, thereby bringing to this division's attention any trouble, such as overload, grounds, etc., in order that corrective measures may be taken immediately.

It has not been the practice of the management to budget repairs. Records are kept of repair costs, however, and are given to the superintendent of each department every month. All maintenance orders are returned, when completed, to the

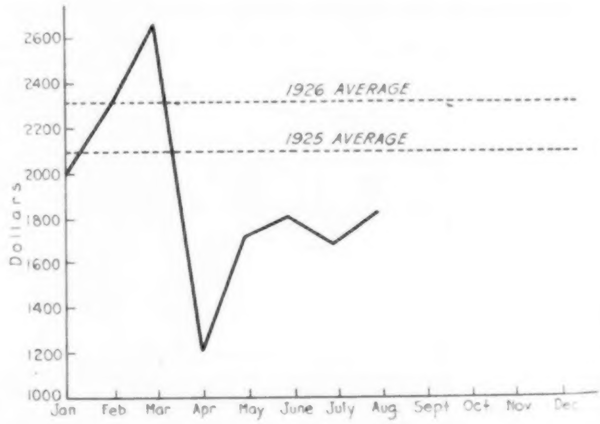

FIG. 3 MACHINE-SHOP OPERATING COSTS FOR 1927 AS COMPARED WITH AVERAGES FOR 1925 AND 1926

department requesting the work to be done, showing the amount of labor and material expended so that the superintendent has the opportunity to check the job and enter complaint if he believes it justified. In the saw works the superintendents of the various departments meet once a month, at which time the operating costs are presented. The details of these figures, such as non-productive labor, tools, supplies, and repairs are discussed and comparisons made with previous months on the basis of the billing value of the finished product in order that each superintendent may be familiar with the trend in his respective department.

Three years ago the author started giving each division head in the Maintenance Department the cost figures over which he had direct control, and also a chart showing the total expense charged against his division. These charts include depreciation, taxes, insurance, etc., in addition to the direct charges. Fig. 3 is the expense chart for this year for the Mechanical Division and when compared with the averages of the last two years gives a very good idea of what can be accomplished. The machine shop of this division not only handles maintenance jobs, but also the building of new machines and some production work.

There are 143 men employed in the maintenance and operating groups. This force is made up of the following:

| | | |
|---|---|---|
| 29 Machinists | 12 Engineers | 9 Electricians |
| 6 Tool makers | 8 Elevators operators | 9 Carpenters |
| 2 Millwrights | 20 Firemen | 4 Painters |
| 7 Blacksmiths | 2 Electrical operators | 2 Plumbers |
| 2 Pattern Makers | 6 Truck drivers | 7 Steam fitters |
| 2 Iron workers | 2 Auto mechanics | 2 Tinsmiths |
| 2 Roofers | 1 Oiler | 2 Riggers |
| | 7 Laborers | |

In order to compare maintenance costs of machinery the usual practice is to base it on a percentage of productive labor. Productive labor is a definite quantity, and the executive wants to know how much of every dollar of productive labor is spent for repairs. These figures for the saw works, by departments, are as follows:

| Department | Percentage of productive labor |
|---|---|
| Maintanance (Planers, shapers, lathes, drill presses, and milling machines) | 0.4 |
| Saw Tool (Lathes, shapers and milling machines) | 0.6 |
| Handle (Woodworking machines) | 0.7 |
| Hand Saw (Shears, presses, grinders) | 1.7 |
| Long Saw (Shears, presses, grinders) | 1.8 |
| Drop Shop (Hammers) | 1.9 |
| Milling Saw (Gear cutters) | 2.9 |
| Circular Saw (Shears, presses, large grinders) | 3.4 |
| Band Saw (Shears, presses, large grinders) | 3.5 |
| Jobbing (Shears, presses, lathes, large grinders, and furnaces | 6.3 |
| Hardening (Furnaces) | 8.0 |

From these figures it will be noted that, in departments where the costs are very nearly alike, the class of machinery is similar.

In order to give some insight into the maintenance costs of machinery by classes it may be of interest to compare them on the basis of percentage of value. The percentage for the machinery in the Saw Works on the basis of present book value is as follows:

| | | Percentage of book value |
|---|---|---|
| Group I | Planers, Milling machines, Shapers and slotters, Lathes, Drill presses, Gear cutters, Boring mills, Screw machines | 0.5 to 1.0 |
| Group II | Buffers and polishers, Filing machines, Small grinders, Woodworking machines, Drop hammers | 1.5 to 3.0 |
| Group III | Shears, Punch presses, Large grinders | 4.0 to 5.0 |
| Group IV | Heat-treating furnaces | 8 |

The figures given in these tables may not check with those in similar industries but they give some idea of what may be expected in an industrial plant having as widely varying activities.

# Inspection Methods and Quality Control in the Manufacture of Aircraft-Engine Parts

By HUGH W. ROUGHLEY,[1] PATERSON, N. J.

THERE was a time not so many years ago when the inspection department in a manufacturing organization was considered a good talking point and a novelty to show to visitors going through the factory; aside from that, it was considered one more item of overhead expense. Within the last decade, however, manufacturers carrying on quantity production have recognized the importance of efficient inspection throughout all processes of fabrication and assembly. The purchasing department must have assurance that raw material is in accordance with purchase order and specification requirements; manufacturing-department costs must be held down to a minimum by the rejection of defective parts in the early operations rather than permitting a part to be completely finished only to be rejected at final assembly; and, most important of all, the engineering department must know that each part going into the finished product is in accordance with blueprint dimensions and material specifications.

In the manufacture of Wright aircraft engines, inspection is of paramount importance. From the time the raw material enters the factory until the finished engine is finally tested and packed for shipment, all raw material and every operation in the process of manufacture is subjected to the exacting scrutiny of a large force of specialists, men adequately trained to carry on the exact inspection found necessary through long experience in the manufacture of reliable aircraft engines.

## Inspection of Raw Material

Going into detail we shall first take up inspection methods covering raw material. Bar stock, forgings, castings, etc., which will meet chemical and physical requirements and at the same time be free from seams, cracks, laps, blow-holes and mis-runs, are carefully inspected upon receipt. All purchased material is delivered to the inspection department, accompanied by receiving reports identifying the material as to size, specification, and quantity. After checking material for quantity, size, and certified chemical properties against the purchase order, it is then checked against the bill of material and also against the drawing to insure its conformance with engineering requirements.

In the case of bar stock, if purchased heat-treated, 100 per cent hardness test is made on both ends of each bar on either a Brinell or Rockwell testing machine. Tensile tests pieces are made on each lot of material and tested to insure physical properties called for in the drawing or specification. Bars are carefully inspected for seams and cracks, any bars showing imperfections being rejected. Each accepted bar is stamped with specification number and lot number on each end in order to positively identify material from the raw state to the finished product. An exact record is entered in the metallurgical log book, giving specification number, lot number, heat number, amount of material received, amount of material accepted, amount of material rejected, and name of vendor.

In addition to stamping specification number and lot number, each bar is painted its entire length with the color combination designated for its particular material specification. This furnishes a convenient method of identification in the stock room and through the manufacturing departments so that the identification of material which is not up to requirements is possible at any stage of production, from raw material to finished product. For instance, twenty-three different grades of steel are purchased for various parts of Wright engines—tough steel of low carbon content to be case-hardened for piston pins, knuckle pins, and gears; high-speed tool steels, tungsten and cobalt chrome for exhaust valves and guides; high-carbon chrome nickel and high-carbon vanadium steels for highly stressed parts such as connecting rods, studs, bolts, and nuts; carbon steel for washers, keys, pipe flanges, etc.—most of which is received in long bars of identical appearance, so far as quality is concerned. It is evident, therefore, that positive identification of material is of the utmost importance.

## Inspection of Forgings

Inspection of forgings is carried out along lines similar to inspection of bar stock. Extraordinary care is given to the inspection of crankshaft, connecting-rod, and rocker-arm forgings, inasmuch as they are subjected to extremely high stresses.

In order to meet the exacting engineering specifications for crankshaft forgings it is necessary to have the steel manufacturers make special heats. After the heat has been poured, several chemical analyses and a number of metallographic examinations from different sections of the ingot are made, after which those acceptable are cropped at each end, using only 50 per cent or the center portion. This is done in order that only steel of the highest quality, free from slag, pipes, and non-metallic inclusions, will enter into forgings for crankshafts.

At the forge shops inspection again plays its part. The first shaft off the dies is sectioned through its center line and deep-etched in 50 per cent hot hydrochloric solution to show structure. The flow-lines in the shaft are then studied by the metallurgical department and, if approved by the chief metallurgist, the forge ship is permitted to proceed with the order. To produce crankshafts to meet these exacting requirements, expensive breakdown and edging dies are required in addition to finish-forging dies.

After heat treatment, each forging is given a serial number and is brinelled on each end and in each cheek. If the hardness is uniform, tensile and impact tests are made from each end of the shaft and portions of the impact specimens are polished and carefully examined under a high-powered microscope in order to determine that shaft has been properly heat-treated. A photomicrograph is then made and filed with the record of each individual shaft which already contains the heat number of the steel used, the chemical analysis of the heat, and the physical properties, thus giving a complete history of each shaft. After shafts are completely machined they are again brinelled on each cheek in order to insure that proper heat-treatment penetration has been accomplished. After final inspection for dimensions, shafts are again carefully inspected with a magnifying glass and high-powered binoculars.

A careful record is kept on file in the inspection-department office showing the engine number, the serial number of the crankshaft installed therein, and the complete history of the shaft from the time it was forged, including part number, heat treatment received, and final physical properties obtained at the time the

[1] Quality Manager, Wright Aeronautical Corporation.

Presented at the Second National Meeting of the A.S.M.E. Machine Shop Practice Division, Cincinnati, Ohio, September 24 to 27, 1928.

specimens of the particular shaft were tested at the forge shop.

Steel for connecting rods has the same requirements as that for crankshafts and the rods are given the same inspection at the forge shop, being carefully examined for imperfections. Upon receipt at our factory each connecting-rod forging is given a serial number in order that it may be identified as to heat of steel used in its fabrication, vendor supplying the steel, and vendor making the forging.

Connecting-rod forgings are rough-machined, heat-treated,

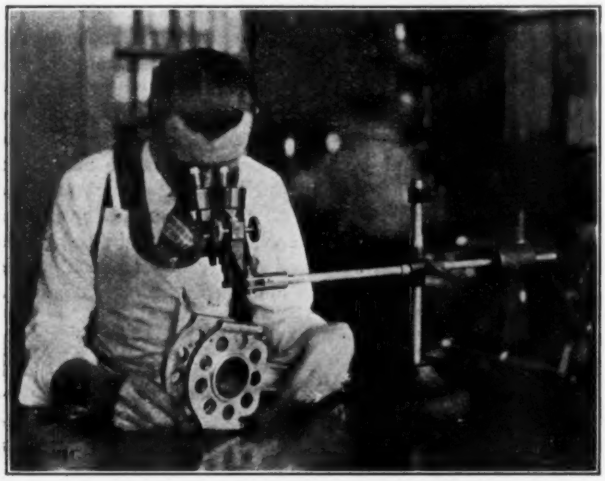

Fig. 1 Examining Finished Master Rod With 32-Power Binoculars

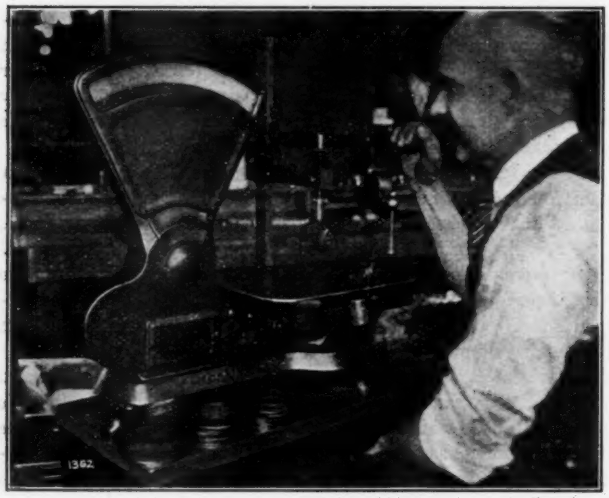

Fig. 3 Testing Piston Rings for Tension

and again carefully inspected for any small seams which did not show up previously. Physical tests are then made as follows: The rods are carefully brinelled and if within the hardness limits, one tensile specimen and one double-notch izod impact test specimen are made for each five treated. In ordinary commercial practice, only one tensile test is made for each furnace charge, which usually comprises in the neighborhood of 150 rods. After rods are completely machined and polished, they are given a final inspection for small imperfections under a strong magnifying glass and a high-powered microscope. (See Fig. 1.) At the same time a final check for hardness is made in order to eliminate the possibility of incorporating an unheat-treated rod in an engine.

Rocker-arm forgings are ground to remove flash and rough-finished all over. They are then heat-treated and all of the scale and surface imperfections of any nature are removed by scratch-brushing and sand-blasting. This is a very difficult operation to perform, owing to the fact that the rocker is of the I-beam-section type. Rockers are then carefully inspected for any imperfections and given a 100 per cent hardness test before being finish-machined and finally inspected for imperfections on the finished surfaces.

Fig. 2 Checking Free Height and Solid Height on Spring-Weighing Machine

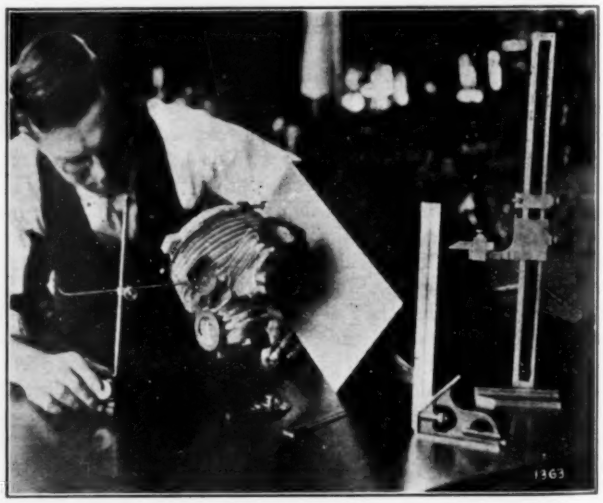

Fig. 4 Laying Out Cylinder-Head Casting to Insure Boss Diameters and Wall Thickness Meet Drawing Dimensions

### Inspection and Manufacture of Small Parts

Piston-pin stock is rough turned on the outside diameter, bored out, cut off, heat-treated, sand-blasted, checked for hardness, and examined for seams. After pins are finished ground they are lapped to a high-grade finish on a production lapping machine.

Numerous small parts having a hardness above 350 Brinell are machined from annealed bar stock, then heat-treated, and finally given a 100 per cent test for hardness, a representative number of tests being made to insure proper heat treatment. This procedure applies alike to gears, push-rod ball ends, washers, special studs, etc.

Connecting-rod bolts are classified along with crankshafts and connecting rods and are made of steel with identical specifications, requiring tensile and impact testing. In order to be sure that the material for these bolts is free from the slightest imperfection, the bolts are machined to within $^1/_{32}$-in. of finished size and inspected under a microscope.

In order to conserve production facilities, some parts are purchased completely finished. This practice also gives us the advantage of the vendor's years of specialization on a certain product. All parts purchased, however, are manufactured by the vendor to our specifications and are carefully checked against blue-print and specification upon receipt.

Valve springs, which ordinarily appear to be of secondary consideration, receive a careful inspection as to diameter of wire and careful check for spring load at proper compression height and also at solid height. In order to make accurate check of this, it was necessary to build a special spring-weighing machine. (Fig. 2.)

Piston rings might also appear of relative unimportance as long as their width and diameter check with the blueprint. As a matter of fact, however, the piston ring is one of the most important internal parts of an aircraft engine. Rings must be perfectly round and have at least 95 per cent bearing against the cylinder wall when installed on a piston assembly. To test this condition, a specially constructed light testing gage is used which should show contact throughout the entire circumference. The wall pressure is also of major importance and in order to check this condition accurately, it was necessary to provide an attachment to be used in connection with a sensitive scale. (Fig. 3.) All piston rings are inspected 100 per cent for dimensions,

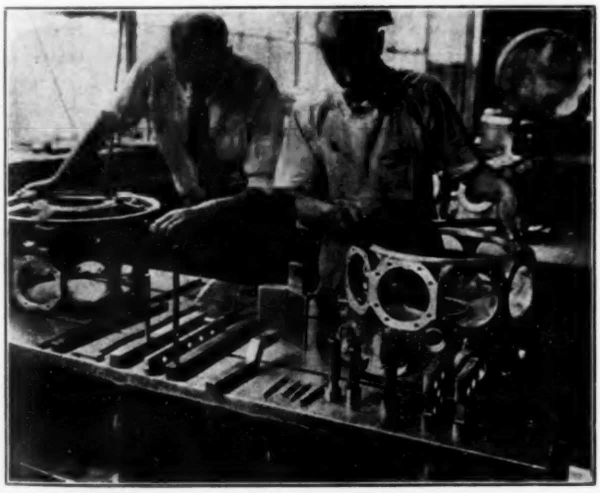

Fig. 5 100 Per Cent Final Inspection After All Machining Operations and Enameling Before Main Crankcase Is Delivered to Finished Stores
(Note gages required for rapid inspection.)

weighed for wall tension, which should range from 8 to 11 lb., and tested in a light gage to insure perfect bearing against cylinder walls. Rings failing to meet any of the above requirements are rejected.

### Inspection of Castings

Rigid inspection of castings is of utmost importance in maintaining standards of quality. Nine different aluminum alloys and eight different bronze alloys are used and a careful inspection of castings is inaugurated immediately after the castings are knocked from the molds. Each casting and each test bar is stamped with its heat number in order that identification of material may be positively established. The inspector then fills out the log sheet for the particular heat, showing the heat number, the different elements going to make up the charge for a particular alloy, the furnace temperature, the pouring temperature, the part number of each piece, the number of pieces poured, and the number of pieces accepted on preliminary inspection.

Of the nine different aluminum alloys used, seven are tested for physical properties in the condition as cast and tensile tests

Fig. 6 Corner of One of the Final-Inspection Cribs

are made each day for each alloy, representing a single day's production. The two other aluminum alloys, which are used in casting crankcases and cylinder heads, require heat treatment in order to obtain maximum physical properties. All heat-treated castings are stamped with heat number of the melt and lot number representing the particular heat treatment. In this way any castings which fail on test to meet the physical requirements can be properly identified for rejection.

After being thoroughly cleaned and sand-blasted, castings are given a final inspection and all cylinder heads, pistons, crankcase rear sections, and manifolds are pressure tested in order to insure sound castings and then very carefully inspected for mis-runs, shrinkage cracks, and "coldshots."

It is of the utmost importance that periodic layout inspections be made on all castings in production. Even though many of the patterns are of metal construction throughout, the periodic layout inspection is carried out in order to insure uniform wall thickness and conformance with drawings. (Fig. 4.)

### Inspection During Manufacture

Throughout the manufacture of the various parts, a large force of floor inspectors is required in order that each piece may be checked by an inspector who is familiar with that particular operation before an operator is allowed to proceed with the remainder of the order. In addition to this, the floor inspector floating among the various machines in his department checks pieces from time to time to see that quality standards on the particular part are maintained. Before a particular order for a certain operation is allowed to be moved to the next department for the succeeding operation, the inspector signs the back of the work order to show that he has checked the first piece and, in addition, has fair assurance the greater percentage of the work is in accordance with the quality standards set for that particular part.

Any parts found defective on floor inspection are rejected and delivered to the salvage department, the number of parts so rejected being deducted from the order. Floor inspectors are also on the lookout for seams, blow-holes, or flaws of the most minute character and if it is found that a large percentage of the parts are in such condition, the job is stopped and the entire lot of this particular material is rejected and delivered back to rough-stock inspection where it is put through a careful inspection, only such material as shows no defects whatsoever being placed back in rough stores.

A number of major parts, such as crankcase sections, receive 100 per cent inspection on each operation. On items of this kind each acceptable operation is stamped with the inspector's number.

This marking insures the operator taking up the next operation that previous operations are in accordance with the drawing dimensions and quality standards. However, aluminum alloy, known for its peculiar tendency to change its shape and size after the removal of stock from certain sections, necessitates 100 per cent inspection after each machining operation and the enameling operation which requires heating the crankcase to 200 deg. fahr. for approximately two hours in order to bake the enamel and give an acceptable finish. (Fig. 5.)

## Final Inspection

Upon completion each engine part is thoroughly washed and cleaned and sent to one of several final inspection cribs where it is given 100 per cent final inspection. The inspection cribs are well lighted, well ventilated, and equipped with the most modern precision instruments, such as thread comparators with high magnification for accurately checking pitch, diameter, and lead of threads, fluid gages, and amplifying gages for detecting taper or-out-of round condition on close-dimensioned parts. (Fig. 6.)

Each acceptable piece is stamped by the inspector, each inspector using his own identification number, so that any part can be traced back to the inspector making final inspection. In the case of hardened pieces, the inspector's number is etched.

Parts which pass final inspection are delivered to finished stores for issue to the assembly department. After assembly each engine is given a production test, following which it is disassembled and all parts carefully examined for defects which might have developed while the engine was being operated under power. The engine is then reassembled and, after final test, is thoroughly washed and cleaned and given a final inspection for appearance and check against the sales order as to accessories furnished before being sent to the packing department to be ready for shipment.

# High-Speed Gearing

## Some of the Requirements of High-Speed Reduction Gears and How They Are Attained Commercially

By IRA SHORT,[1] SOUTH PHILADELPHIA, PA.

IT IS A KNOWN fact that steam turbines, in order to attain their maximum efficiency, must operate at comparatively high speeds, and that for the same reason some of the apparatus which they drive, such as pumps, propellers, d.c. generators, etc., must operate at much slower speeds. Some method of speed reduction must therefore be employed, and in order for it to be successful it must be efficient, silent in operation, reliable, and of long life. All of these requirements are met in correctly designed and carefully manufactured helical-tooth gearing.

The points brought out in this paper are limited to reduction gears furnished by the Westinghouse Electric and Manufacturing Company, which up to the present time has built more than 3000 geared units ranging from 5 to 32,500 hp. and totaling well above 2,500,000 hp.

The first gear manufactured by the company, shown in Fig. 1, was a 6000-hp. experimental one built in 1909. It was necessary to have the pinion and wheel for this gear cut in Germany as there was no machine in this country large enough for the purpose. The test of the gear was very successful, and the efficiency was found to be more than 98 per cent. It is customary to guarantee an efficiency of from 97.5 to 98.5 per cent for single-reduction gears, and from 95 to 97 per cent for double-reduction gears.

Fig. 2 shows the results of an efficiency test of a 1500-hp. double-reduction gear reducing from 3360 r.p.m. to 90 r.p.m. These tests were run by connecting a turbine first to a water brake and carefully calibrating the former for various powers and speeds with a given steam condition. The turbine was then connected to the same brake through two sets of identical reduction gears, the slow-speed shafts of which were bolted together. The high-speed pinion of one gear was connected to the turbine, and the high-speed pinion of the other to the brake. Then by operating the turbine under duplicate conditions as when direct-connected to the brake, the difference in power absorbed by the brake, with the gears in use, indicated the loss of power due to the gears. Assuming the loss of each gear to be equal, the curves in Fig. 2 show how the efficiency of a gear varies with the load and speed.

In running this efficiency test care was taken to maintain the viscosity of the oil constant, as it was found that the gear loss was almost directly proportional to the viscosity of the oil.

### Action of Gears

A correctly designed gear should, if properly operated and barring accidents, have a life equal to that of the driven and driving machines. Correct design proportions insure that the parts will be amply large to transmit the power. This is especially true as regards the teeth.

Fig. 3 represents a section of a pair of meshing teeth in three typical positions. Figs. 4 and 5 are the velocity diagrams for the positions *c* and *a*. At position *b* the lines representing the velocity of the pinion and wheel will coincide, or there will be true rolling and no sliding. From these figures it can be seen that the motion between the teeth is a combination of rolling and sliding, and that while the rolling is always in the same direction, the sliding is toward the pitch line on the wheel tooth and away from the pitch line on the pinion tooth.

The action may be summarized as follows:

| | Rolling | Sliding |
|---|---|---|
| Pinion tooth, Fig. 6....... | Root to tip | Away from pitch line |
| Wheel tooth, Fig. 7........ | Tip to root | Toward pitch line |

This is shown diagrammatically in Figs. 6 and 7, the straight arrows showing the direction of sliding and the curved arrows the direction of rolling. An examination of these diagrams shows that with gear teeth there are only two types of motion, namely,

*a* Fig. 8, rolling combined with sliding, both being in the same direction; and

*b* Fig. 9, rolling combined with sliding, in *opposite* directions.

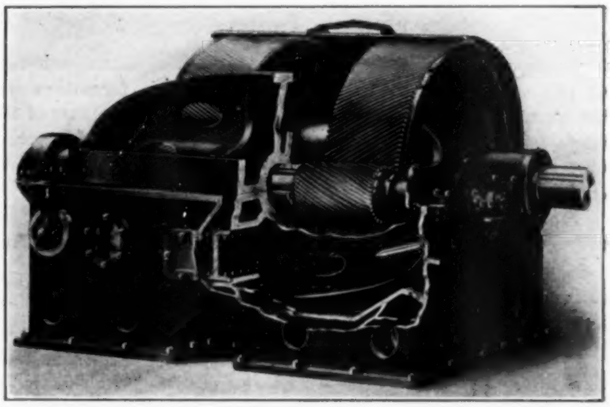

Fig. 1 6000-Hp. Experimental Gear

Further, it will be seen that above the pitch line both on the pinion teeth and on the wheel teeth the motion is of the (*b*) type, while below the pitch line it is of the (*a*) type.

Above the pitch line the action will be conducive to the production of a polish, but below it the conditions will not be so favorable. The following may be approximately what occurs; Because of the elastic nature of the material the slipping will be more or less jerky, thus tending to form the surface material into small ridges. Below the pitch line the motion will tend to leave these ridges behind, while above it the motion will tend to smooth them out. This action is represented diagrammatically in Figs. 8 and 9.

Tests have shown that abrasion is much more rapid with the (*b*) type of motion than with the (*a*) type.

### Wear of Gear Teeth

There are two distinct types of abrasion or wear occurring at the meshing faces of gear teeth:

1 A regular change in the shape of the tooth profile, and

2 The formation of a number of cavities or pits on the tooth face.

A good illustration of the first type of wear is shown in Fig. 10. This is reproduced from a photograph of an ink impression

[1] Marine Engineer, South Philadelphia Works, Westinghouse Electric & Manufacturing Co.

Presented at a joint meeting of the A.S.M.E. Machine Shop Practice Division and the American Gear Manufacturers Association, Buffalo, N. Y., October 12, 1928.

made from some worn pinion and gear teeth. The original tooth shape has been drawn in to show better the wear that has taken place. It will be seen that the wear varies considerably over the profile, and is greater below the pitch line than above.

Even with the great amount of wear indicated, these teeth meshed together well as indicated in Fig. 11, and seem to have developed an "enveloping" tooth which has been tried out in an endeavor to obtain more contacting tooth surface.

There is considerable wear at the tips of the gear teeth, but very little at the pitch line. It has been found in several installations that the metal flowed because of the combined rolling and sliding action until the thickness of the gear teeth at the pitch line after being in operation for some time was actually greater than when the gear was originally put in service. And it is believed that the metal flowing from the tips of the gear teeth has maintained the pitch-line thickness very close to the original thickness. It is also found that the (*a*) type of motion drags metal off the pinion teeth, forming what is generally termed a "wire edge."

Wear such as that indicated here is usually due to the failure of lubrication of the teeth, allowing metal-to-metal contact. This particular gear was subjected to considerable vibration from the propeller, which seems to have punctured the oil film and so hastened the abrasive action.

### Wear Due to Pitting

Consider now the second type of wear, which is the formation of pits or cavities on the meshing faces. This formation has been explained in a number of ways such as actual seizure of the metals, pulling the metal out from one surface; explosive action of a particle of oil between the teeth, burning the tooth surface; and fatigue of the metal.

Fatigue of the metal seems to be the best explanation of this formation. The conditions are such at the point of contact between two meshing teeth that it is difficult to form an exact idea of the actual stresses set up. The stresses have been investigated by photoelastic methods, and it appears that a maximum shear stress occurs a short distance below the surface, and travels along with the point of contact. Should there be any slight imperfection in its path or some irregularity on the meshing surfaces, the stress will be considerably increased and by repeated application will cause a fatigue crack, and finally a pit.

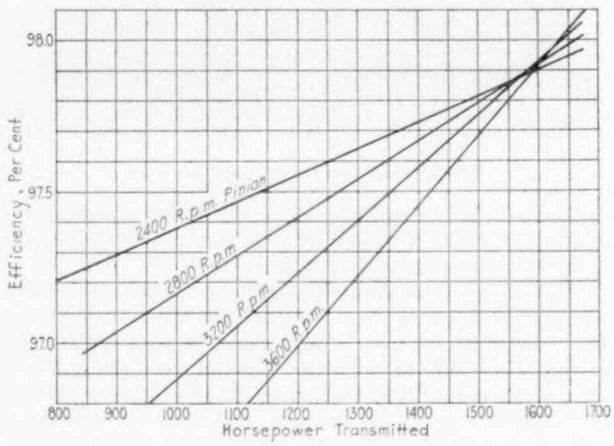

Fig. 2 Efficiency Test of 1500-Hp. Gear

Fig. 12 shows a photomicrograph of a pit. A small triangular piece was cut from a tooth, the pitted surface being on one side of this triangle. This was mounted in some low-fusing alloy and the whole polished together so that the edge of the specimen where this pitting occurred would not be disturbed by the polishing and the character of the metal at the extreme edge of the pitting could be studied. A peninsula of metal is seen standing out between pits and a distortion of the grains is evident at this point, the body of the steel being apparently normal.

A gear that has been in service for some time generally develops

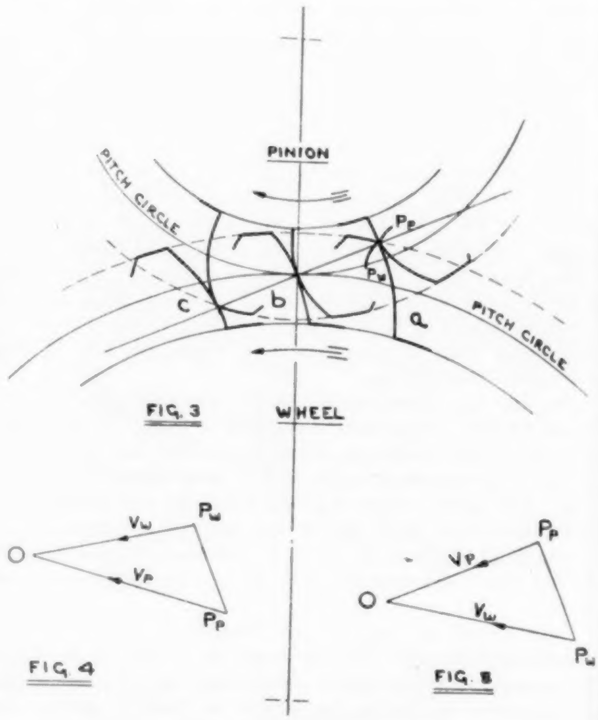

Fig. 3 Pair of Meshing Teeth

Fig. 4 Velocity Diagram, Position *c*

Fig. 7 Tooth Action, Gear Teeth

Fig. 8 Rolling and Sliding in Same Direction

Fig. 9 Rolling and Sliding in Opposite Directions

a row of scattered pit marks along the pitch line of the gear teeth, and more or less widely scattered pitting on both the pinion and gear teeth. The row of pitting along the pitch line of the gear teeth is probably due to the excessive pressure carried at this point because of the building up of the metal. The scattered pitting is probably due to other high spots on the pinion and gear, with a resulting high pressure at these points. When it is remembered that in the generation of the involute curve by a series of cuts by a flat surface as indicated in Fig. 13 there are miniature corners left, it is possible that a corner of the gear tooth comes in contact with a corner of the pinion tooth.

Pitting is considered to be in the nature of a corrective agency as metal is removed from the high spots, allowing the surrounding area to carry their share of the load. It is found that pitting generally starts on a new machine shortly after it is put in service, and gradually decreases and finally stops completely after a few months.

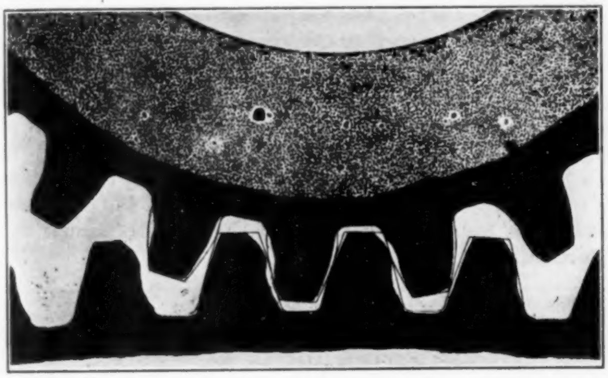

Fig. 10 Worn Teeth

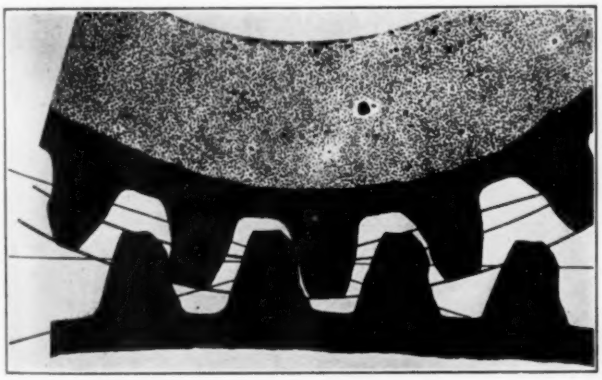

Fig. 11 Meshing of Worn Teeth

### Allowable Loading of Teeth

In practice, if correct alignment is maintained to insure uniform tooth contact, a tooth pressure of 100 lb. per lineal inch of width of face per inch of pitch diameter can be safely carried. With a 5-in. pinion a pressure of 500 lb. per inch of face can be used, and with a 10-in. pinion, of 1000 lb. A pressure of 320 lb. per inch of face per inch of diameter has been carried with no signs of failure.

The allowable load that can be continuously carried on a gear tooth is directly proportional to the radius of curvature of the contacting teeth. The radius of curvature of the tooth changes from the base to the tip, but for all practical purposes can be taken as being directly proportional to the pitch diameter. The pinion tooth, having the smaller radius of curvature, is more highly stressed and limits the allowable load.

In addition to the stress at the contacting surfaces, the tooth can be considered as a cantilever beam, and the tooth load tends to break the tooth at the root. If the number of teeth in the pinion is maintained constant with various diameters, the stress at the base of the teeth will be constant if the load is varied directly as the pitch diameter.

For some time a tooth shape that was much broader at the base was used to prevent tooth breakage. This was developed with a standard hob by cutting one less tooth than that corresponding to the blank diameter. If the blank was the theoretical diameter for, say, 27 teeth, then 26 teeth would be cut. This was designated as a "long-addendum tooth," as the pitch line was lower than standard.

Fig. 12 Photomicrograph of a Pit

Fig. 13 Generation of Involute

Theoretically there is less sliding with a long-addendum tooth

than with a standard tooth. The teeth in the position $a$ in Fig. 3 are well lubricated as the cavities between the approaching teeth are filled with oil. When the teeth reach the position $b$ there is rolling and the oil supply has been cut off by the following teeth, and from $b$ to $c$, lubrication is poor. With the long-addendum tooth the period of time between $a$ and $b$ was decreased and

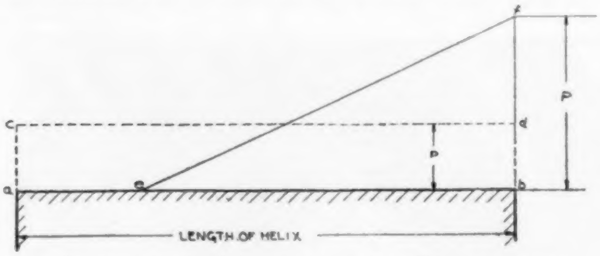

FIG. 14 CHART SHOWING LOAD WITH MISALIGNMENT

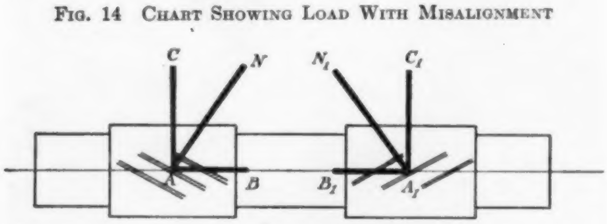

FIG. 15 LOADING OF GEAR TEETH

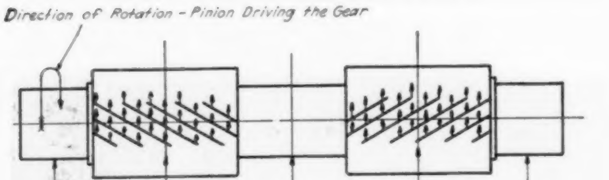

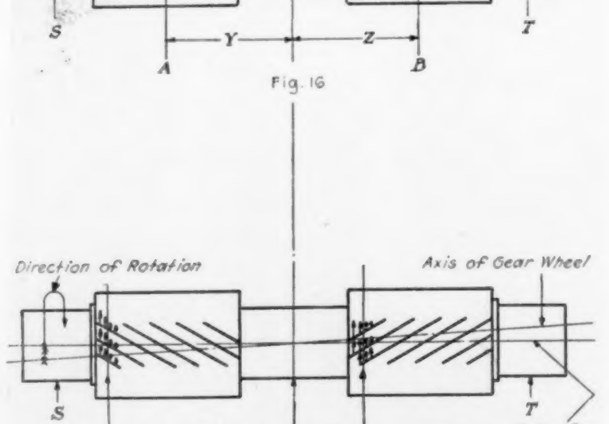

FIG. 16 UNIFORM TOOTH LOADING

FIG. 17 NON-UNIFORM TOOTH LOADING

the time between $b$ and $c$ was increased. The result was that lubrication of the teeth failed, and "scoring" or "galling" took place at the root of the gear tooth and the tips of the pinion teeth.

All gears with this type of tooth scored to some extent. Some stopped after one or two scrapings, while others continued to score. Some were remedied by turning off the tips of the pinion teeth to remove the metal causing excess sliding. The design was changed on other gears and a standard tooth shape was adopted, or the correct number of teeth corresponding to the blank diameter was cut.

It was found that scoring would take place on the second reduction of double-reduction gears more so than on the first. The relative amount of sliding and loading on each was the same. It would be thought that the high velocity of the first reduction would cause scoring, but it is now believed that the second-reduction teeth were in contact long enough to pierce the oil film, while the high-speed teeth, being in contact only about one-sixth as long, did not have time to do this.

Photoelastic studies have shown that teeth with a small radius at the root have a very high stress concentration at the base of the tooth. Special hobs having the straight sides of the cutting edges joined with a radius instead of being cut off flat on top generate a tooth with a large radius at the base and eliminate this high stress concentration.

## IMPORTANCE OF CORRECT ALIGNMENT

Correct alignment is essential to prevent overloading of the tooth surface. If the teeth are in line the tooth contact can be represented by the line $cd$, Fig. 14, where the pressure $P$ is uniform across the face and the total pressure is $ab \times ac$. If misalignment occurs the load may be carried by only that portion of the face represented by $eb$. For the same speed and power the area of the rectangle $acdb$ must equal that of the triangle $ebf$. Therefore

$$ab \times bd = {}^1/_2\, eb \times bf \quad \text{or} \quad \frac{bf}{bd} = \frac{2ab}{cb}$$

If we assume $eb$ equal to $^3/_4\, ab$, then

$$\frac{bf}{bd} = \frac{8}{3} = 2.67$$

This shows that on any gear where misalignment is likely to occur the allowable tooth pressure, assuming uniform contact, must be kept low to insure that the pressure under misalignment conditions will not be excessive.

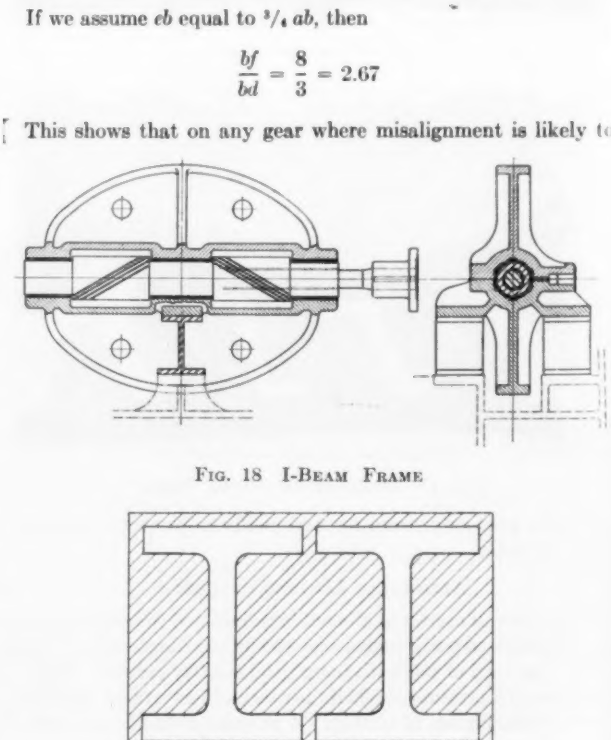

FIG. 18 I-BEAM FRAME

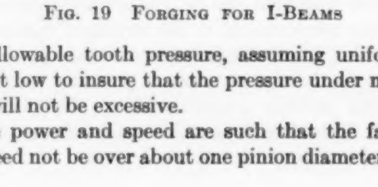

FIG. 19 FORGING FOR I-BEAMS

When the power and speed are such that the face width of each helix need not be over about one pinion diameter, the pinion

and wheel may be supported in bearings rigid with the housing if the designed pressure is not too high.

Our practice is to make all gears below about 500 hp. of rigid or fixed-bearing design. Above 500 hp. we use the floating-frame design which allows the pinion to automatically maintain correct alignment with the gearwheel.

With rigid bearings a certain amount of misalignment is expected with the resulting concentration of load. The two shafts may be aligned perfectly to give uniform loading with a uniform temperature of the housing. The housing is apt to be distorted either from bolting it to its seating, or the bearings may operate at different temperatures, causing one corner of the housing to raise more than another. It requires only a very small amount of misalignment to cause concentration of load.

With turbine-driven gears the pinion runs at speeds of from 3,000 to 10,000 r.p.m. At high pitch-line speeds trouble may be experienced in lubricating the gear teeth as the centrifugal force throws the oil off the teeth. Also any hammer blow due to slight inaccuracies of the contacting teeth varies as the square of the velocity of the teeth. The pitch-line speed is generally held below 120 ft. per sec., although speeds of 140 ft. per sec. are not unusual and speeds as high as 200 ft. per sec. have been used.

The pitch-line speed limits the pinion diameter for any speed of revolution, and for increased power at that speed it becomes necessary to increase the face width. A face width as high as five pinion diameters has been used, although the maximum is

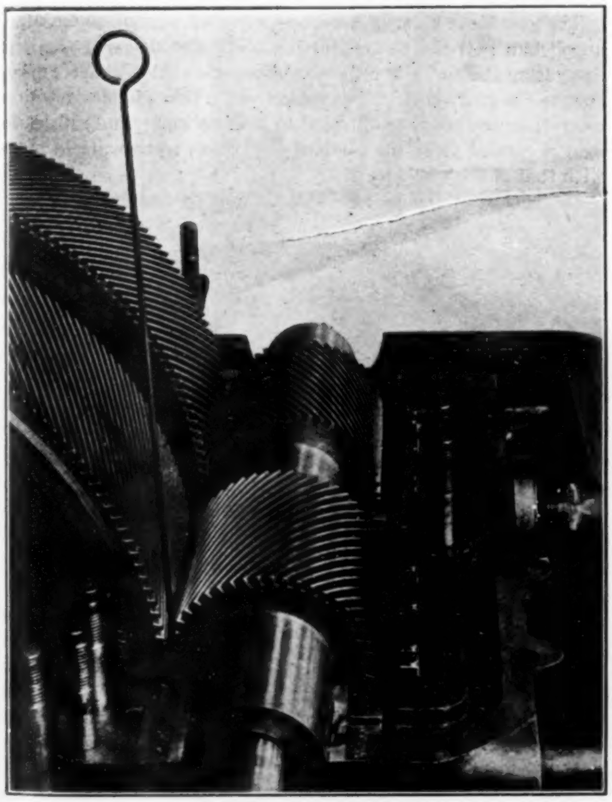

Fig. 20 Use of Block Gages

generally held to four diameters or less. A long pinion is liable to have concentration of load at the ends of the face on account of deflection between the bearings. With a total face width of more than three diameters a center pinion bearing is necessary.

All high-speed gears at the present time are cut with helical teeth as the tooth action is much smoother than is possible with spur gears. The teeth slide into mesh instead of coming into mesh abruptly as do spur gears. The helical angle varies from 20 deg. to 45 deg.

With helical teeth the actual tooth pressure is normal to the

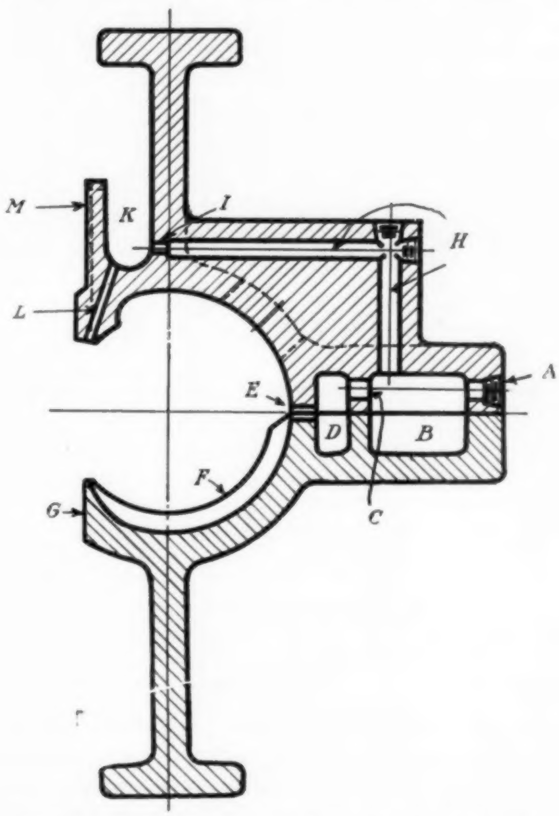

Fig. 21 Section of Frame Showing Oiling System

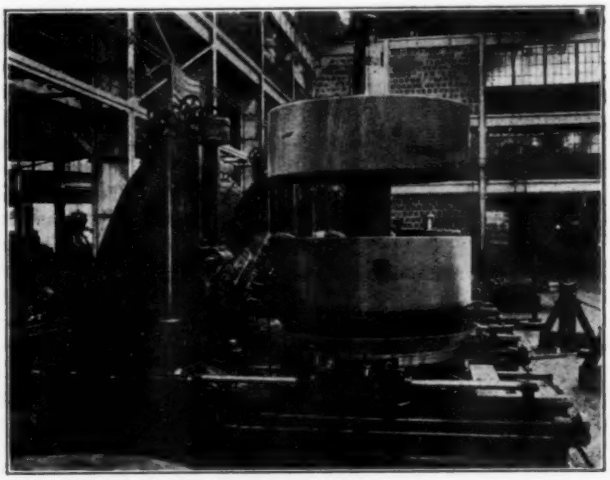

Fig. 22 Gear Hobber

tooth as represented by $AN$ in Fig. 15. This force can be assumed to be divided into two components, $AB$ parallel to the axis and $AC$ tangential to the pitch line and normal to the axis. The force $AC$ is the tooth pressure generally spoken of with reference to gears.

The pinion is generally connected to the drive with a coupling allowing free axial motion. Therefore $AB$ will be equal to $A_1B_1$, and as the helical angles on the two helices are equal, $AC$ will be equal to $A_1C_1$. The loads carried by the two helices will then be equalized.

If the tooth pressure is uniformly distributed across the face this tooth pressure can be considered as concentrated in the center of the helix or equidistant from the center of the pinion as shown in Fig. 16.

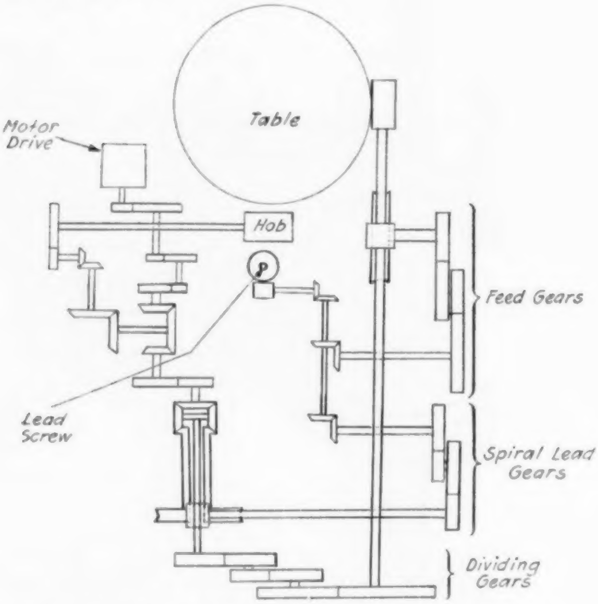

Fig. 23 Showing Arrangement of Hobber Gearing

If there is misalignment the conditions will be as represented by the triangle in Fig. 14, or it can be considered as $A$ concentrated at distance $Y$ and $B$ at distance $Z$ from the pinion centers, Fig. 17.

It has just been shown that the total pressures on the two helices are equal, therefore with misalignment there is a resulting moment $AY - BZ$ tending to rock the pinion about the center bearing to bring it back into line. If the pinion is supported at the center in such a way that it is free to rock it will automatically align itself.

This may be accomplished in a practical manner by supporting the pinion as shown in Fig. 18. The pinion is supported by three bearings which are mounted in a heavy frame. This frame is very rigid in order to maintain the three bearings in alignment. The frame is fastened to the gear housing by means of two I-beams the top web of the beam being bolted to the frame and the lower web to the housing. The flexure of the vertical web of the I-beam allows a limited rocking motion of the frame with very little restriction.

The movement of the frame is minute and may be only in the neighborhood of 0.001 in. at the end of a 4-ft. pinion, thus the bending stress in the web of the I-beam is very low. The web is in either tension or compression to the extent of the tooth pressure. This amounts as a rule to less than 10,000 lb. per sq. in. The I-beams are made of forged steel and are annealed after being rough-machined to approximate size.

It is known that the weakest part of a forging is at the center. Forgings for these I-beams are therefore made large enough to machine into two I-beams as indicated in Fig. 19, the center part being then discarded, leaving sound metal for the vertical web of the I-beam.

The horizontal component of the tooth pressure is carried by struts at either end of the pinion frame. These struts limit the motion of the frame to a vertical plane in the case of a side-pinion gear. The correct center distance is obtained by calculation. On either end of the pinion and wheel are turned collars a little below the root of the teeth. Block gages are made which when just fitting between the collar indicate the correct center distance. The struts are adjustable to allow this block gage to just fit below the collar, as shown in Fig. 20.

It is sometimes thought that this frame is intended to compensate for inaccuracies of gear cutting. This is not the case as the frame is only supposed to take care of misalignment between the pinions and wheel. It has been found, however, that inaccuracies in gear cutting are indicated by a working motion of the frame with each revolution of the wheel. If such is found to occur the teeth are recut to correct the error, and if necessary the hobbing machines are corrected.

In comparing the tooth pressures on different gears, the probability of misalignment must be considered with its resultant load concentration, also the total load-carrying surface of the tooth. If we take a pair of gears with teeth of normal height and turn the tips off the pinion and gear teeth until the working depth of the teeth is about one-half what it was at first, we shall have doubled the tooth pressure per inch of contact on the tooth, even though the tooth pressure per lineal inch of face is the same.

## Lubrication of Teeth

The gear teeth must be copiously supplied with oil to maintain an oil film between the contacting teeth and to carry the heat away from the pinion in order to maintain it at the same temperature as the gearwheel. The pinion teeth, being in contact more often than the wheel teeth, tend to heat up more, and unless the heat is carried away the pitch of the pinion teeth will not agree with that of the wheel teeth.

In order that the pinion shall be well bathed in oil without circulating an excessive quantity, the oiling system shown in Fig. 21 has been adopted and has proved very satisfactory. Oil is admitted to the frame through a flexible oil connection from the housing, and flows into a passage which extends for the full length of the frame, supplying oil to the three pinion bearings and to the teeth. Oil is supplied to the teeth from oil pans formed in the pinion frame.

Fig. 24 Construction of Master Wormwheel

With correct alignment and well-lubricated teeth the life of a gear is indefinite. Gears with self-aligning floating frames and lubricated as described above have been in practically constant service since 1911 with no appreciable wear of the teeth. The marks left when the high spots were scraped off on first starting the machine are still visible.

If, however, the teeth are subject to severe vibration due to misalignment of the coupling connection to the driving or driven

machine or to torsional disturbance from either, the teeth will deteriorate. It will generally be found that the deterioration will go only so far until the teeth will have taken a new form such that more surface is supporting the load. This was found to occur with the gear of Fig. 10. It will be noted from Fig. 11 that there is a large surface supporting the load instead of a line contact.

### Noise in Gears and Its Elimination

Experience has shown that noise from a gear can be traced to one or more of the following sources:

1 Errors of hobber reproduced in gear.

Fig. 25 Resonator

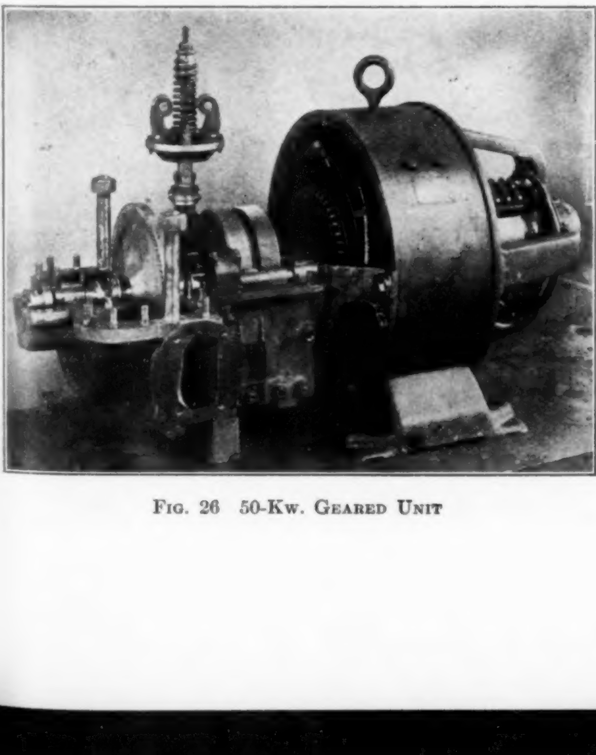

Fig. 26 50-Kw. Geared Unit

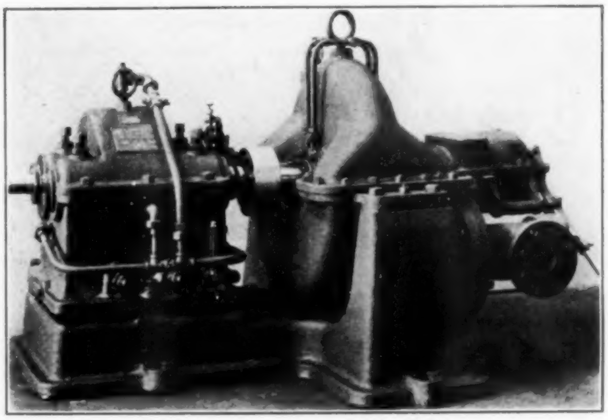

Fig. 27 150-Hp. Geared Turbine

2 Variable deflection of gear teeth with phases of tooth contact.

3 Vibration transmitted from connected machines.

Fig. 22 shows a gear-hobbing machine, and in Fig. 23 its gearing is shown diagrammatically. It is necessary that the accuracy of this machine be as great as possible, because any errors in it will be reproduced in the gear that is being cut. This is especially true of the master wormwheel which rotates the gear blank while it is being cut. If the circumferential pitches of the teeth are not equal in the master wormwheel, the teeth being cut will not be pitched accurately and the result will be a noisy gear.

Fig. 24 shows the construction of the master wormwheel used in order that the errors of circumferential pitch shall be the minimum. By having the wormwheel split as indicated, one half can be revolved with reference to the other half. It is originally cut on the same machine or a similar one on which it is to be used by a hob which is a duplicate of the worm which will drive it. One half of the wheel is then turned 180 deg. with reference to the other. The teeth are matched up on one side, and if spaced accurately all teeth will match. The amount the teeth overlap indicates the accumulation of circumferential error in pitch.

The wormwheel is then bolted together and doweled. It is placed in its position in the hobbing machine and driven by a cast-iron worm. Abrasive is placed between the teeth which grinds away the overlap. The halves are again separated and turned, say, 90 deg. or until the maximum overlap in error is determined, and the teeth are again lapped in. Each lapping reduces the existing error approximately one-half. The process is repeated with different relative positions of the two halves until no appreciable error can be found.

The machine is then assembled with a bronze worm made to fit the teeth of the wormwheel.

The hobbing machines are checked occasionally with test rings made in halves, similar to the master wormwheels. These rings are generally 100 in. in diameter and are cut with any convenient number of teeth. For convenience in measuring the error, spur-gear teeth are cut. One-half of the ring is then revolved until the maximum errror is determined. On a machine recently checked the maximum accumulative error on a 100-in. wheel was found to be 0.002 in. When it is considered that this wheel was cut with 400 teeth and an error in 200 teeth was then 0.002 in., or the error in pitch from tooth to tooth was only about 0.00001 in., we begin to realize the accuracy of the machine.

It has been found that the wormwheel driving the table should be supported on journals which are an integral part of the worm to insure against the worm's revolving with an eccentric motion and thus causing the table to be accelerated and retarded with

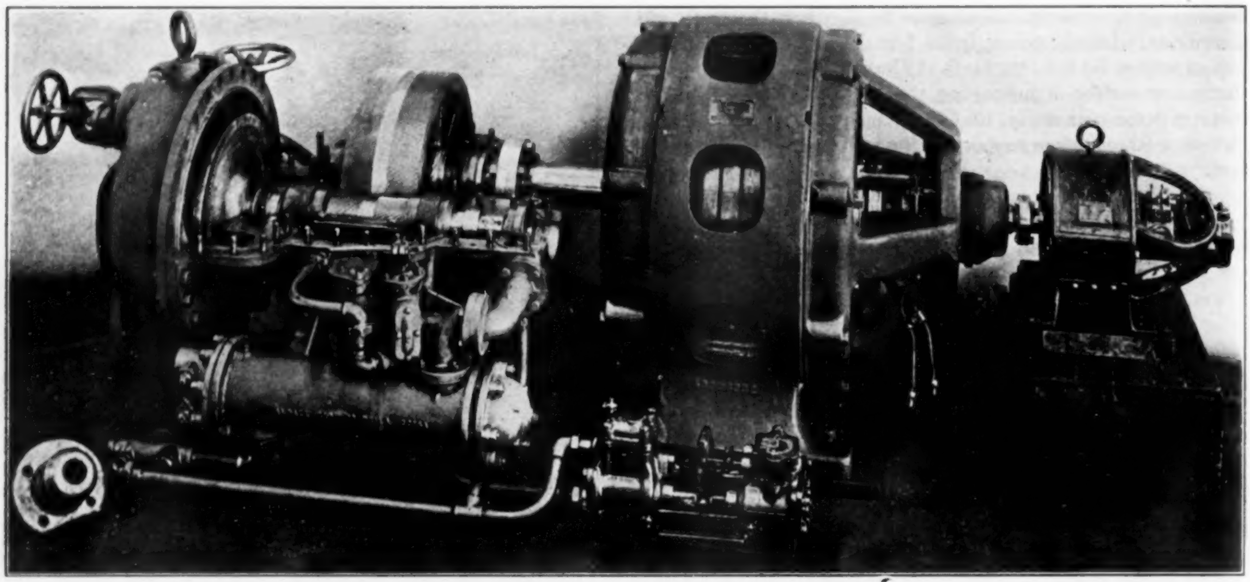

Fig. 28 200-Kw. Geared Unit

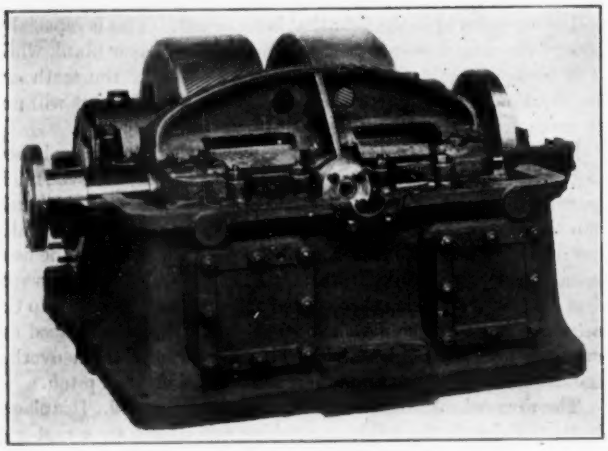

Fig. 29 1000-Kw. Reduction Gear

each revolution of the worm. Also the shaft driving the worm should be extra heavy to preclude torsional vibration, with the same result to the gear being cut.

It is also desirable that the hob be supported on journals which are an integral part of the hob to prevent an eccentric motion of the hob. This is practically impossible owing to the cost of the hob. The hob can be tested for eccentricity after being mounted on the arbor of the hobbing machine, if the ends of the hob are ground true with the bore for about $^1/_4$ in. from each end.

In addition to the master wormwheel, all other parts of the machine are occasionally checked to see if the desired accuracy is maintained. The lead screw, for instance, which raises or lowers the hob is checked periodically and must not show an error exceeding 0.0005 in. per foot in length.

The change gears should be recut occasionally to insure that they transmit a uniform angular velocity.

It has been found that the hobbing machine cannot be made accurate enough to prevent very small errors from being reproduced in the blank being cut.

With every revolution of the worm driving the table the gear blank is accelerated and retarded. This is because the worm does not transmit a uniform angular motion to the table. If there are 120 teeth in the master wormwheel this error will be repeated every 3 deg. This angle is termed the "angle of error." There is less error if a "Hindley" or hourglass worm is used, but the error cannot be entirely eliminated.

It has been found, however, that the remaining small errors cannot produce a noise if care is taken to cut the gear on a machine having sufficient teeth in the master wormwheel to bring the "angle of error" well within the "angle of contact." The angle of contact is that angle measured by the line of contact.

With the angle of contact less than the angle of error, the angular velocity of either the pinion or wheel is continually varying, which sets up a sound wave for each error. If the angle of contact is greater than the angle of error, we bridge across the error and obtain a uniform angular velocity of both pinion and wheel.

It has been found that unless the teeth are so proportioned as to give a constant deflection at all phases of engagement, sound waves will be set up because of this deflection. By making

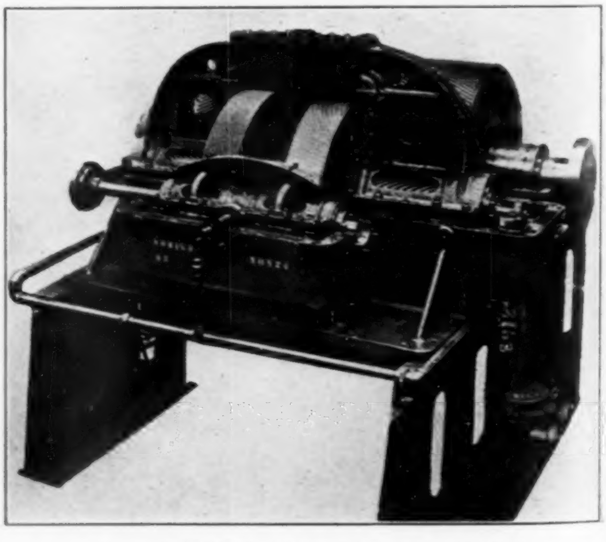

Fig. 30 2000-S.Hp. Marine Reduction Gear

the line of contact exactly two pitches long and also the face width of each helix an integral number of axial pitches wide, the tooth deflection will be constant.

To obtain the best results, two or more cuts are required to finish the teeth. Generally the first cut finishes the tooth to within about 0.010 in. of the finished size, and the finishing cut brings the teeth to size.

On the smaller gears of the rigid-bearing design the two helices of the gearwheel are cut in a single-piece rim. It has been found necessary to take the roughing cut on both helices before taking the finishing cut, otherwise the finished teeth on the first helix will be distorted by the roughing cut on the second helix.

On the pinions of these gears it has been found desirable to rough-turn the bearings and faces and rough-cut the teeth before grinding the journals to size. The finish cut is made after grinding the journals, and the pinion is centered in the hobs to the ground journals to insure its running true.

On all sizes of gears it is essential that the gear center be properly annealed to relieve all internal strains and insure its keeping its shape after the teeth are cut. The wheels are generally built up of a cast-iron center, forged-steel shaft, and forged-steel rim.

The rim is made of heat-treated carbon steel having 0.20 to 0.30 per cent carbon. The pinions are made from heat-treated carbon steel having 0.50 to 0.60 per cent carbon. For the smaller-size gears pinion material can be purchased in bar stock ready heat-treated. The larger gears using the floating-frame construction have a hollow pinion fitted with an internal flexible drive shaft of chrome-nickel steel.

### Analysis of Gear Noise

To analyze the noise emitted from a gear it is necessary to be able to trace its origin in order to determine the cause. A very simple instrument for this purpose is shown in Fig. 25. This consists of a small portable cylinder and piston connected to ear pieces. The piston is moved in the cylinder until the air column in the latter is in resonance with the sound from the machine,

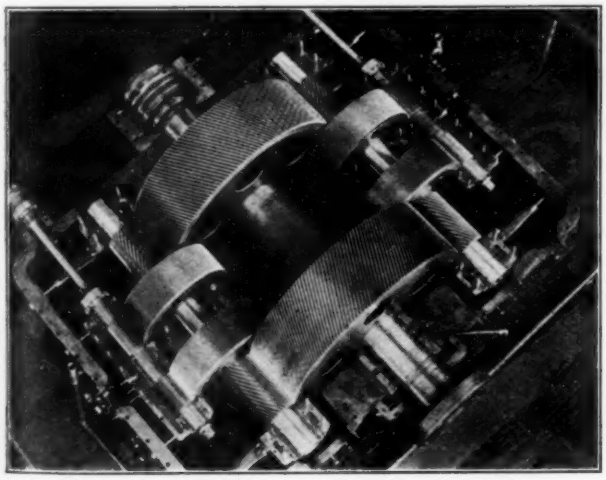

Fig. 31 3000-S.Hp. Marine Reduction Gear

when the sound will be heard distinctly. In using this "resonator" the length of the air column is first made very short and gradually increased in length until the maximum sound is heard, when the length of the air column is noted. The piston is then moved further until the same note is again heard, and the length of air column is noted. The distance between these two points is then exactly one-half wave length of the sound. Knowing the velocity of sound to be about 792,000 in. per min. under average conditions and by noting the speed of the machine at the time of checking the sound wave, the sound waves per revolution can be determined from the formula—

$$\text{Waves per rev.} = \frac{\text{Velocity of sound, inches per minute}}{\text{R.p.m. of machine} \times \text{wave length in inches}}$$

Knowing the waves per revolution, the source of the sound can generally be traced. A hobbing-machine error will generally

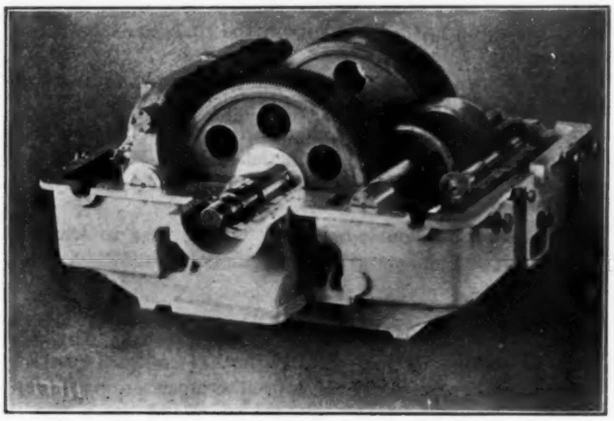

Fig. 32 Model of 3000-S.Hp. Marine Reduction Gear Shown in Fig. 31

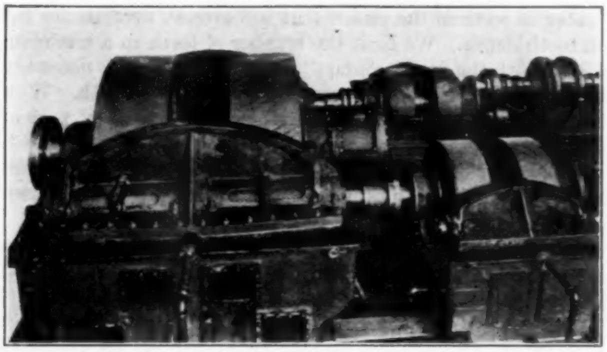

Fig. 33 5500-S.Hp. Marine Reduction Gear

show up as the same number of sound waves per revolution as there are teeth in the master wormwheel.

On all gears a note will be heard corresponding to one sound wave per tooth on the wheel. This note can be reduced to a minimum by using the "even contact" design, which insures a constant deflection of the teeth.

### Typical Gears

Fig. 26 shows a 50-kw. generator set. This has a fixed bearing gear having the gearwheel overhung from the generator shaft. Lubricating oil is supplied by a gear pump driven from the governor shaft. The speed reduction is from 7200 to 1200 r.p.m.

Fig. 27 shows a fixed-bearing gear usually employed with a steam turbine for pump or blower drive. It is often used with motor drive as a speed-up gear. When employed with a turbine the inboard turbine bearing is omitted and a rigid coupling used, making the turbine rotor and pinion a three-bearing set. This type of unit is used for powers up to 500 hp. An oil pump on the end of the gear shaft supplies oil to the gear and turbine bearings.

Fig. 28 shows a 200-kw. generator set comprising a fixed-bearing geared turbine having the turbine rotor overhung from the pinion. These sets are built in sizes from 75 to 500 kw. An impeller on the end of the pinion serves as a governor for the turbine, and part of the high-pressure oil is used in an ejector for supplying the bearing oil. The reduction is from 6000 r.p.m. to either 1700 or 900, depending on the generator used.

Fig. 29 shows the type of gear used for the larger power-generator drives and made in sizes of from 500 to 3000 kw. The reduction is generally from a turbine speed of 3600 r.p.m. to either 514, 720, 900, or 1200, depending on the characteristics of the generator.

Fig. 30 shows a double-reduction marine gear to transmit 2000 s.hp. on a single pinion with a reduction of 3680-438-90 r.p.m.

Fig. 31 shows a double-reduction marine gear to transmit 3000 s.hp. on two pinions with a reduction of 3340-585-90 r.p.m.

Fig. 32 shows a one-eighth-size model of the gear shown in Fig. 31.

Fig. 33 shows a double-reduction marine gear to transmit 5500 s.hp. on two pinions with a reduction of 3500-578-95 r.p.m.

## Discussion

THE discussion of the paper took the form of a series of questions which, with their answers, have been summarized as follows:

Nikola Trbojevich[2] asked whether we would use a fine or coarse pitch if we had a set center distance. He also asked if the strongest region of the gear is at the pitch line. Our practice with a fixed center distance is to use the smallest number of teeth in the pinion that will give an involute for the full tooth depth. We limit the number of teeth to a minimum of 31. With the "even contact" design it is generally necessary to increase the number of teeth by using a finer pitch. With the teeth having a large radius at the root the weakest part of the tooth seems to be the point of engagement. The teeth will generally wear out before breaking off. A well-lubricated tooth will show very little or no wear. Our experiments have shown no difference in the amount of noise with fine and coarse pitch.

H. J. Eberhardt[3] asked if we have had any trouble removing the abrasive after lapping the master worm wheels. We have had no trouble of this nature.

A. B. Zaenglein[4] asked if the lubricant made any difference in the noise. We have found that a very heavy lubricant reduces the noise to some extent but we have also found that the loss is directly proportional to the viscosity of the oil. To have the most efficient gear, the lightest oil possible should be used.

It has been asked if pitted teeth wore themselves in. Pitting is generally a corrective action and the teeth will wear in to fit each other. The teeth shown suffered excessive wear due to vibration from the propeller which punctured the oil film between the teeth.

It has been pointed out that on tests run with an even number of teeth in contact on slow-speed gears, no improvement could be noted over the gear not having an even number of teeth in contact. Most of our experiments have been made on high-speed gears and we have been able to make a gear more noisy by turning off the teeth and then make the same gear quieter by turning off still more of the teeth. It seems to be possible to distinguish the high pitch more easily and also to note variations in sound of high pitch.

It has been asked if with a set of four gears with different numbers of teeth, we could, using the resonator, trace the sound to determine which particular gear was at fault. The resonator will determine the wave length of the sound or the number of sound waves per minute. If one of the gears operates at a speed such that the product of the number of teeth and the r.p.m. is equal to the number of sound waves per minute, it is pretty surely to be the gear at fault.

It has been asked whether after getting the worm wheel perfected it was possible to get a worm that works correctly with it. The worm is ground to suit the final gear. The worm does not drive the table at a constant speed and it is necessary to have enough teeth in the master wheel so that the "angle of contact" overlaps the "angle of error," as described in the paper.

It was asked how much backlash is allowed. On all gears of all sizes and with all pitches the pinion is placed tightly in mesh with the gear and then they are spread apart 0.0004 times the center distance in inches plus 0.004 in.

It was asked if we have ever tried to eliminate the noise by altering the design of the gear case. We have tried lagging the gear cases and making them of cast iron as well as steel, and the only cure seems to be to eliminate the cause.

# The Pratt & Whitney Gear-Shaving Process

By H. D. Tanner,[1] Hartford, Conn.

The two present methods of generating involute gear teeth, both spur and helical, in soft gear blanks are the hobbing method and the gear-shaper method. Both come under the classification of forming-generating in that the form of the gear tooth generated, while it differs from the form of the cutter used, depends partly upon the form of the cutter.

Gears are usually hobbed at the angle at which they are to run; that is, a 20-deg. gear is hobbed with a 20-deg. hob. A 20-deg. gear can be hobbed at an angle greater than 20 deg. and also at a lesser angle, and even down to 0 deg. although a hob is an impractical tool at very small angles.

Gears are also usually shaped at about their running angle, although the generating angle could be varied slightly if there were reason for it. The shaper cutter, however, cannot generate involute teeth of any practical height at small angles. For instance, the smallest angle at which a 21-tooth cutter can generate a full involute on a standard full-height 15-tooth gear is 16 deg., 9 min., and 1 sec.

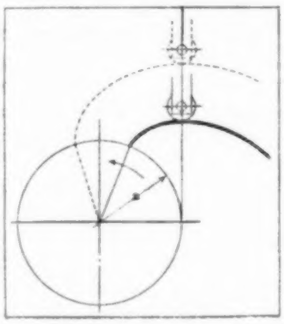

Fig. 1 The Involute as a Cam

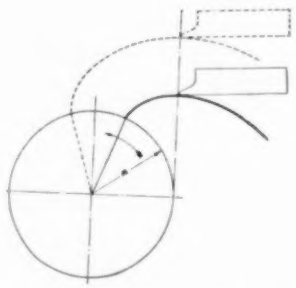

Fig. 2 Shaving the Involute

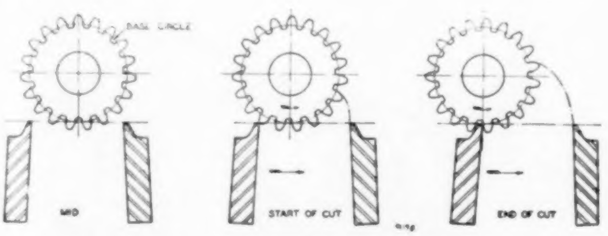

Fig. 3 Cycle of Shaving Machine

The gear-shaving process, the invention of James H. Barnes, of Dayton, Ohio, is a practical method of generating involute spur or helical gears at 0 deg. Acknowledgment is given the able and generous cooperation of the Chrysler Corporation in the development of the process.

The involute curve is generated by a point in a straight line rolling on a circle. A simple conception of this curve, as in Fig. 1, is that of a uniform-rise cam where the rise per revolution along a line tangent to a circle or radius $a$ is equal to the circumference of the circle. If this cam is revolving at a uniform rate in the direction shown by the arrow, the cam roll will rise at a uniform rate. If the cam revolves in the reverse direction, the roll will fall accordingly.

If now, as in Fig. 2, we place a roughed-out cam on the same center, set a cutting tool with its edge on the tangent line, and cause it to move up or down with the cam roll, the revolution of the rough cam against the cutting edge will remove the surplus material and leave the second cam exactly like the first or master cam.

In the actual machine a large cam, with two opposed involutes, and two cam rolls are used. Two cutting tools also are used, and the cycle is as shown in Fig. 3. At the left the gear is in the starting or loading position, and the tools are shown with their cutting edges on a line tangent to the base circle of the gear. In the center the gear has revolved in the direction shown by the arrow, the tools have been moved at exactly the correct rate to the right along the tangent line, and the left-hand tool has started to cut an involute curve on a tooth. At the right the same tool has come into contact with the base circle of the gear and has completed its cut. At this point the movement of the gear is reversed, the tools move back to the left, and the right-hand tool, following the path of the dot-and-dash line, finally cuts an involute on a tooth. The gear is again reversed, and while the tools are returning to their original position it lags behind just enough to index one tooth.

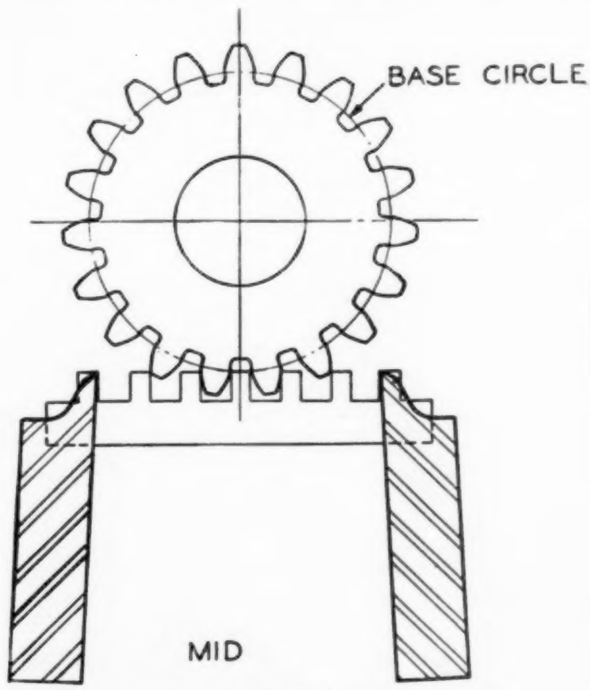

Fig. 4 Zero-Degree Rack-Generation Analogy

It now becomes apparent that the process is one of zero-degree generation and that the active profiles of the gear teeth are generated by rolling the gear in mesh with a zero-degree rack, as in Fig. 4. The active profiles of this rack are the top edges of its teeth, which coincide with the cutting edges of the tools. The remainder of the profile of the rack does not come into contact with the gear. We are then required to make tools with straight cutting edges slightly longer than the face of the gear to be cut and to place the tools in the shaving machine with their edges lying in a plane tangent to the base cylinder of the gear. If the

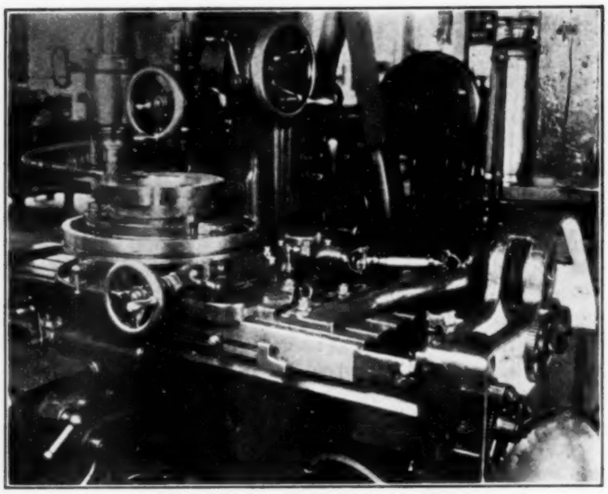

Fig. 6 Cam Milling

edges are parallel to the center line of the gear, a spur gear will be produced. If they are parallel to each other but at an angle to the center line of the gear, a helical gear will be produced. The form of the cutter is the most simple possible with the exception of a point, which is not a very practical cutting tool for gear teeth.

All expense connected with the making of any precision form used in the machine is confined to the master involute cam. Fig. 5 shows a cam for an 18-tooth, 6-diametral pitch, 20-deg. gear. Cams are made of S.A.E. 10115 steel, hardened, seasoned, and ground. They are 12 in. wide across the tangent to the base circle and $1^1/_2$ in. thick. All of the machining operations are conventional with the exception of the milling and grinding of the involute profiles.

The cams are milled, as in Fig. 6, on a standard vertical milling machine with a circular milling attachment and a special end bracket arranged for differential change gears. The machine is set up with a milling cutter in the position of the roll in Fig. 1,

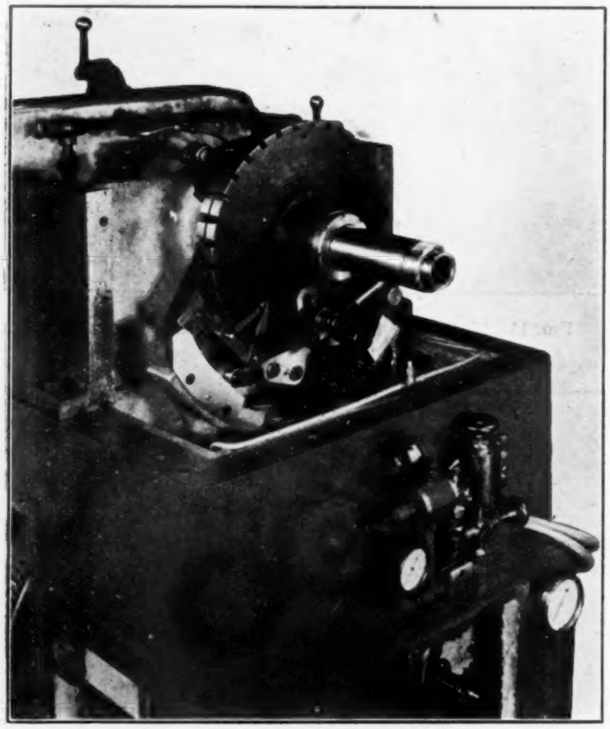

Fig. 15 Close View of the Indexing Mechanism

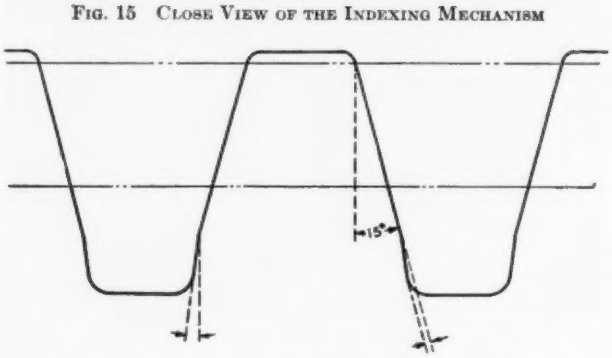

Fig. 16 Normal Section of the Roughing Hob

and the change gearing used is such that the cam makes one complete revolution while the table travels a distance equal to the circumference of the base circle of the gear for which the cam is being made. This being only a roughing operation, a lead is used which is within 0.010 in. of correct for a full revolution of the cam.

The cams are ground, as in Fig. 7, on a standard cylindrical grinding machine fitted with a special generating fixture. The cam is mounted on an arbor having a disk of base-circle diameter on each end, and this assembly is rolled on a steel track, which is the tangent line of Fig. 1 The grinding wheel is placed with its center in the plane of this flat track, and an involute is very accurately generated. The fact that the cam is rolling on a stationary line instead of revolving against a moving line, as in the machine, does not alter the relative motions.

To prevent the disk from slipping on the track, steel bands are used, as in some gear-tooth grinders. The bands are wrapped around the base-circle disk close to but not in contact with the track, the disks at this point being reduced in diameter about the thickness of one band.

The cam is inspected by using a dial indicator, as in Fig. 8, in place of the grinding wheel, its stem being placed in the plane of the track. The bands are removed during the checking operation so that they cannot influence the result.

Fig. 9 is a front view of the machine with the guards removed, showing the master cam and one of the roll housings.

Fig. 10 is a front view of a complete machine set up for a cluster gear, showing all operating controls.

Fig. 11 is a group of seven machines as they appear under actual operating conditions.

Fig. 12 is shown to illustrate the author's conception of the proper way to handle finished gears, with a steel rack for cluster gears. As the machine has been described in detail in *American Machinist* of May 17, 1928, no further description will be given beyond that of the cycle of operations through the shaving of one gear.

In Fig. 13-A the machine is shown in loading position. The gear is placed on the arbor, a C-washer is dropped into a groove in the arbor, the plunger is raised to bring the rack tooth into contact with the gear, centering it, and an air-operated drawbar pulls the arbor back to clamp the gear against the end of a collet in the work spindle. The plunger is dropped and the machine started. The cross-slide carrying the tools moves to the left, the gear turns clockwise, and the right-hand blade cuts, removing all stock in excess of 0.004 in. above finished size, as shown in Fig. 13-B. At the end of the cut the gear and slide reverse direction, and while returning to the starting position the gear is indexed one tooth, relative to the tools, in a clockwise direction. The slide continues on to the right, as shown in Fig. 13-C and the

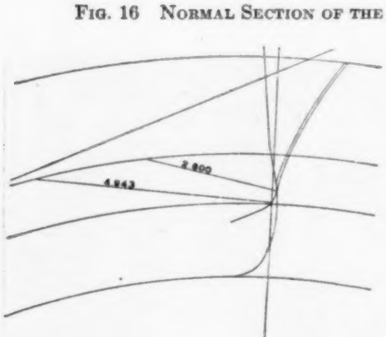

Fig. 17 Diagram of 17-Tooth, 20-Deg. Angle, 20-Deg. Hobbed Gear

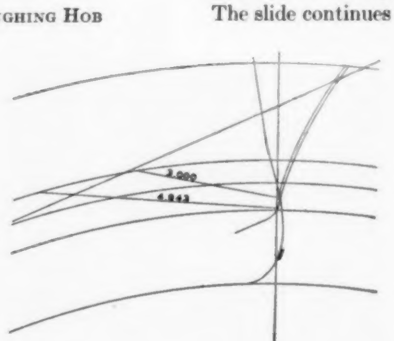

Fig. 18 Diagram of 17-Tooth, 20-Deg. Angle, 15-Deg. Hobbed Gear

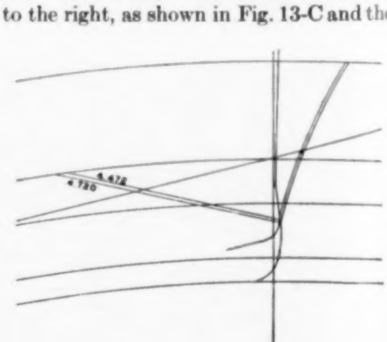

Fig. 19 Diagram of 33-Tooth, 20-Deg. Angle, 15-Deg. Hobbed Gear

left-hand blade cuts. Again reversing directions, the gear and slide return to the central position, and continue on to repeat the cutting cycle. When all the teeth have been cut once, the blades are automatically moved together 0.004 in. and all the

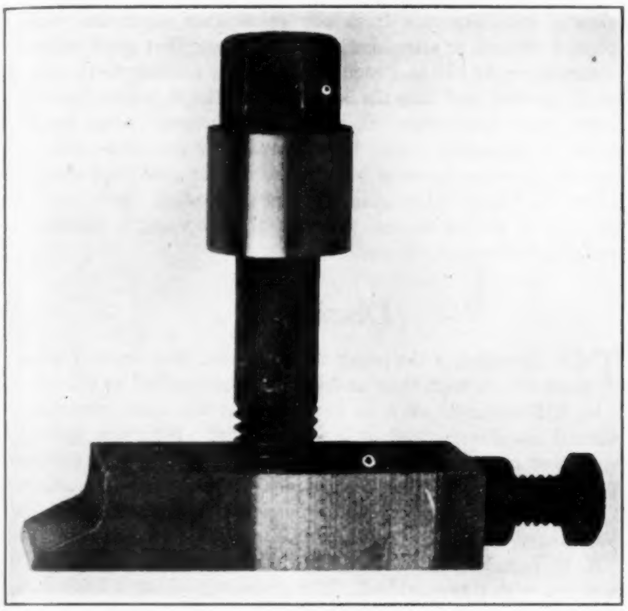

Fig. 20 Cutting Blade

teeth are again cut, 0.002 in. being removed from each side of each tooth. A third and a fourth cut of 0.001 in. each per tooth side are taken, and the machine is automatically stopped. The machine speed is 45 cycles per minute.

Indexing is done by means of a hardened, seasoned, and ground 14-in. notched plate. The location of the plate and index mechanism on the rear end of the spindle is shown in Fig. 14. Fig. 15 is a close-up view of the index mechanism and shows the operating cams more clearly.

It is preferable to rough-cut gears in a hobbing machine, although a gear shaper can and sometimes must be used. This preference is owing entirely to the more favorable shape, for gear shaving, produced at the base of the tooth by the hobbing method. A tooth section of the type of hob used is shown in Fig. 16. To produce a definite undercut in the gear the point of the hob is made thicker than standard by from 0.007 to 0.010 in. on each side. All hobs are made to generate at a pressure angle of 15 deg. as this produces more nearly the desired shape in the undercut curves. For the same reason all gears are cut to full Fellows depth. Otherwise, hobs are made and used as in regular production roughing.

In Fig. 17 is shown the roughed and finished profile of a 17-tooth, 20-deg. pressure-angle gear. It has been hobbed with a thick-point 20-deg. hob, on a 1-diametral pitch gear, to a depth of 2.250 in. instead of the standard 2.157 in. The hob profile is shown just as it is finishing the gear profile. The outer involute profile and clearance curve is the gear as hobbed, and the inner profile is the finish-shaved profile. The involute profile only is shaved, the remainder of the tooth being left as produced by the hob. That part of the involute starting at the base circle has been removed by the hob to give the shaving tools a clearance space into which to cut. The undercut curves are designed to cross the base circle 0.004 to 0.006 in. inside of the finished involute curve. It is found that 0.004 in. is as small as is commercially practical. The line 4.943 is the relative length in inches of the theoretical line of action to the pitch circle of this gear when it is in mesh with a 33-tooth gear on a standard center distance. The line 2.800 is the actual line of action resulting from the removal of the base of the involute.

Fig. 18 is the same 17-tooth gear roughed with a thick-point 15-deg. hob to the same depth. The involute curve is identical with that of the first gear, and the undercut curve crosses the base circle at the same point but at a different angle, which removes less of the involute, resulting in an increase in length of the actual line of action to 3.000 in. Generating at small angles is in this respect more effective the more teeth there are in the gear.

Fig. 19 is the mating 33-tooth gear roughed and finished under the same conditions. The theoretical line of action to the pitch

Fig. 21 Fixture for Setting the Cutting Blade

line is 4.472 in. long and the possible is 4.720 in. The possible being longer than the required, there is no loss of action in this gear from this method of roughing, although there would have been if a 20-deg. hob had been used. The maximum possible number of teeth in contact with this pair of gears is 1.595, and the actual in this case is 1.265. As the loss of action comes from a removal of active profile from the 17-tooth gear close to its base circle, where its use causes a high relative sliding velocity, the loss is not very keenly felt.

Fig. 20 shows one of the shaving tool with its clamping bolt

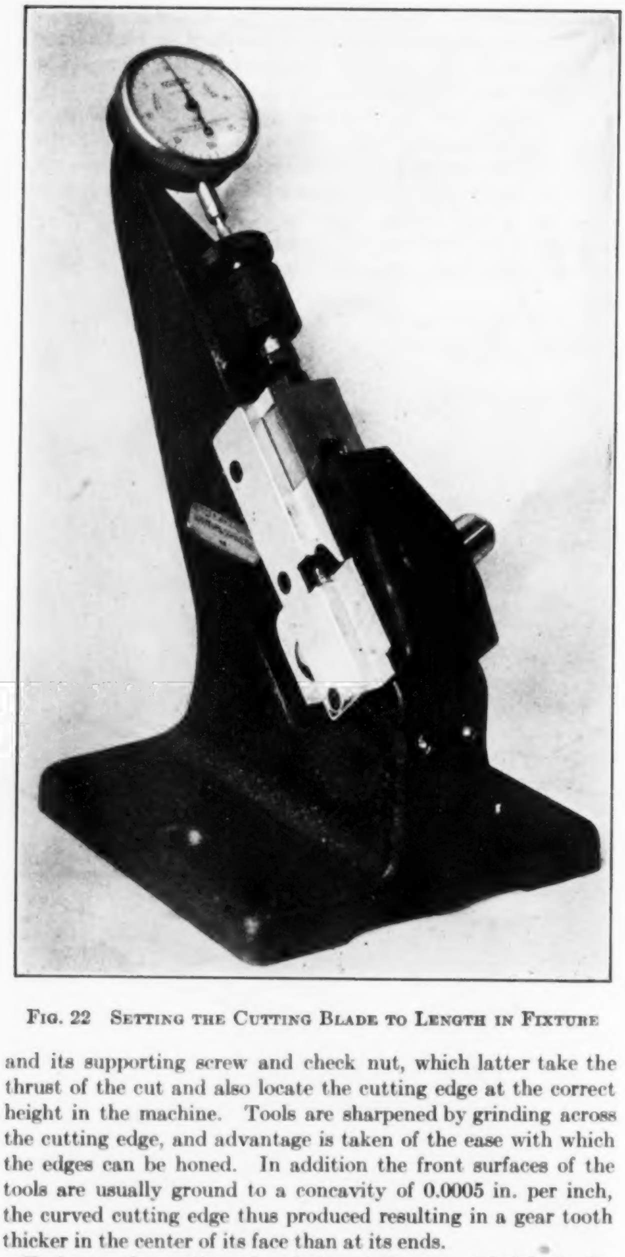

Fig. 22 Setting the Cutting Blade to Length in Fixture

and its supporting screw and check nut, which latter take the thrust of the cut and also locate the cutting edge at the correct height in the machine. Tools are sharpened by grinding across the cutting edge, and advantage is taken of the ease with which the edges can be honed. In addition the front surfaces of the tools are usually ground to a concavity of 0.0005 in. per inch, the curved cutting edge thus produced resulting in a gear tooth thicker in the center of its face than at its ends.

To insure the cutting edges being at the correct height in the machine a fixture is used, as shown in Fig. 21, where the dial indicator is set to zero with a gage which is correct for some particular machine.

In Fig. 22 a tool is shown in the place of the gage, and the supporting screw has been adjusted to bring the indicator to the same zero.

Any carbon tool steel that will hold a keen edge at a hardness of from 63 to 65 on the Rockwell C-scale is satisfactory for cutting tools. The tools will cut from 500 up to 1200 teeth after grinding, depending largely upon the machinability of the gear material. A honing of the cutting edges in the machine will usually give half as many more before the tools need regrinding. The usual cutting compounds are satisfactory, and no unusual heat treatment of the gears before cutting is necessary, although the author prefers the material a little harder than is customary.

The final active profile of a shaved gear is produced by one pass of one cutting edge, and thus is a continuous surface in the direction of roll or slide. Such tool marks as occur from an imperfect cutting edge lie in this direction of roll or slide, and can produce little or no noise.

The point contact of the convexed teeth is very effective in cases of misalignments from any cause that otherwise would produce crossed or edge bearings. All know that gears cannot be commercially cut and mounted with all mating teeth absolutely parallel, and that the bearing cannot be distributed evenly under these conditions. Points of high pressure must be accepted as necessary evils. The convexed or crowned tooth locates the point or zones of high pressure at or near the center of the tooth, the actual bearing, of course, spreading over about 75 per cent of the tooth, but never, if the crowning is sufficient, reaching the ends of the tooth.

## Discussion

The discussion of the paper took the form of a series of questions which, with their answers, are summarized as follows:

H. J. Eberhardt[2] asks, Is the crowning the main advantage claimed for this method or is it accuracy? We claim general consistent accuracy and a character of finish—namely, cutting in the direction of roll—which is ideal for a gear-tooth surface. The crowning is an incidental possibility, of which we take advantage.

A. H. Lane[3] asks, What is the widest tooth that you are able to shape with this machine? The present machine is limited to 2 in., but the limit depends upon the power which can be put into such a machine. We are not using the machine at present on bronze gears or other nonferrous gears, although bronze gears were cut on the original experimental machines. In general, the machine follows the characteristics of other gear-cutting machines in that the softer or more machinable materials can be cut with a better finish and a higher degree of accuracy. The softer metals will probably be cut with fewer cuts, although a cut of 0.002 in. is all that can be taken at one time successfully.

Chester B. Hamilton[4] asks, Are there any modifications, entries, etc., obtainable this way, and when we shape these gears do we find it necessary to shave an entry modification. We have found no modification of the involute required. A correction for hardening distortion is made by cutting the gears in the green, so that the normal pitch or spacing of the involutes on the base circles is made slightly longer than standard on the driving gears. This correction in general amounts to from 0.0001 to 0.0004 in. The heat treating of these gears causes a change in the normal pitch which makes them approximately correct.

I am asked how we finish hardened gears. Hardened gears are not being shaved in these machines at present, although we have shaved chrome-vanadium steels up to a hardness of 75 scleroscope. It is entirely practicable so far as the machine is concerned, but we have not found any cutting steels which would stand up to this work.

Nikola Trbojevich[5] says that he does not understand how we cut helical gears if the base circle is below the root diameter. He is correct. We cannot shave them under these conditions.

A member states that an internal gear can be shaved by making a hardened pinion and having each tooth a different height, and that General Barnes has a patent in which he shows a section of this type of gear. He is not cutting it at present, however.

# Some Practices in the Use of Machine Tools in the Electrical Industry

By J. R. Weaver,[1] East Pittsburgh, Pa.

This subject of machine tools and their use in manufacture covers quite a varied problem, and the author is going to deal with it in a general way from the experience obtained in the manufacture of electrical apparatus. Of course the question of using standard machine tools or special machine tools depends entirely upon the activity of the apparatus being manufactured. Standardization will undoubtedly increase this activity, and it is believed that the electrical manufacturers are standardizing as rapidly as is possible. There is still much to be done, and most of the equipment that we install must be suited for general conditions and yet, at the same time, it must be adapted to high production.

There are several ways in which high production or increased activity can be obtained from a standard tool. One of them is adapting special fixtures that will allow multiple or continuous cutting. Where the work does not warrant a special high-production or single-purpose machine, a standard machine equipped with a special multiple holding fixture such as a rotary fixture on a standard milling machine, a rotary table on a drill press, or two separate fixtures on a milling-machine table, can be used. Any one of these methods permits loading while machining is being done, thereby eliminating lost time on the part of the operator.

Owing to the necessity of meeting special requirements of the customer, work in the electrical business is so diversified that standard machines with special holding fixtures are used extensively. Another method is to arrange several machines in sequence operated by one operator, which may not increase the production, but will reduce the cost because one operator is operating several machines. We are using both methods with very good success, and in several cases we have as many as seven or eight machine tools operated by one operator, depending upon the time element in each operation. In our die-making department, where we are installing measured day work, which is an incentive payment plan, one operator is handling two shapers. We also have one operator on two standard milling machines without any special fixtures. Semi-automatic and automatic machines are usually grouped so that one operator can handle several machines. With equipment having controlled feeds and rapid power traverse, it is surprising how well machines of this type adapt themselves to multiple operations.

Wherever sufficient economies can be realized, special machines are installed which are purchased from machine-tool builders or designed and built by ourselves. We also have certain operations that cannot be done on machines that are on the market, and these we have to build ourselves.

Although we believe that fixtures should be designed and built by the manufacturer of the machine tool and installed on the machine while it is being built, we find it quite inconvenient in that it extends the time of delivery of the machine. Owing to the amount of correspondence which takes place and the misunderstandings that oftentimes arise, it is usually advisable to build our own fixtures. However, we try to take advantage of machine-tool builders' experience.

[1] Superintendent, Manufacturing Equipment Department, Westinghouse Electric & Manufacturing Company. Assoc-Mem. A.S.M.E.

Presented at the Second National Meeting of the A.S.M.E. Machine Shop Practice Division, Cincinnati, Ohio, September 24 to 27, 1928.

### Comparing Planing and Milling

The subject of comparing various operations and the methods of performing them is quite interesting in our industry, and the author wishes to mention and to describe briefly several of them. We have been carrying on various studies of planing versus milling on our products, expecially on our larger work. We find on some work, especially on form surfaces, that planing is much more economical than milling for the reason that we can maintain our form and size with the least expenditure. It must be admitted that milling cutters, if of any size at all, are very expensive and that it is necessary to have several sets owing to the fact that the machines must be kept operating. When only a single set of cutters is available, the machine is idle while they are being ground, but with a planer and a simple planer tool the investment is not so great and the time required to perform the operation is not very much longer, if any. However, on flat surfacing especially where there are a lot of pads to be finished, etc., the author believes the milling machine is better adapted than the planer.

We do considerable surface grinding on castings, and we find this to be a very economical way of finishing surfaces providing there is not more than $^1/_4$ in. of metal allowed for finish. This includes both cast-iron and cast-steel castings, and I was very much surprised to learn recently that one of our 54-in. machines removed $1^1/_4$ in. of stock from the base of a pedestal at one pass. This of course was an accident, but apparently no damage was done. However, I do not know whether this could be repeated with the same results.

We are going quite extensively into welded fabricated steel construction work on our apparatus, which is reducing our machining time considerably, and the thought occurs that it may be possible, to some extent at least, to apply the same construction to machine tools. This is just a thought, and the author is not prepared to go into details of design. It seems that in certain instances fabricated construction could be used to advantage. In the case of a lathe a fabricated bed could be made, and if cast iron ways are desired, they could be attached to the steel construction and still make a lathe bed that would be just as good as if all were of cast iron and for less money.

We have gone into this construction on our jigs and fixtures very extensively and find that we have not only reduced costs but have shown an advance in delivery of three weeks on each jig. This is due to the fact that it takes about three weeks to obtain a casting, including the time that it takes to make the pattern.

Fabricated parts can of course be bent or shaped very closely to the final dimensions, so that a very small amount of machining is required, and in quite a number of cases none at all. If this practice were adopted, it would probably mean that it would not be necessary to build machines as heavy and rugged as in cases where steel castings are used.

We have been experimenting with some special alloy steel on which we have been able to increase our cutting speeds and certain operations as much as 250 per cent and still obtain good results. This special alloy steel combined with fabricated steel construction would mean that machine tools ought to be built for and run at a much higher speed. Machines of this type would not be required to take as heavy cuts as is necessary on castings. This special alloy steel mentioned is just in the experimental stage, and

although the results up to the present time are promising, we are not prepared to make definite recommendations.

We have also been experimenting with the chromium plating of cutting tools quite extensively and on materials other than metals we have had very good success with this process, but when cutting steel and cast iron we find that the plating chips off at the cutting edge. The cutting tool gives no better results than a standard cutting tool.

### Die Casting and Hot Pressing Employed

The manufacture of apparatus from alloys of aluminum, copper, brass, zinc, etc., introduces die casting and hot pressing, which reduce machining quite considerably. In most cases machining is eliminated entirely. We have set up three processes for handling these alloys, grouped as follows:

*Die Casting.* By this method we make castings from zinc-base alloys and aluminum. This is done under pressure in a metal die, with the result that the casting does not usually require any machining except drilling or tapping, as the case may be. High activity is necessary for the use of this process as it requires a metal die and is rather expensive even though the operation of casting is very rapid.

*Permanent Molding.* This method is used for making castings from iron aluminum bronze, or aluminum alloy. This is somewhat similar to die casting except that no pressure is used and that molds are set in machines designed for opening and closing them quickly and that the pressure for the casting is obtained from the size of the gate and header. This has proved very satisfactory, and owing to the fact that steel molds are used in this operation, the castings are very close to the finished dimensions.

*Hot Pressing.* This process is used on castings or forgings that are designed from forged brass or copper. The types of presses used for the operation are drop hammers, screw presses, crank presses, and hydraulic presses. A very dense forging is obtained from this process, and it is very close to dimensions, so that the least amount of machining is necessary. One objectionable feature of this method is that, when using a press or a drop hammer, flash dies must be used, and on small forgings the flash is often greater than the piece itself. This naturally increases the losses due to excessive material and increases the cost of forging. We have been working for some time with closed dies for some of our work, eliminating practically all flash. We are having very good success with this type of die, depending of course on the size and shape of the piece that we wish to forge. Where the forging required is thin, we find that the flash die is necessary, but where the forging has a considerable amount of body to it, a closed die can be made, eliminating practically all flash.

These various processes, it is understood, are used to some extent on cast iron and steel, but in our experience we have only applied them to the alloys mentioned, with good results in eliminating machine work.

There is no question but all manufacturers are reducing as far as possible the amount of finish on their castings and forgings. If this continues, it looks as though at some time in the future the equipment will be of lighter construction, of high speed, and easily handled, depending on the development of cutting tools. With the new designs in machine-tool equipment it looks as though the manufacturers must look for savings in other directions rather than just on machine tools. It is hard to predict just how much improvement can be obtained from the redesigning of machine-tool equipment, but it appears as though they have gone as far as it seems possible.

## Discussion

Erik Oberg.[2] A good deal is being done in cutting-tool experiments, both in this country and abroad. A new type of cutting tool has been brought out in England and Germany and in this country. Undoubtedly, this will affect the machine-tool business, ultimately, to a great extent. A new lathe has been brought out in Germany that has unusual power and speed. It is claimed that this new lathe is able to take heavy cuts on forgings at 500 ft. per min. That is so tremendous compared with anything done hitherto that, if correct, it cannot but affect the machine-tool business.

E. F. Du Brul.[3] Concerning the point brought out by Mr. Oberg, many of us remember the revolution which came in the machine-tool business by the discovery of high-speed steel. When Mr. Taylor brought some chips to the meeting of the A.S.M.E. at Cincinnati in 1901 or 1902, we were all astonished at their size. Mr. Oberg has reported a tool cutting forgings at the rate of 500 ft. per min. It is purely a question of putting power behind a cutting tool, if it has been found that a material can be cut that fast. Mechanical ingenuity is not so limited but that enough power can be put behind the tool to get from it all that it can do. That means a revolution in machine-tool design, just as high-speed steel created a revolution nearly five years ago.

Die casting is another revolutionary process. There has been interesting work done around Bridgeport, Conn., on a principle, evolved by a Frenchman, of casting steel by centrifugal force. The centrifugal force acts to condense any material poured in the mold. Such a casting has much greater tensile strength than castings made without the centrifugal pressure. The developers claim to have demonstrated that they can cast any material in these molds and to quite large dimensions. This means a substitution of steel parts for iron. Of course the new parts will create a new demand for machine tools of some sort. These revolutionary processes and materials throw the doors of opportunity wide open to those who are able to enter. These are the user companies that have the money to buy the new machines, and the builders who have the money or credit to design the new machines that will take the high-speed cuts. The possibilities are something tremendous. It will do no good to complain about this condition; the thing to do is to recognize its possibilities and do everything to push it ahead and get the big market which it opens.

# Progress in Oil- and Gas-Power Engineering

## Contributed by the Oil and Gas Power Division

Executive Committee: E. J. Kates, *Chairman*, L. H. Morrison, *Secretary*, J. W. Morton, C. M. Manly, and H. A. Pratt

WHILE the preceding two or three years of oil-engine history were characterized by increasing compression pressures, 1927 has marked the beginning of what may prove to be a long struggle for higher speeds. The pressure increases that have taken place in recent years in several manufacturers' products were effected not so much with the aim for higher output as for the sake of convenience in operation. Cold starting was the object, occasionally also the elimination of water injection. As a result of this tendency, the low-compression or semi-Diesel engine which a few years ago represented the majority of oil-engine horsepower manufactured almost disappeared from the picture in 1927.

The present trend is unmistakably toward higher speed in order to obtain more power per pound of engine weight. The incentive is the conquest of the mobile field for the heavy-oil engine. The distinction of having attained the greatest recent progress therein belongs to the Diesel locomotive (4).[1]

### Diesel Locomotives

From a timid beginning a few years ago, we have at present an established type of switching locomotive in the United States, used by at least ten railroads and several industrial companies with satisfaction and effecting considerable saving (47). Orders have been placed for at least three main-line locomotives by at least two railroads (24), and their construction is nearly completed. Two destined for the New York Central are being built in this country and have electric transmissions. One of them will be equipped with a 6-cylinder, 750-hp., 500-r.p.m. Ingersoll-Rand solid-injection engine, the other with a 12-cylinder, 800-hp., 325-r.p.m. McIntosh & Seymour air-injection engine. The one to be delivered to the Boston and Maine Railroad is being built by the Krupp Company, Essen, Germany. It is to be equipped with a 6-cylinder, 1300-hp., 470-r.p.m. Krupp solid-injection engine, and has gear transmission with magnetic clutches.

In Europe not less than 19 companies are engaged in the construction of Diesel-engine locomotives and rail cars. Several of them have achieved notable commercial success (4). At least nine locomotives of the Canadian National Railways have been fitted with Beardmore engines (33) of 400 hp., 750 r.p.m., using electric transmission. Some of them have been in use for over two years and have exceeded a mileage of 100,000 without a refit. The British Company is now building 12-in. × 12-in., 12-cylinder V-type engines developing 1200 b.hp. at 750 r.p.m. with an overload capacity of 1500 b.hp. at 900 r.p.m. The complete engine weighs 22,000 lb. or about 18 lb. per hp. Such an extremely low weight for this type of engine is a truly remarkable engineering achievement. Two of these engines giving a total of 3000 hp. are now being built in one large locomotive, giving a tractive effort of 100,000 lb. and hauling a 750-ton passenger train at 70 miles per hour.

Engines built by a number of German Companies (M.A.N., Deutz, Benz, Krupp), and also several Italian (Fiat and Tosi) and Swiss (Sulzer) companies have been successfully installed recently in locomotives and connected with electric, hydraulic, pneumatic, and mechanical transmissions of a great variety (15). Perhaps the most interesting foreign development is the direct-driven Kitson-Still locomotive (26), the double-acting engine pistons of which are driven by the internal combustion of oil on one side and steam on the other: the steam is generated by the heat of the exhaust gases. It is not so much the high thermal efficiency of this combination which commends it for locomotive use, as it is the flexibility which the steam provides (and which the internal-combustion engine lacks) and makes the cumbersome transmission unnecessary. The French Schneider works (4) is also building a locomotive on this principle and the trials on both are awaited with keen interest.

Out of at least 17 different systems of transmissions which are being tried for oil-engine locomotives, only the electric drive has proved itself beyond doubt so far, but the developers of the other systems are busy and it cannot be predicted which one will be ahead 12 months from now. In spite of the considerably higher first costs of the oil-electrics, operating experience gained in the last two years (45) shows that the Diesel locomotive is more economical to operate than the steam locomotive.

### Automotive Diesels

For automotive application still higher speeds and lower weights are required. Last year's progress in this field includes the new Junkers (23), Benz (3), Dorner (29), and the improved M.A.N. (23) and Peugeot (9) truck engines, scores of which have already been installed and sold in Europe. These engines have crankshaft speeds of 1000 r.p.m. and over, and weights of around 20 lb. per hp. A M.A.N. three-ton truck with a modified piston (Acro patent) and injection system is being demonstrated here by the Robert Bosch Company (25), Long Island City. Its fuel economy is remarkable (about 0.6 cent per mile), while its flexibility and ease of handling leave nothing to be desired.

Among the other recent mobile and semi-mobile applications, the Caterpillar tractor, engined with a 75-hp., 650-r.p.m. Atlas Imperial Diesel (39), may be mentioned as a promising American development. High-speed engines recently developed by the Fairbanks, Morse & Company (40) [800 r.p.m., 12$^1/_2$ hp. per cylinder], Foos Gas Engine Company (10) [700 r.p.m., 80 hp. per cylinder], Cummins Engine Co. (42) [600 r.p.m., 12.5 hp. per cylinder], Bessemer Gas Engine Co. (43) and Hill Diesel Engine Co. (28) open the field for still wider use of the oil engine for dredging, excavating, road construction, small boats, and rail cars. The Treiber Company together with the American Brown Boveri Corporation are developing high-power light-weight engines, one of them being of the 9-cylinder radial type.

Besides those already mentioned at least six American companies, mostly manufacturers of gasoline engines, are, it is rumored, engaged in developing automotive oil engines, and we may be able to report definite accomplishments next year.

For aircraft application (2) the weight becomes of predominant importance. Although its higher thermal efficiency and reduced fire danger are in favor of the heavy-oil compression-ignition engine and its development is being pushed by the American and English governments, its use cannot become general before the engine weights are brought down to figures which compare favorably with those of gasoline engines. It may be added, however, that no principal reason is known why engines working

[1] Figures in parentheses refer to references listed in the Bibliography.

on the Diesel principle cannot equal or excel carburetor engines in power output per pound of engine weight. On this continent the Attendu engine (6) [3.6 lb. per b.hp.] and the Sperry supercharged engine (5) represent promising experiments. Abroad, Junkers is planning on fitting his airplanes with his two-cycle, opposed-piston-type engines, and one of the new British dirigibles will be fitted with Beardmore engines, if rumor is correct.

### Giant Diesels

Looking at the other end of the picture, the progress made in high-powered Diesels is no less gratifying. Shipbuilders are the best customers for large Diesels. The increased popularity of the Diesel with ship owners is shown by Lloyd's figures. On September 30, 1,163,630 i.hp. of marine oil engines were under construction against 568,969 i.hp. of reciprocating steam engines and 309,900 hp. of turbines. Oil-engine tonnage increased to $52^1/_2$ per cent from $19^1/_2$ per cent four years ago. From a spectacular standpoint the most outstanding installations were single engines of the Doxford opposed-piston airless-injection type, 5000 screw hp. in four cylinders, in two single-screw vessels; and single engines of the Burmeister & Wain double-acting four-cycle type, 9000 screw hp. in eight cylinders, in three double-screw vessels. The latest set of these, installed in the *Saturnia* (44), is supercharged with two electrically driven turbo-blowers, which increases the output of each engine to 10,000 screw hp. The *Augustus* (35), the largest motorship in the world, 33,000 gross tons, equipped with four M.A.N. engines, 700 screw hp. each, has made her maiden voyage this November. The largest cylinder output ever attained was obtained this year from a Sulzer experimental one-cylinder engine, delivering 2900 i.hp. (46).

In this country several more Shipping Board vessels were converted into motorships (10). Nine main and 27 auxiliary engines were tested and delivered by six companies during the last fiscal year. Contracts have been awarded recently for the construction of eight more engines of about 4000 hp. to four different companies. Two are two-cycle single-acting, four are two-cycle double-acting, and two are four-cycle double-acting. The contracts are on the basis of $74 per b.hp., including scavenging blowers.

In the stationary field more high-powered Diesels are being installed in electric central stations. In the Commerce Mining and Royalty Plant in Oklahoma, three Nordberg two-cycle engines have been installed totaling 6750 b.hp. The favorable experience with the 15,000-hp. Diesel engine installed in 1926 for the Hamburg Electrical Works induced a Berlin electric-power company to place orders with M.A.N. for two 10-cylinder 12,000-hp. engines, 215 r.p.m. (21.3 ft. per sec. piston speed) to be used as stand-bys. America's largest Diesel power plant, the Panama Canal plant at Miraflores (27), consisting of three single-acting two cycle Nordberg engines and having a peak-load capacity of 12,375 hp., has been completed this year and serves a similar purpose.

### Diesels for Peak Power

It is readily admitted that unless favored by particular local conditions, the Diesel engine cannot compete with steam and water turbines for large power generation. On the other hand, both calculations and experience have shown convincingly that their combination with steam and water power for peak loads and emergencies offers decided economical advantages (11). For short-period operations, the higher fuel cost of the Diesel is more than offset by its lower interest on first cost compared with water power and by its lower cost of keeping it prepared for emergency, compared with steam power. The water-power central station at Bremen installed two 3000-hp. Sulzer Diesel units to cooperate with water turbines. The 4500-hp. Diesel set of the Société des Forces Motrices du Refrain operates satisfactorily together with water and steam turbines. The possibilities of the Diesel engine for central stations are not yet fully realized (19).

### Continuous Production

In medium-size engines, so far as design is concerned, no striking progress made in the last twelve months can be recorded. Many of the new models recently introduced in this country are licensed by foreign patent owners. Among the recent changes the popular adoption of the box frame and the improvement of the exterior appearance of the engines are most noticeable.

On the other hand, more and more engineering skill is being applied to production. Refined finishing methods are finding their way into Diesel machine-shop practice. Grinding and honing of cylinders, broaching of wristpin bushings, and lapping of spray needles, pump plungers, and even valve seats are used with success.

Larger builders have made progressive steps toward continuous production of engine units, using interchangeable parts, conveyors, and systemized material-handling methods.

The manufacture of small- and medium-size gas engines has lost its significance since the advent of the gasoline and Diesel-type engines. Where industrial gas is available as a by-product of blast-furnace and steel-mill operations, large gas engines are still most economical generators of power. The Allis-Chalmers Company is building gas engines in units up to 4000-hp.

### Accessories

Many good accessories which have recently been placed on the market, either increase the usefulness of oil engines or relieve their builders from making such items themselves. Air and oil filters, centrifuges for lubricating and fuel oil, charging and scavenging blowers, distant-reading cooling-water and exhaust thermometers, and high-speed indicators are only a few of a worthy list. Fuel pumps and spray nozzles were not considered accessories until recently, yet at least one foreign and one American manufacturer are contemplating manufacturing these delicate engine parts and selling them to the oil-engine builders. Such a specialization in manufacture will probably further reduce the cost and increase the utility of the oil engine.

### Trend of Design

While accurate figures are not easily obtainable, the trend is unmistakably toward hydraulic (solid) injection. Out of the total horsepower of stationary engines built in this country, 53 per cent was of the airless-injection type in 1924, 56 per cent in 1925, and 58 per cent in 1926, excluding the low-compression engines (3). In Germany and England this trend is still more pronounced. Hydraulic injection is not yet generally applied to the largest sizes, but Doxford and Burmeister & Wain have recently built airless-injection engines with 1250- and 1125-b.hp. cylinder capacities, respectively. It is being tried experimentally both on the Sulzer double-acting engine and on the Harland-B.W. design.

The struggle between two-cycle and four-cycle is still undecided. The respective figures for American stationary engines for the last three years are as follows:

| | 1924 | 1925 | 1926 (Estimated) | |
|---|---|---|---|---|
| Two-cycle...... | 42 | 51 | 49 | Per cent of total horsepower |
| Four-cycle..... | 58 | 49 | 51 | |

In marine application the two-cycle seems to gain over the four-cycle, while for locomotives the opposite is the case.

The most spectacular advance, however, has been made by the double-acting principle. Not long ago double-acting engines were considered experimental, but now there are six different makes of double-acting engines in operation at sea and five more in a very advanced degree of development. Perhaps one reason why shipowners favor the double-acting two-cycle design is because it resembles most the familiar reciprocating steam engine.

As regards construction, a trend toward more rigid frames is noticeable. The A-frame is being displaced by the box frame with individual or cast-in-block cylinders. Rigid connections between the individual cylinders or cylinder heads frequently serve the same purpose. The reduced vibration and bearing wear achieved with the rigid construction justify the additional expense.

The chain drive of the camshaft, introduced not long ago, has won further adherents.

The use of aluminum and alloys for pistons is being tried with promising results. The use of high-grade materials for other engine parts together with refined finishing methods is also progressing, especially with high-speed machinery.

Efforts are being made to secure higher mean effective pressures for two-cycle engines. Crankcase scavenging is slowly losing ground, while the use of blowers is gaining for both charging two-cycle and supercharging four-cycle engines. At present the employment of blowers is restricted to large engines, but their introduction for medium and small engines is predicted.

In the controversy over direct spray injection as against a precombustion chamber, both parties are holding their ground, and no gain for either can be recorded.

New injection systems are still being introduced and a perplexing number of varieties are already available. Some of those recently developed take a middle place between the direct pump injection and the accumulator (common rail) system, by accumulating with each pump stroke only fuel enough for one injection, and using a mechanically operated valve for timing the injection.

The possibility of controlling turbulence by directing the intake air has been firmly established by the Hesselman, Krupp, Junkers, and Langley Field experiments, proving conclusively that the rotation of the air is not killed by the compression. German designers have already taken advantage of this fact, apparently with good results.

By supercharging with the Büchi system (45) using exhaust turbines for driving the blowers, the Swiss Locomotive Works has succeeded in increasing the rating of a four-cycle engine by not less than 50 per cent without any increase of the exhaust temperature, if reports are reliable.

## Research

The oil-spray investigation of the National Advisory Committee for Aeronautics at Langley Field is yielding results. The subjects investigated lately and reported upon by the committee are: An investigation of the coefficients of discharge of liquids through small, round orifices, by W. F. Joachim (48); some factors affecting the reproducibility of penetration and the cut-off of oil sprays for fuel injection, by E. G. Beardsley (49); and factors in the design of centrifugal-type injection valves for oil engines, by W. F. Joachim and E. G. Beardsley (50). Experiments with various compression chamber designs (31) and novel injection nozzles are in progress, and favorable reports will probably soon follow.

As a result of the oil-spray research at the Pennsylvania State College (34) the development of an electric recording multi-diaphragm-type oil-pressure indicator has been reported (39), by which oil-pressure fluctuations of several thousand pounds taking place in a few thousandths of a second have been recorded and time-pressure diagrams taken.

Some experiments on oil jets and their ignition have been carried out by A. L. Byrd (17) at the University of Cambridge, using square orifices for injection of the fuel.

In Germany, elaborate investigations have been conducted for the determination of the globule sizes of atomized oil sprays. Kuehn counted the number of globules received on a smoked-glass plate, Sauter (21) used light absorption and also an electric charging method to determine the average size of the particles, and Wöltjen (2) injected the fuel into a non-miscible liquid of the same density and photographed the drops thus obtained.

The ignition of oil sprays has been investigated by Neumann (13) and Sass (41). The old dispute whether or not evaporation is essential for the ignition of liquid fuel, seems to be settled in favor of the latter.

Interesting temperature measurements on an Acro engine have been made by Stribeck (32). The interpretation of his results, however, is still the subject of lively discussions.

The Marine Oil Engine Trials of the Institution of Mechanical Engineers (20) have cleared in five reports many doubtful points in regard to the adaptability of the oil engine to ship propulsion.

The scavenging of two-cycle engines has received additional attention. Tests on a crankcase-scavenging engine have been reported by Holm (36). Many others are being kept secret.

Most of the investigations mentioned are being continued and further results are expected in the near future. The "secondary discharges" of automatic nozzles pointed out first by Eichelberg (14) and experimentally observed by Beardsley may clear up the problem of the so-called "after dribbling."

Investigations in the direction of increasing the speed and the m.e.p. are being quietly carried out in manufacturers' laboratories.

As to fuel economy, 0.354 lb. per b.hp-hr. has been reached (30), and 0.3 lb. per b.hp-hr. is being predicted by an English authority.

Of the researches in allied fields, the production of synthetic fuels and the nitration process invented by the firm of Krupp, by which steel on the surface is made as hard as quartz and not deformed, may have important consequences on the development of oil engines.

## Activities of the Industry

Oil-engine business in general was not particularly brisk during the last twelve months. Production was kept up fairly well, but the profit sheets show a decline. Yet more and more capital is flowing into the industry due to the increased interest in Diesel engines. The Conversion Program of the Shipping Board calling for an expenditure of $25,000,000 gave a healthy impetus to the industry. Out of this sum $2,783,256 was spent in the fiscal year preceding June 30, 1927, and $2,290,300 worth of engines has been contracted since.

The Oil Power Week, held April 18–23 under the auspices of the A.S.M.E. and six other engineering societies, focused general attention on the production of power by the use of oil, by means of simultaneous meetings, discussions, and publicity. One hundred and six meetings were held throughout the country, and many valuable papers presented. The $100 Rudolph Diesel prize was awarded to W. F. Joachim of Langley Field Memorial Aeronautical Laboratory for his paper entitled "Oil Spray Investigations of the National Advisory Committee for Aeronautics" which was presented at the Oil Power Conference at The Pennsylvania State College, State College, Pa., and will be published later in the Oil and Gas Power Division's Quarterly. [See Trans. A.S.M.E., vol 50 (1928), no. 1, paper no. OGP-50-6.]

## The Needs of the Industry

This report would be incomplete if it ignored certain handicaps the industry is confronting. Diagnosing a disease always

helps to find the proper cure. It would perhaps be futile to deny that our oil-engine industry is not taking the place that it rightfully deserves. On September 30 out of 1,163,630 i.hp. of marine oil engines under construction in the world, only 13,090 were being built in the United States, compared with 365,440 in Great Britain, 244,370 in Germany, and 157,850 in Italy. It is true also that fewer ships were under construction in this country than in those mentioned, but certainly not less than in Switzerland. Yet Switzerland is building $6^1/_2$ times as many (85,000 i.hp.) marine Diesels as we are. As stated before, $52^1/_2$ per cent of the merchant vessels under construction in the world are motorships, but only 14.4 per cent of the American tonnage. With 76 per cent of the world's petroleum produced in this country, it is very safe to say that less than 10 per cent of the oil engines are made here. The 1926 exports in Diesel and semi-Diesel engines amounted to less than three million dollars, while in metal-working machinery it exceeded eighteen million. For other countries the proportion would be more nearly the reverse.

Production costs are high, selling costs are high, the competition of the electric-power companies is destructive, the power users have not sufficient confidence in oil engines—these are the explanations most frequently offered, but none of them is of such a nature that the manufacturers cannot do anything about it. A closer cooperation between the engine builders would accomplish a great deal in the direction of reducing selling costs and enlarging the market by an intelligent and systematic education of the power users as to the economic possibilities of the oil engine. Research, preferably cooperative research, would help to produce more efficient engines. We have heard from D. R. Pye, the English authority, just a few days ago that "a great deal of further research with the jerk pump is needed to place the designer in a position to know what are the characteristics of the jet he is producing." The cut-and-try method which is being practiced now is the most expensive of all, and will continue to be as long as we are in the dark as to the fundamentals.

Reduction in production costs could be achieved by specialization and adoption of modern production methods. The "part maker," a familiar figure in the automobile industry, has a justified place in the oil-engine industry as well. Few oil-engine builders are equipped to produce high-quality pistons, fuel pumps, and injection nozzles economically. Making fewer parts in larger quantities, we shall be able to adopt methods of quantity production: interchangeability, the use of jigs, fixtures and rapid-inspection gages; adopt continuous synchronized production, and do away with chalk and file and large-part storage.

The industry needs more trained men. In connection with oil engines, more than in most other fields, we formerly depended on men trained abroad. With immigration largely cut off, a shortage is being felt. A greater supply of skilled oil-engine operators would undoubtedly improve the market. Each competent operator helps to turn the sentiment in favor of the Diesel engine and is undoing some of the wrong done in the past by the many incompetent Diesel operators. We need more factory men skilled in erecting Diesel engines and machining delicate engine parts. We need more field service men able to diagnose troubles and give proper service to customers. We need more engineers trained in the design and developments of Diesel engines, men with sufficient theoretical background and some familiarity with the work that has already been done on the subject. Too often we see costly duplication of mistakes that could easily be avoided. Our technical schools do not give proportionate attention to the teaching of internal-combustion engines. If the oil-engine manufacturers would fall in line with the others in cooperating more closely with the colleges and universities, more emphasis would be laid upon oil engines and more students would be interested in the subject.

### The Outlook

From this survey it appears that the outlook for the future is nothing but promising. The oil-engine industry, which survived in spite of the numerous handicaps, may look for something better if the handicaps are removed. Technical progress is satisfactory, and with intelligent effort it will be accelerated. A tremendous market is here, of which only a small fraction has been exploited so far. There is room for every one. We have little doubt that we shall see a spectacular expansion of the oil-engine industry in the near future. We wish that a happy and prosperous New Year may mark the beginning of it.

The undersigned wishes to acknowledge his indebtedness to all those companies and individuals that have submitted information and thus assisted in preparing this Report.

P. H. Schweitzer.

# Experimental Combustion Chambers Designed for High-Speed Diesel Engines

By CARLTON KEMPER,[1] LANGLEY FIELD, HAMPTON, VA.

*In this paper the preliminary requirement of the high-speed fuel-injection-engine problem is given, and analyses of the cycles used in this type of engine are included. There is also given a discussion of the effect of increasing speeds on the output of engines employing these cycles. The requirements of combustion chambers are set forth and results of experiments using three different types are given. The engine and testing apparatus are fully described and illustrated, and curves showing the performance of the engine when equipped with each of the special types of chambers are also shown.*

THE DESIGN of combustion chambers to meet the requirements of high-speed Diesel engines forms a part of the National Advisory Committee for Aeronautics' research program on the fundamental principles of fuel-injection engines. An outline of the proposed research on aircraft-type fuel-injection engines was prepared in 1920 at the request of the Bureau of Engineering of the Navy Department, which was interested in the development of these engines as power plants for large airships. Since that time progress has steadily been made toward the development of a high-capacity fuel-injection engine for aeronautical use.

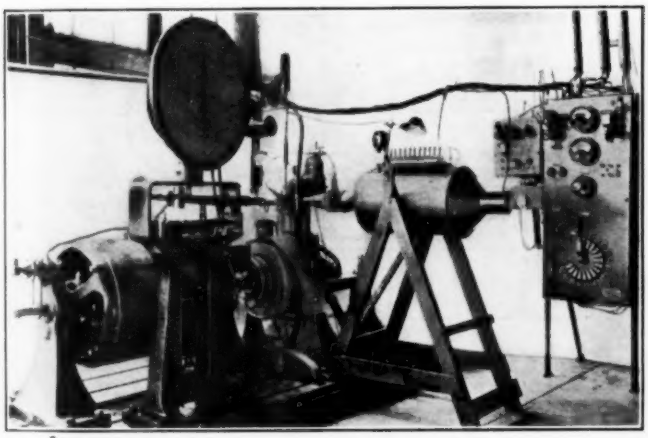

FIG. 1 ARRANGEMENT OF TEST ENGINE AND APPARATUS

In order to compete with present-day carburetor engines, it is necessary that the weight-power ratio of the fuel-injection engine be reduced from 25 lb. per hp. to a value of approximately 3 lb. This reduction in weight may be brought about by increasing the speed of the fuel-injection engine from the relatively low speeds of 300 to 600 r.p.m. to a speed of 1800 r.p.m. The attainment of this engine speed in a fuel-injection engine is complicated, however, by the problems of spray distribution and atomization, turbulence, and the time required for vaporization and ignition of the fuel. Consider a four-stroke-cycle engine running at 1800 r.p.m. and having an injection interval of 30 deg. The time corresponding to this interval of injection is approximately 0.003 sec. The time lag of ignition, as determined for slow- and medium-speed fuel-injection engines, depends upon the combustion-chamber design and the type of fuel-injection system, an average value, however, being approximately 0.020 sec. If the capacity of the fuel-injection engine is to be increased at high engine speeds, then it is necessary that the time lag for ignition be shortened or the entire charge of fuel will be injected into the cylinder and combustion will take place at constant volume with resulting excessive explosion pressures.

A preliminary requirement of the high-speed fuel-injection-engine problem is the selection of a possible engine cycle to give high efficiencies without requiring excessive cylinder pressures. An analysis of the Otto or constant-volume cycle shows that its use with compression pressures sufficiently high to cause auto-ignition of the fuel presents difficulties, due to the resulting high explosion pressures. An analysis of the Diesel or constant-pressure cycle shows that the cut-off ratio, which is defined as the ratio of the volume of the cylinder contents at cut-off to the clearance volume, to give the required mean effective pressure would result in values greater than 2.00. At high engine speeds this value of cut-off ratio would probably result in after-burning, with excessive fuel consumptions. The limitations of the above cycles have led to the adoption of the dual combustion cycle, in which a small portion of the fuel charge burns at constant volume and the remainder at constant pressure.[2]

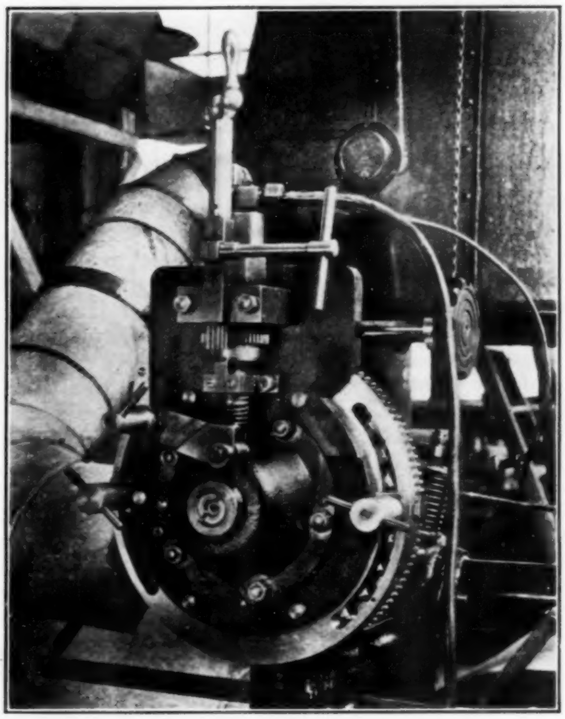

FIG. 2 CAM-ACTUATED FUEL-INJECTION PUMP

[1] Junior Mechanical Engineer, National Advisory Committee for Aeronautics.

Contributed by the Oil and Gas Power Division and presented at the Spring Meeting, White Sulphur Springs, W. Va., May 23 to 26, 1927, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

[2] "Thermodynamic Cycles in Relation to the Design and Future Development of Internal Combustion Engines," William J. Walker, Ph.D. Proceedings of the Institution of Mechanical Engineers, vol. 2, p. 1235, 1920.

This cycle is approximated in several large, low-speed oil engines. In operation these engines burn a small part of the fuel charge at constant volume, which raises the pressure and temperature enough to burn the remainder of the fuel charge at constant pressure.

Before high-speed fuel-injection engines can be built to run on the dual combustion cycle it is necessary that the fuel system

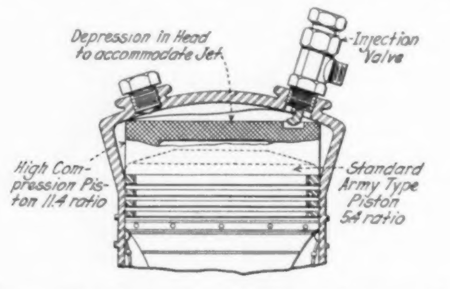

Fig. 3 Combustion Chamber of Standard Liberty Cylinder As Used for Fuel-Injection Research

so prepare the fuel that it will ignite almost instantly on injection. If the fuel charge injected by the valve has no time lag of ignition, then the principal requirement of the combustion chamber is to produce enough turbulence to cause complete combustion of the fuel. This is somewhat of an ideal condition, since the fuel injected at present is not a vapor but an atomized liquid.

Because of the time lag of ignition of the fuel with present

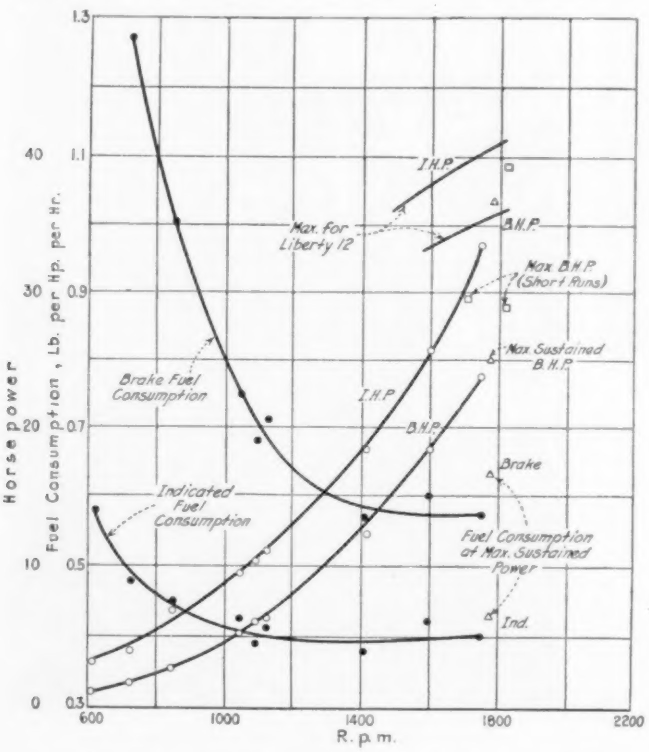

Fig. 4 Single-Cylinder Liberty Engine, Compression Ignition, Fuel Consumption at Part Loads

(Propeller load, 24 b.hp. at 1750 r.p.m. taken as normal. Lip-nozzle diam., 0.18 in.; compression ratio, 11.4:1; Diesel-engine oil.)

fuel-injection systems, the injection of the complete fuel charge into a high-speed engine results in substantially constant-volume combustion of a large part of the fuel charge, resulting in explosion pressures which may exceed 1600 lb. gage. In order to avoid these excessive explosion pressures many engine designers use a precombustion chamber in which the fuel is partially burned, further combustion of the fuel taking place in the cylinder proper. The connecting neck or orifice between the two chambers is proportioned to meter the products of the partial combustion in the precombustion chamber to obtain constant-pressure combustion in the cylinder.

This method of metering the burning gases to give combustion at constant pressure is not thought to be the solution of the fuel-injection problem for high-speed fuel-injection engines. Although the precombustion chamber makes possible the burning of heavy fuel oils without admixture of a volatile element, the use of the orifice at high engine speeds increases the thermal and reduces the mechanical efficiency of the engine. It may be shown that the use of the orifice results in the following losses: First, a friction or pumping loss of the gas due to forcing it through the orifice at high velocity; second, a loss in piston pressure caused by the lag of the gas pressure; and third, an increase in the heat loss to the jacket water, due to the scrubbing action of the gases. The use of the orifice, however, makes possible the attainment of a high degree of turbulence and improved

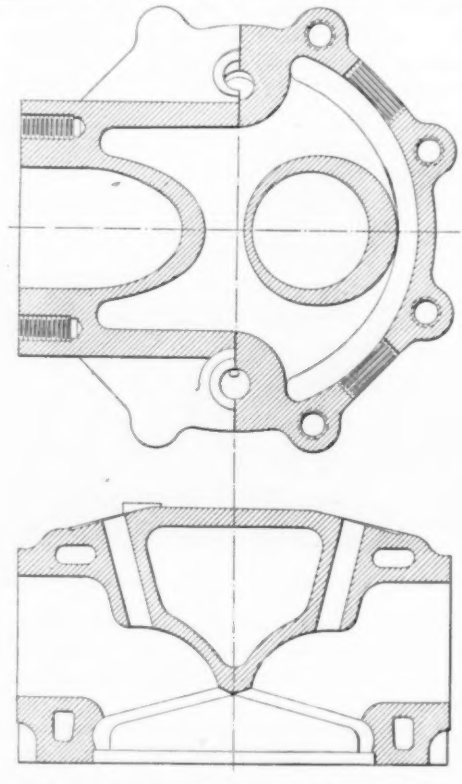

Fig. 5 Combustion-Chamber Design No. 1

combustion efficiency. This improvement in efficiency is shown by the lower fuel consumption when taken on an indicated-horsepower basis.

## Requirements of Combustion Chambers

The type of combustion chamber having the lowest heat losses is that presenting the least surface area for a given volume. If this were the only requirement it would lead to the design of spherical combustion chambers. For actual engine operation, however, there are other requirements, such as provision for turbulence, location of valves, simplicity, and ease of construction, which prohibit the use of the spherical combustion chamber.

In the design of combustion chambers for high-speed fuel-injection engines the most important requirements are, first, that the fuel spray shall be completely distributed throughout the combustion chamber, and second, that the degree of turbulence shall be sufficient to produce complete burning of the fuel in the short time available. It is only recently that reliable data have been obtained as to the behavior of fuel sprays when injected into gases under pressure. The data obtained by the National Advisory Committee for Aeronautics in its investigation of oil sprays for fuel-injection engines, by means of ultra-high-speed photographic apparatus, enable the combustion chamber to be designed to fit the fuel spray. The other requirements for fuel-injection-engine combustion chambers are the same for any type of combustion chamber. Thus the combustion chamber must be designed mechanically strong enough to withstand the explosion pressures. It must also give a rapid dissipation of heat and prevent large differences in temperature which may lead to cracking of the cylinder head. Particular attention should be given to the location of the inlet valve to provide an unobstructed flow of the air into the cylinder.

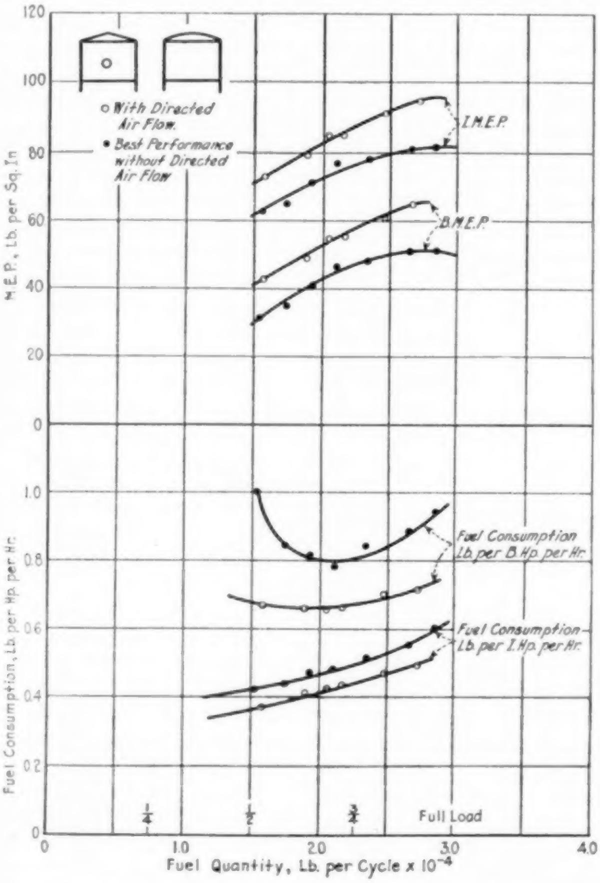

FIG. 6 FUEL-INJECTION PERFORMANCE, LIBERTY TEST ENGINE, COMBUSTION CHAMBER NO. 1, HAVING DIRECTED FLOW OF INLET AIR

(Maximum explosion pressure, 800 lb. gage; speed, 1500 r.p.m.)

Some of the successful commercial fuel-injection engines have obtained the necessary turbulence by reducing the cross-section of the combustion chamber for a short distance and then enlarging it into a bulb-shaped chamber containing the inlet and exhaust valves and the fuel-injection valve. The flow of gas through the connecting orifice produces a high degree of turbulence, and if the entire charge of air is placed within the bulb when the piston is on top center, the degree of combustion obtained is usually good.

### Description of Engine and Apparatus

The engine tests which determine the performance of a given design of combustion chamber are made at the Langley Memorial Aeronautical Laboratory of the National Advisory Committee for Aeronautics on single-cylinder test engines having a 5-in. bore and a 7-in. stroke. The engines are coupled to 50–75-hp. electric cradle-type dynamometers. The cylinder heads are bolted to special steel cylinders which in turn are fastened to the engine crankcase. The test engines use standard airplane-engine valves, pistons, and connecting rods. Arrangements are provided to maintain fuel-oil and water temperatures at constant values. A general view of one of the engines and test apparatus is shown in Fig. 1.

The fuel-injection system of this engine comprises, at present, a primary gear pump supplying oil at 90 lb. per sq. in. gage pressure to a cam-actuated impact type of injection pump, Fig. 2, and an automatic fuel-injection valve. The opening pressure and design of the fuel-injection valve control the pressure within the injection pump. The type of valve determines the necessary opening pressure, and for the present work, using a spring-loaded injection valve, the static opening pressure is 6000 lb. per sq. in. gage. The valve is so designed that the maximum injection pressure is also approximately 6000 lb. gage. The fuel used is a grade of Diesel fuel oil having a specific gravity of 0.847 at 80 deg. fahr.

The engine power is determined by means of a torque scale and a magnetically operated stop watch and counter. The fuel consumption is obtained by timing, with a stop watch, the flow of 200 cc. of fuel. The quantity of fuel delivered by the pump for any given pump adjustment may be determined from the total number of engine cycles passed through during the time the 200 cc. of fuel is burned.

The maximum cylinder pressures have formerly been determined by the use of a balanced-valve type of pressure gage. This has been replaced, however, by a diaphragm type of valve which is operated by the pressure of the gases within the cylinder. The pressure of the cylinder gases trapped above the diaphragm is indicated by a calibrated pressure gage. Engine tests have shown that it is unnecessary to provide means for cooling the diaphragm of this type of cylinder-pressure indicator. To obtain satisfactory results, however, the diaphragm of this gage must be protected from the formation of excessive carbon deposits.

### Combustion Chambers

For the preliminary testing of the operation of airless-injection engines at high speeds a standard Liberty aircraft-engine cylinder was used and fitted with a special aluminum piston to give a compression ratio of 11.4 to 1. The fuel pump used with this cylinder was designed to give a constant rate of injection independent of the engine speed. The combustion chamber is outlined in Fig. 3, and it may be noted that it was difficult to arrange a suitable fuel-injection valve to reach all the air in the combustion chamber. When operating under power it was found necessary to inject the fuel charge into the cylinder 50 deg. before top center in order to obtain reasonably good combustion. This long interval between injection and burning of the fuel charge resulted in explosion pressures of 1300 to 1600 lb. gage. The life of the aluminum pistons when operating under the above conditions was found to be very short. The force of the explosion either cracked the piston crown or the piston-pin bosses. Sufficient data were obtained, however, to indicate the possibilities of running fuel-injection engines at high speeds.

The curve of Fig. 4 indicates the power output and fuel economies obtained with the standard Liberty cylinder and a special piston giving a compression ratio of 11.4:1. It may be noted that the power output is 34 per cent less than that obtained per cylinder by the Liberty engine at a speed of 1750, and the fuel economy, 0.53 lb. per b.hp-hr., is 0.03 lb. per b.hp-hr. more than that obtained in the Liberty.

### Cylinder Head No. 1

The first combustion chamber designed for fuel-injection work is shown in Fig. 5. This design was recommended for test because of its uniform shape and simplicity of design. Due to the Liberty type of valve mechanism used on the test engine, it was

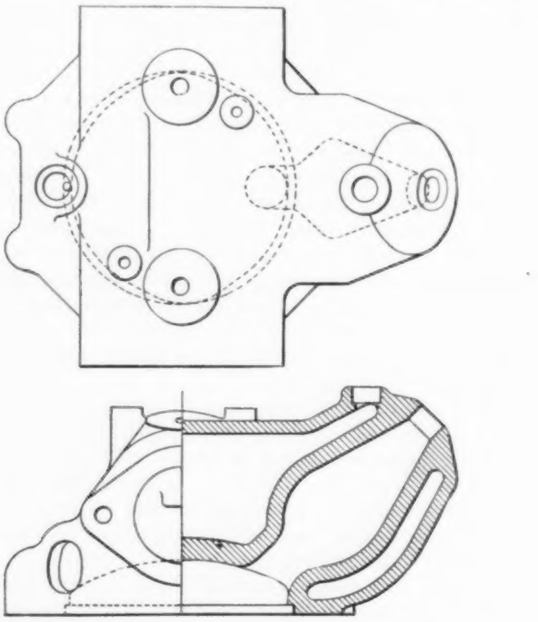

Fig. 7 Combustion-Chamber Design No. 2

impossible to place the fuel valve centrally in the combustion chamber. The only suitable fuel valve that could be used with this combustion chamber was one having an impact surface which produced a flat, fan-shaped spray of fuel. This cylinder head was tested with a standard Liberty Navy piston giving a compression ratio of 12.7 to 1.

This type of combustion chamber when fitted with a spring-loaded fuel-injection valve and an impact type of cam-operated fuel-injection pump gave poor performance. It was found possible, however, to vary the injection timing and to maintain maximum explosion pressures of 800 lb. gage. The performance with this type of combustion chamber was an improvement over that of the standard Liberty cylinder, in that the operation of the engine was smoother and no trouble was experienced with cracking of the standard aircraft aluminum pistons.

The experiment was tried of improving combustion by directing the flow of the inlet air through the inlet valve. The curves in Fig. 6 give the performance of this combustion chamber with and without directed air flow. It may be noted that it was found possible by directing the flow of the inlet air to increase the indicated mean effective pressure (i.m.e.p.) from 82.0 to 96.0 lb. gage with a corresponding decrease in the fuel consumption from 0.60 to 0.51 lb. per i.hp-hr. This increase in performance, obtained by directing the flow of the inlet air toward the fuel-injection valve, was thought to be caused by the complete removal of the products of combustion surrounding the fuel valve. The fuel, therefore, was injected into a charge of relatively pure air which gave improved combustion.

### Cylinder Head No. 2

Fig. 7 shows the outline of the first type of combustion chamber used having a bulb type of precombustion chamber. This cylinder head was fitted with a standard Army type of Liberty piston arranged to give a compression ratio of 9.9 to 1. The corresponding low-compression pressure of 280 lb. gage made for difficulty in starting from cold, and it was necessary to heat the jacket water or to preheat the inlet air.

As shown by the performance curve in Fig. 8, the combustion chamber, when fitted with an eccentric-driven fuel-injection pump and a diaphragm-type fuel-injection valve, gave better performance than either of the other two tested. The brake mean effective pressure (b.m.e.p.) at full load, which is considered as the fuel weight giving 15 per cent excess air, and 1800 r.p.m.

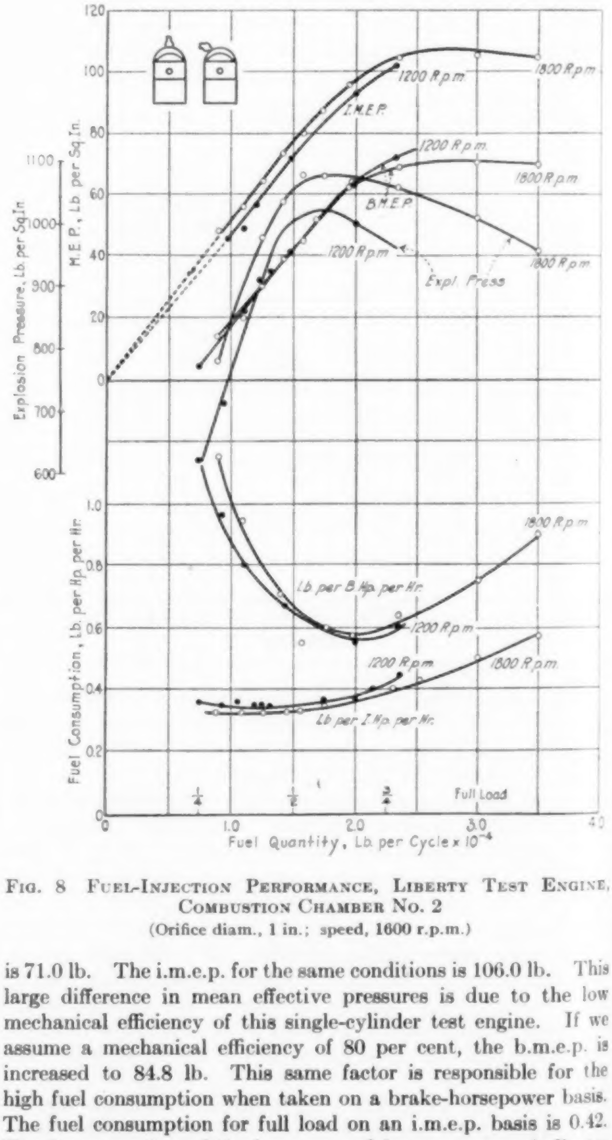

Fig. 8 Fuel-Injection Performance, Liberty Test Engine, Combustion Chamber No. 2
(Orifice diam., 1 in.; speed, 1600 r.p.m.)

is 71.0 lb. The i.m.e.p. for the same conditions is 106.0 lb. This large difference in mean effective pressures is due to the low mechanical efficiency of this single-cylinder test engine. If we assume a mechanical efficiency of 80 per cent, the b.m.e.p. is increased to 84.8 lb. This same factor is responsible for the high fuel consumption when taken on a brake-horsepower basis. The fuel consumption for full load on an i.m.e.p. basis is 0.42. The linear portion of the b.m.e.p. and i.m.e.p. curves indicates that for a fuel quantity of less than 0.0002 lb. per cycle, combustion is practically complete. For fuel quantities greater than this, however, the curves tend to flatten, which indicates that

the air within the cylinder is not supporting efficient combustion of the injected fuel. The curve of maximum pressures shown was plotted from data obtained with a balanced-valve type of maximum-explosion-pressure indicator. The ball of the indicator was balanced with nitrogen gas.

### Cylinder Head No. 3

A third type of combustion chamber was designed to give a high degree of turbulence within the pear-shaped bulb on the compression stroke and within the cylinder on the expansion stroke. This high degree of turbulence was obtained by locating the $^9/_{16}$-in. orifice to direct the air flow tangentially into the bulb and also produce a tangential discharge of the products of the partial combustion within the bulb into the cylinder. The ratio of the volume of air in the bulb to the volume of air in the cylinder was approximately 1 when the piston was on top center. This head was tested with a compression ratio of 13.5 to 1, the compression pressure obtained in the engine being 450 lb. gage. The operation of this combustion chamber under all loads was smooth and regular. For full-load operation at 1800 r.p.m. the b.m.e.p. with a mechanical efficiency of 80 per cent was approximately 85.0 lb. The corresponding fuel consumption was 0.60 lb. per b.hp-hr.

Tests have shown that the power output may be increased approximately 8 per cent by rounding the orifice edges and flaring it to discharge the burning gases over one-half the piston area. Results indicate that flaring the orifice has permitted the fuel from the bulb to reach more of the air in the cylinder.

### Conclusions

In conclusion it may be said that the performance of combustion chambers designed to give partial combustion and a controlled amount of turbulence, indicates that it is possible to increase the r.p.m. of the fuel-injection engine without encountering excessive explosion pressures. The tests completed emphasize the fact that an increase in capacity of the high-speed fuel-injection engine depends upon the ability to obtain higher mean effective pressures and an improvement in the mechanical efficiency of the engine.

Increasing the mean effective pressure above its present relatively low value, as compared with the carburetor engine, depends primarily upon complete mixing of well-atomized fuel with the air charge and the reduction of the time lag of ignition. The required amount of turbulence to give complete mixing of the fuel and air may be obtained by the design of the combustion chamber. It is believed, however, that the necesssry reduction in the time lag of ignition can only be brought about by better preparation of the fuel charge before injection into the engine.

The problem of increasing the mechanical efficiency of the engine and reducing its weight may be solved by an application of the engine design and construction principles of the aeronautic engine.

## Discussion

Robertson Mathews.[3] The limitations of our engineering diction are so often encountered that the writer feels inclined to take exception to the title of Mr. Kemper's paper. He would like to see "airless-injection" substituted for "Diesel." It is particularly important that papers of this character bearing on engine development contain no false terminology. Future research workers may come to doubt the value of records in which engines that use no air for injection and operate either on the Otto or else the dual combustion cycle, have been called Diesels. The fame of Dr. Diesel requires no false diction.

[3] Detroit, Mich.

One note that is struck in this paper is particularly pleasing, namely, the considerable emphasis of the weak points of the problem. Still more stress could probably have been placed upon the disadvantages of the bulb design. Since the size of engine under consideration is likely to be called upon to serve a field requiring wide flexibility, the self-timing of the fuel distribution by the bulb is not attractive.

The loss of effective effort upon the piston owing to the restricted flow of gases through the neck of the bulb, is an item that has appealed to the writer's curiosity for a long time. On the one hand there is a piston that is moving relatively slowly compared with the nozzle velocity of gases. On the other hand there is the differential pressure through the neck required to produce a gas velocity sufficient for the gas to follow the piston. A discussion with numerical determinations for this problem might be of interest.

Since the data show that the engine was operated at as widely different speeds as 1200 and 1800 r.p.m., it is regretted that the paper could not have been of sufficient length to qualify further some important statements. Under "Description of Engine and Apparatus" the author states that the valve is so designed that the maximum injection pressure is also approximately 6000 lb. gage. Either a highly interesting nozzle has been designed or the stated pressure applies to some particular r.p.m. In the second paragraph of the paper we read: "The time lag of ignition, as determined for slow- and medium-speed fuel-injection engines, depends upon the combustion-chamber design and the type of fuel-injection system, an average value, etc." This statement seems worthy of more attention in view of a later statement. Among the conclusions, we read: "It is believed, however, that the necessary reduction in the time lag of ignition can only be brought about by better preparation of the fuel charge before injection into the engine." This is a strong statement. It appears like a veiled recognition of the limitation of the time required for vaporization. Having arrived thus far the writer would like to see the N.A.C.A. attack with vigor the problem of the determination of the time limits to the rate of fuel vaporization.

Alan E. L. Chorlton.[4] With regard to smaller engines running at high speed, the opportunities of varying the form of the combustion chamber are really very small, and the Akroyd-Stuart type with reduced connecting duct between the chamber and the cylinder proper is hardly admissible, because the air outside the combustion chamber, as it cannot be all attacked or fuelized by the injection fuel, brings of necessity results with this type of chamber which have lower mean pressures than the plain type, that is, as in design No. 1.

When the writer began development work in connection with high-speed engines some six years ago, both types were considered, and as in his country (England) information was available regarding the Akroyd-Stuart type, it could, from his own practical experience, be rapidly compared with the other before a beginning was made. However, engines of both types were constructed.

The result of years of work on this form of engine is that the No. 1 type is the preferred one for the smaller, quick-running type, with plain injection and without an explosion cup or antechamber; it is thought that this will be the ultimate form. A number of engines of this type have now been built, and the accompanying tabulated results of some tests were given by the writer in a paper before the Institution of Mechanical Engineers.

While further experiments have since been made, these results

[4] Chief Engineer, Wm. Beardmore & Co., Ltd., London, England. Mem. A.S.M.E.

| Test series | Duration of test, hours | Speeds, r.p.m. | B.hp. | Fuel, lb. per b.hp-hr. | Cooling-water temperatures: Inlet, deg. fahr. | Cooling-water temperatures: Outlet, deg. fahr. | Fuel |
|---|---|---|---|---|---|---|---|
| A | $4^1/_4$ | 689.3 | 160.26 | 0.418 | 121.5 | 127.4 | Shell Mex Diesel |
| B | 3 | 700.0 | 172.0 | 0.385 | 120.0 | 128.0 | Shell Mex Diesel |
| C | 3 | 1007.0 | 424.0 | 0.365 | 140.0 | 150.0 | Shell Mex Diesel |
| D | 1 | 1023.3 | 263.0 | 0.355 | 181.0 | 185.5 | Anglo-Persian |

indicate how this engine has quite passed out of the experimental stage, and in fact numbers of them are now under construction for widely different purposes such as airships, railways, locomotives, and other power productions, etc.

It will interest members to know that as development work has gone on, mean pressures have gradually been raised, until now we have on test indicated mean pressures of as high as 150 lb. without supercharge, running at 1000 r.p.m., with a fuel consumption of less than 0.35 lb. per b.hp-hr.

The mechanical efficiency of such engines is usually 85 per cent, which of course means a correspondingly good economy as compared with the indicated power, and further, less wear and tear.

It does appear from practical experience with these engines, owing to the high class of manufacture and the thin-walled, less-heat-stressed material that can be put into them, that despite their speed they appear to have longer lives in front of them than the thick-walled, slow-speed marine engines.

Regarding the author's remarks concerning fuel injection at the end of the second paragraph of the paper, the writer would suggest to him that to get the best results he should aim for, instead of being opposed to, more combustion at constant volume, and design his engine to operate with such high pressures. He will find, it is believed, that the general move will ultimately be in this direction.

The dual cycle is really a method of analyzing a heat cycle theoretically, rather than a new cycle. The conditions in any of the cycles in actual practice do not conform to the theoretical, and therefore allowances have to be made for them in all cases as in specific heat, dissociation, and after-burning.

The practical variation when working in principle at constant-volume combustion would be by graduating the discharge of the fuel—that is to say, reducing it in the earlier part; thus the results of tests indicated previously are obtained with the maximum pressure not exceeding 800 lb. and in effect, therefore, some constant-pressure working is achieved. In any case, however, delayed combustion or after-burning must be avoided with quick-running engines.

The writer notes what is said in regard to the precombustion chamber, and on the whole agrees with the author. The general trend in development is always to simplify, and the precombustion chamber will go in time.

With reference to the question of turbulence, one often wonders whether this important factor is not being rather overstressed. At any rate, in the high-speed engine the rate of burning on the constant-volume cycle produces pressures for which undue turbulence does not seem necessary. Thus the extra turbulence set up in the Akroyd-Stuart engine, due to the neck, which has been found to be useful for the slower-speed engines, does not seem necessary for the high-speed. No doubt the whole matter is composed of variables such as the speed of injection, the turbulence, the form of atomization, so combined that it is difficult to allocate correct and separate values to each. Where the atomization of fuelizing of the air is not so good, then, relatively, turbulence must be increased.

In the writer's practical experience, he has not so far passed 1400 r.p.m., but as this was for a relatively large cylinder—as small cylinders go—viz., $8^1/_4$ in. × 12 in., the speed of combustion indicated that higher speeds should be capable of attainment. Actually the least loading of parts, due to the action of inertia, took place at 1350 r.p.m.

With reference to the weight of the engine, in the writer's experience the engine weight when the crankcase is built of aluminum alloy can be obtained at even less than the 3 lb. per b.hp. indicated in the paper.

A great deal of work has been done in connection with sprays, and a comparison of all this work is urgently needed.

From the writer's experience with high-speed engines, it does seem that the pump used, together with its fluid circuit, hydraulic-ram effect, etc., and the spraying mechanism, is the most important feature of the whole problem. More so, perhaps, than the forms of the combustion chamber (which because of the engine sizes are really very limited) and the question of turbulence, which latter the writer is prone to think is somewhat overstressed at the present time.

The form of apparatus to be used for measuring the fuel for multi-cylinder engines requires to be of a singularly accurate and consistent type. Experimental tests with one cylinder may show quite good results, but with an 8-cylinder engine, unless all cylinders are adjusted within a very narrow margin the results will be considerably inferior.

The production of a special piece of apparatus for this work is therefore highly important. The question of the form of atomizer itself is also of great importance.

The work done by the writer's company in this direction indicates that an airplane engine can be constructed with weights very little in excess of those now common. Taking, for instance, the air-cooled radial as the type, it indicates that figures of consumption of 0.35 lb. per b.hp-hr. can be obtained, and with the advent of the exhaust-driven turbine it does not seem unreasonable to look forward to as low a figure as 0.3 lb. per b.hp-hr. within the next two years with the further development work now going on with the engine proper.

As a member in another country, but by periodic visits alive to the urge present in all American investigations, the writer would like to suggest to the Society that it take upon itself the duty of correlating the experimental work now going on so that all of it shall be pursued on agreed lines and no overlapping shall occur.

In the oral discussion following the reading of the written communications, L. H. Morrison[5] asked whether in obtaining turbulence the author made use of a director or deflector such as the Hesselman, whether with different speeds better results were obtained by changing such a deflector and how the 15 per cent excess-air figure was arrived at.

Wm. T. Magruder[6] asked if the low volatility and slow-burning properties of Diesel-engine oils did not limit the speed of the engine. At 1000 r.p.m. or even 2000 r.p.m. it might be possible to burn the fuel, but when it came to 4000 r.p.m. it would not even have time to ignite.

The Author. In regard to the discussion by Mr. Chorlton what he says may be true. That is, we may be giving too much attention to turbulence, but at the present time, from what we have done, it would seem to be absolutely necessary for high-speed work. We may be wrong about the type of fuel combustion chamber that we are using at present, but from the results we have obtained it shows an improvement over the other types we have tried. We have to admit that the plain type to which

[5] Associate Editor, *Power*, New York, N. Y., Assoc-Mem. A.S.M.E. and Chairman of session at which Mr. Kemper's paper was presented.

[6] Professor of Mechanical Engineering, Ohio State University, Columbus, Ohio. Vice-President A.S.M.E.

Mr. Chorlton refers was not given a fair trial due to the fact that we were not able to locate a fuel valve centrally in the combustion chamber.

Referring to Chairman Morrison's questions, the Hesselman has a deflector mounted on the inlet valve. Our deflector was inserted in the inlet manifold so as to direct the air around the inlet valve. We hit upon the idea about the first time we started our fuel-injection work, but it was not tried until later. Soon after we made our experiments Hesselman brought out his engine in which the same principle is used.

No better results were obtained by changing the deflector. The work done, it should be understood, was not intended to be a report. It is merely a short technical note of something that we stumbled on accidentally. It is interesting to see that some time after we stumbled on it, or at about the same time, Hesselman brought out an engine in which diverted turbulence was the basic principle. But that work has been discontinued. Our big problem now, is to get the b.m.e.p. somewhere around 130 lb. per sq. in.

We are at the same time carrying on a theoretical analysis of the variation of specific heats with variation of temperature, and from the data calculated so far we have been able to compute a probable value. Of course, we are not exact, but the value is somewhere close. The committee at present is doing a good deal of work on the variation of the specific heats of the gases of combustion. When it is completed, we should then be able to say whether it is 14.9 or 16.6 per cent excess air or some such definite figure. It is somewhere in the neighborhood of 15 per cent. We have done the best we could to arrive at a volumetric efficiency and also determine the compression ratio of the pistons, etc. With the data we have been able to obtain at present, we have made corrections for everything that we could.

In reply to Professor Magruder, it may be said that we might so prepare the fuel that when it goes into the engine cylinder it is all ready to burn. That is a problem that we are now taking up. If we can heat up the fuel and keep it under pressure so that the instant the valve opens we inject a vapor, then the time lag of ignition is gone.

# The Study of Oil Sprays for Fuel-Injection Engines by Means of High-Speed Motion Pictures

By EDWARD G. BEARDSLEY,[1] LANGLEY FIELD, HAMPTON, VA.

*Apparatus for recording photographically the start, growth, and cut-off of oil sprays from injection valves has been developed at the Laboratory of the National Advisory Committee for Aeronautics at Langley Field, Va. The apparatus consists of a high-tension transformer by means of which a bank of condensers is charged to a high voltage. The controlled discharge of these condensers in sequence, at a rate of several thousand per second, produces electric sparks of sufficient intensity to illuminate the moving spray for photographing it. The sprays are injected from various types of valves into a chamber containing gases at pressures up to 600 lb. per sq. in.*

*Several series of pictures are shown. The results give the effects of injection pressure, chamber pressure, specific gravity of the fuel oil used, and injection-valve design, upon spray characteristics.*

THE FIRST successful compression-ignition oil engine, using air injection, was built about 1897 by Dr. Diesel. It was not until about 1912 that McKechnie constructed the first practicable so-called solid- or hydraulic-injection engine. Since that time the solid-injection engine has been gradually developed and the demand for it has so increased that today a considerable number of engine builders are manufacturing this type. Much progress has been made, and a great deal of knowledge has been gained concerning solid-injection engines.

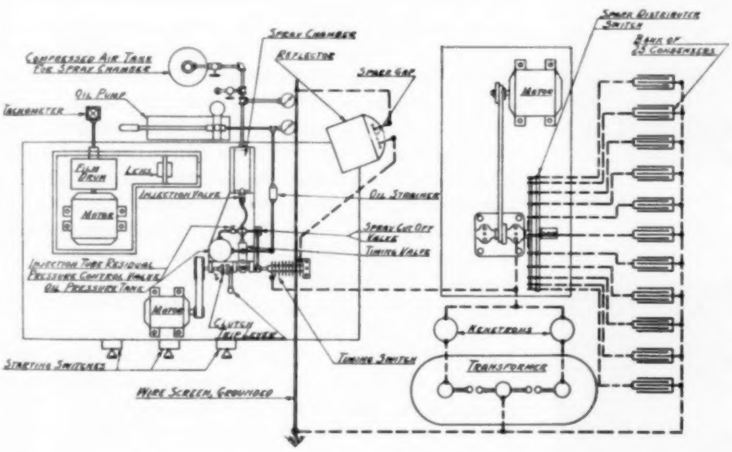

FIG. 1 DIAGRAMMATIC ARRANGEMENT OF SPRAY-PHOTOGRAPHY APPARATUS

The part of the engine about whose operation we have the least information thus far, is probably one of the most important parts, namely, the injection valve. Sprays from injection valves have been examined in the atmosphere as to their cone angle, fineness of atomization, and rapidity of combustion when ignited. They have been injected into water and the penetration noted visually. However, the complete behavior of a spray injected into dense air has always been a matter for conjecture and theoretical computation. Yet it is something which is very important, and because of this lack of definite knowledge the design of an injection valve to give the best results in a particular combustion chamber has been to a large degree a process of cut and try.

The study of the compression-ignition, solid-injection type of engine, with regard to its possible development for aircraft use, was started at the Langley Memorial Aeronautical Laboratory at Langley Field, Va., in 1921. The general problem was analyzed and an attempt made to attack it from all angles. One of the things about which actual knowledge was desired was the characteristics of sprays from injection valves. While the fit between the spray and the combustion chamber is not of so much importance in the case of a low-speed, low-capacity engine, it is vital for the high-speed, high-capacity engine useful for aircraft. The spray was therefore to be studied with regard to its penetration, general shape, and atomization when injected into dense air.

It was thought that the method by which it would be possible to obtain the greatest amount of information about oil sprays was to take high-speed motion pictures of their start, development, and cut-off, which would show their penetration, general shape, and possibly their atomization. With this end in view preliminary apparatus was designed, built, and tested during the summer of 1921. How-

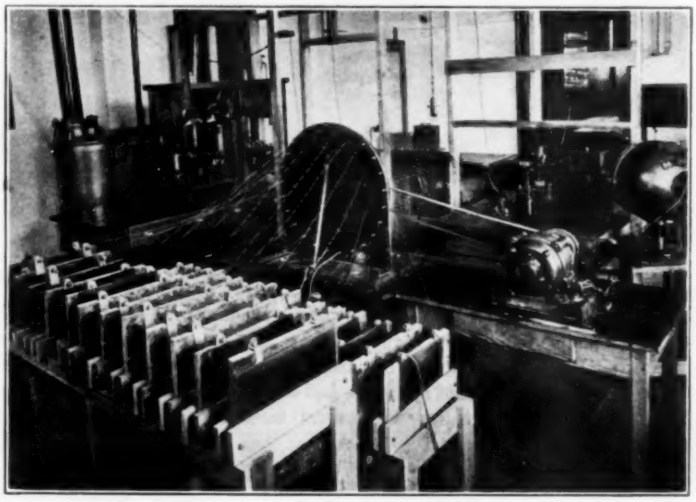

FIG. 2 GENERAL VIEW OF SPRAY-PHOTOGRAPHY APPARATUS

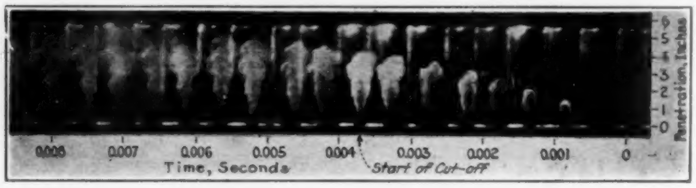

FIG. 3 MEDIUM-CENTRIFUGAL SPRAY FROM INJECTION VALVE NO. 7

(Diesel oil at 0.85 specific gravity injected at 8000 lb. per sq. in.; compressed air at 200 lb. per sq. in. in chamber.)

The following information is obtained from a series of pictures similar to the above:

*Visual Studies.* General spray form; peculiarities in spray form; cut-off; phenomena occurring after cut-off; atomization of spray.

*Measurements and Computations.* Spray penetration with time; time of cut-off after spray starts; spray-cone angle; volumetric growth of spray; spray distribution.

*Effects of Variables.* Effects of injection pressure; effect of chamber-gas density; effect of specific gravity of fuel oil; effect of injection-valve design; effect of injection system.

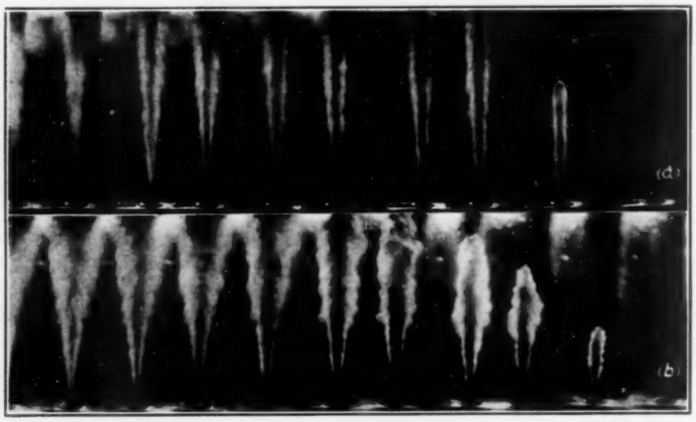

FIG. 4 EFFECT OF CHAMBER PRESSURE ON A NON-CENTRIFUGAL SPRAY

(b) Injection pressure, 8000 lb. per sq. in.; chamber pressure, 200 lb. per sq. in.

ever, it was found impossible to obtain a series of pictures of oil sprays with the apparatus then in use. Finally, in the fall of 1924, the photography of oil sprays in dense air became a reality. From that time to the present day much improvement has been made in the apparatus and methods, and considerable knowledge has been gained concerning the several factors governing the characteristics of oil sprays.

## RANGE OF INVESTIGATION

Various researches have been carried on with the present apparatus to determine the effects of injection pressure, chamber pressure and gas density, fuel oil used, and injection-valve design on oil sprays. Thus the development of single sprays with time, their velocities, penetration, distribution, form, spray-cone angles, actual volumes, and relative atomization are determined for various types and designs of injection valves. Several phenomena connected with injection hydraulics have also been investigated.

The injection valves studied include mechanically operated valves, and automatic-injection valves especially developed for high-speed operation. The sprays are discharged from round orifices with or without directing impact surfaces, and through annular orifices. Spiral grooves with helix angles of from 23 to 90 deg. have been used to break up the spray by means of centrifugal force. The former groove angle gives a spray to which about the maximum amount of centrifugal force practicable has been applied, while the latter gives a non-centrifugal spray.

## APPARATUS FOR TAKING ULTRA-HIGH-SPEED MOTION PICTURES

The problems involved in taking moving pictures of oil sprays from injection valves presented numerous difficulties. The two outstanding problems were the necessity of having a duration of exposure of about a millionth of a second, and the production of photographic records, with this short exposure, at a rate of several thousand a second. The extremely short duration of exposure necessary can be easily computed by assuming that the spray has an initial velocity of 500 ft. per sec., or 6000 in. per sec., and permitting a distortion of $^1/_{100}$ in. of the spray image recorded on a photographic film. For these conditions the duration of exposure must not be more than $^1/_{600,000}$ sec. Calculations will show that it would be practically impossible to build a mechanically operated shutter which would give such a brief exposure. Also, with this infinitesimal duration of exposure the illumination must be very intense in order to produce a satisfactory record on the film. The only solution of the problem seemed to be to use the discharge of electrical condensers, thus eliminating mechanical shutters, the duration of the spark from a condenser discharge being known to be of the short time required.

The next requirement was that the series of pictures of the spray be taken at a rate of several thousand per second. This necessitated the use of a number of condensers arranged so that they could be discharged at the required frequency.

The first electrical system investigated consisted of fifteen Leyden jars, which were charged by a static machine. Because of the dampness of the climate the machine failed to charge satisfactorily, and also the Leyden jar condensers were too small.

A 100,000-volt transformer and kenetron rectifying tubes were next installed. A bank of 30-in. × 30-in. glass-plate condensers was built, but was unsuccessful because of excessive surface leakage and frequent puncturing of the glass plates. Twenty-five condensers were then built with micanite plates for dielectrics, and these have proved successful.

The present spray-photography apparatus, so far as is known, was the first apparatus ever built capable of recording by a series of pictures the growth of oil sprays. A diagrammatic layout of the apparatus is shown in Fig. 1 and a general view

is shown in Fig. 2. The electrical apparatus consists of a high-tension transformer, two kenetron rectifying tubes, a bank of twenty-five condensers, a rotating distributer switch, a timing switch, and a spark gap in front of a reflector for focusing the light on the moving oil spray. Figs. 1 and 2 show the transformer and kenetron rectifying tubes by means of which the twenty-five condensers are charged to 30,000 volts through the rotating distributer switch. One terminal of each condenser is connected to a contact on the switch panel, and the other is grounded. Discharge across the spark gap cannot take place until the timing switch operated by the camshaft is rotated, when each condenser is discharged in sequence across the gap. The frequency of the discharges is controlled by the speed of rotation of the distributer switch. This switch is of the rotating, multiple-break type, by means of which it is possible to make and break a high-tension circuit without serious arcing.

### The Injection System

The apparatus for the production and control of sprays is shown diagrammatically in the left-hand half of Fig. 1. It consists of a high-pressure hydraulic hand pump a pressure tank, timing valve, cut-off valve, initial-pressure control valve, motor-driven camshaft, and spray chamber.

The hydraulic hand pump used is of the ordinary plunger type and is capable of delivering oil at pressures up to 12,000 lb. per sq. in. The pressure tank provides a sufficient volume of oil under pressure to insure a practically constant pressure on the oil during the whole injection period. The timing valve consists of a spring-loaded needle valve which is lifted from its seat by a cam-operated lever. The cut-off valve is a poppet valve actuated by another cam-operated lever. The duration of injection is controlled by adjusting the lever along the cam so as to obtain earlier or later operation of the cut-off valve with respect to the timing valve. The mechanism is so designed that the amount and rate of opening of the valve is practically constant for all cut-off positions of the lever. The initial-pressure control valve, when opened, allows oil to be pumped directly into the injection-valve tube, either for testing the opening pressure of the valve or to provide the correct initial pressure in the injection-valve tube before injection.

The shaft carrying one half of the jaw clutch is driven at 900 r.p.m. by a motor. The clutch is similar to the type used on punch presses, and is so arranged that when the trip lever is struck the two halves of the clutch engage and the hollow shaft carrying the cams is given one revolution. The timing switch is connected to the camshaft by means of a serrated coupling and can be turned so that it will make contact at the proper time to synchronize the beginning of the sparks with the beginning of the spray.

The spray chamber is of cast iron, two sides of which are formed by frames holding optical-glass windows one inch thick, supported on rubber. The window frames are bolted on and sealed with rubber gaskets. Gas pressures up to 600 lb. per sq. in. are used in the chamber.

### The Recording Apparatus

The recording apparatus consists of a camera box containing a lens and a motor-driven film drum. To concentrate the light of the spark upon the spray a reflector is used. It will be noted from Fig. 1 that it is offset from the line of the

chamber and film drum. Only the light refracted by the spray itself passes in through the lens and records the series of pictures of the moving spray upon the film. The film is fastened around a drum 30 in. in circumference which is mounted on the shaft of an electric motor. The speed of rotation of the film, together with the rate of discharge of the condensers, determines the spacing of pictures. An F:2 Taylor-Hobson Cooke lens is used. All pictures of the sprays are taken half-size on commercial photographic roll film.

## Operation of Apparatus

The operation of the apparatus is as follows: The initial pressure in the injection-valve tube is adjusted, after which the control valve is closed. Oil is pumped into the pressure tank to the test pressure, and the air pressure in the spray chamber is adjusted. All test conditions being obtained, the clutch trip lever is struck. The timing valve opens, allowing oil under high pressure to pass to the injection valve and open it, causing a spray to shoot across the chamber. The cut-off valve then opens after the required time interval, releases the pressure, and causes the injection valve to close and cut off the spray. The timing switch is closed when the timing valve is opened and the condensers are discharged across the gap, a series of 25 pictures being taken of the start, development, and cut-off of the spray.

## Spray Photographs

Fig. 3 shows a complete spray from an injection valve employing medium centrifugal force. The injection pressure was 8000 lb. per sq. in., and the chamber-air pressure was 200 lb. per sq. in. The actual penetration of the moving spray in inches and the time in thousandths of a second from the start of injection are given by the scales. The start of cut-off is marked.

The end of the spray after cut-off appears somewhat like a corkscrew. This spiral appearance is probably caused by whirling of the oil drops which have passed around spiral grooves inside the valve, and seems to continue after the oil has left the valve in spray form. It will be noted that the spray seems to have lost its motion in the last few pictures, especially at the nozzle where the spray is practically hanging motionless in mid-air.

The penetration-time curves are plotted from data computed from measurements of the spray images on each film, taking into account the film speed and photographic reduction as has been done in computing the scales on the above-mentioned pictures. The spray volumes are computed by summation of the differential cylinders making up each spray.

In Fig. 4 are shown non-centrifugal sprays from a cylindrical orifice injected at 8000 lb. per sq. in. pressure into the atmosphere, and into 200 lb. per sq. in. air pressure. The sprays appear somewhat like fir trees with drooping branches. This is because the velocity of the drops of oil is practically zero at the outside of the spray and increases toward the center. The oil seems to shoot out through the center and spill over on the sides, much like a fountain of water. On the sides of the sprays, clouds of oil particles appear as bumps, which do not change their position from one picture to another. They show that the oil particles at the outside of the spray are motionless. The included angle for these sprays was increased 50 per cent by injection into dense air. The atomization also appears to be increased, as shown by the pictures.

High-centrifugal sprays injected into the atmosphere and into 200 lb. per sq. in. air pressure are shown in Fig. 5. The reduction in the spray angle with the spray injected into dense air is about 40 per cent. This may well explain the failure of some centrifugal valves to operate successfully in an engine when the spray appeared well suited for the engine combustion chamber from observations made in the atmosphere. This decrease of spray-cone angle is characteristic of all centrifugal sprays.

In Fig. 6 are two sprays, injected into 200 lb. per sq. in. air pressure, which show what might be called scale effect; that is to say, the ratio of orifice area to groove area is the same for both, but a larger orifice and grooves were used for the second spray, and as a result the quantity of oil injected was nearly three times as great.

Fig. 7 shows a spray which has a small secondary spray dis-

charge taking place after cut-off. This phenomenon is thought to be caused by a pressure wave in the oil line, and was eliminated in the second series of pictures by increasing the length of the injection-valve tube, thus damping out the pressure wave because of the increased friction and greater oil volume.

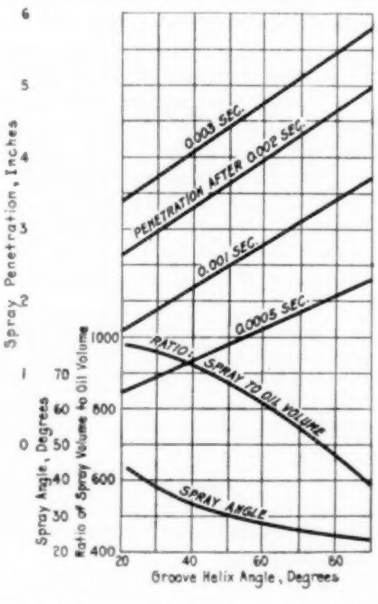

FIG. 11 EFFECT OF GROOVE HELIX ANGLE ON SPRAY CHARACTERISTICS

(Injection-valve No. 7; 0.022 in. diam. orifice; injection pressure, 8000 lb. per sq. in.; fuel oil used, Diesel oil of 0.85 specific gravity; gas in spray chamber, nitrogen at 200 lb. per sq. in.)

### EFFECT OF INJECTION PRESSURE

Fig. 8 shows the effect of injection pressures of from 2000 to 8000 lb. per sq. in. on the penetration of sprays, from a 0.0155-in.-diameter round orifice, injected into 200 lb. per sq. in. air pressure. The curves are almost straight and parallel, which shows that the penetration increased nearly in proportion to the injection pressure. This is a characteristic result. There is of course a limit beyond which increase in the injection pressure would not increase the penetration and might even decrease it. This limit is reached when the drops are atomized so finely as to be too light to penetrate the dense air. The injection pressure affects the spray-cone angle as well as the penetration. Increase in the injection pressure causes a narrower spray-cone angle with a non-centrifugal valve, and a wider spray-cone angle with a high-centrifugal valve.

### EFFECT OF GAS DENSITY

Fig. 9 shows the effect of chamber-gas pressure and density upon the spray penetration after 0.001, 0.002, and 0.003 sec. The main curves were cross-plotted from the curves shown in the insert, which are for nitrogen gas, and from similar curves obtained with helium and carbon dioxide gas in the chamber. Each point is labeled as to the gas which was used in obtaining it. The points obtained by injection into the various gases were all plotted on a basis of absolute gas density. As all of the points lie on the curves, this shows that it is the absolute density of the gas which controls spray penetration, that the viscosity of the gases has no appreciable effect, and pressure affects the penetration only in so far as it controls the density. This indicates that it is the density of the gas in the engine which controls spray penetration in an engine cylinder, and not the compression pressure.

### EFFECT OF SPECIFIC GRAVITY OF FUEL OIL

Fig. 10 shows the effect of the specific gravity of the fuel used upon the spray penetration after 0.001, 0.002, 0.003, and 0.004 sec., with a high-centrifugal valve spraying into 200 lb. per sq. in. chamber pressure. The points for the curves were cross-plotted from the curves for heavy fuel oil shown in the insert, and from similar curves for the other fuel oils.

The penetration is seen to increase with the specific gravity and from the upward trend of the curves; oils of greater specific gravity than those tested would have still greater effects. From the curves, a heavy oil of 0.90 sp. gr. would have 10 per cent greater penetration after 0.003 sec. than an ordinary Diesel oil of a sp. gr. of 0.85. The heavy oil is more viscous than the others, and is not as readily atomized. This makes the spray angle narrower and helps to produce greater penetration.

### EFFECT OF VALVE DESIGN

The effect of the groove helix angle on the penetration, cone angle, and ratio of spray volume to oil volume with a valve injecting into 200 lb. per sq. in. air pressure is shown in Fig. 11. The penetration increases considerably with increase in the angle of the spiral grooves, the 90 deg. or non-centrifugal spray having 60 per cent greater penetration after 0.003 sec. than does the 23-deg. high-centrifugal spray. The spray angle was decreased from 53 deg. to 23 deg. by this same increase in the groove helix angle.

To find the relative distribution, and to obtain an indication of the atomization of the spray, the actual spray volumes were computed. The quantities of oil injected with each valve set-up

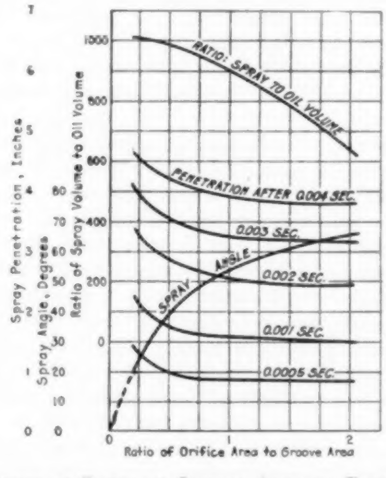

FIG. 12 EFFECT OF RATIO OF ORIFICE AREA TO GROOVE AREA ON SPRAY CHARACTERISTICS

(Injection valve No. 7; 23-deg. spiral grooves; 0.012, 0.022, and 0.040 in. diam. orifices; injection pressure, 8000 lb. per sq. in.; fuel used, Diesel oil of 0.85 specific gravity; nitrogen in spray chamber at 200 lb. per sq. in.)

were, however, different, so in order to put them all on the same basis, the ratios of spray volume to oil volume were computed. These are plotted in Fig. 11 and indicate the spray distribution. The distribution was 100 per cent greater for the high-centrifugal than for the non-centrifugal spray.

The effects of varying the ratio of orifice area to groove area from 0.19 to 2.05 upon the spray penetration, cone angle, and the ratio of spray volume to oil volume, with 200 lb. per sq. in. air pressure are shown in Fig. 12. The penetration increases rapidly as the ratio becomes very small. The ratio was decreased by decreasing the size of the orifice, the groove area being kept constant. Thus the orifice became very small with a small ratio and the rotation of the jet initiated by the spiral grooves

could not continue effectively, through this small orifice. The energy which with a larger orifice was consumed in rotating the oil, went into giving the spray axial penetration in the case of the very small orifice. The spray angle was therefore reduced, and this is shown by the spray-angle curve. The shape of this curve seems to indicate that the spray angle would not be greatly increased by increase in the ratio beyond 2.0.

The curve at the top of the sheet shows the effect of the ratio of orifice area to groove area upon the spray distribution. This curve would seem to indicate that the orifice size has considerable effect upon the spray distribution and possible atomization.

### Conclusions

The test results presented in this paper are examples of the information which it is possible to obtain by means of the spray-photography apparatus described. The results show some fundamental effects of injection pressure, chamber pressure, specific gravity of the fuel oil used, and valve design upon oil-spray characteristics. By means of such investigations, data are obtained which make possible the design of injection valves to produce sprays for various sizes or shapes of engine combustion chambers.

## Discussion

Robertson Mathews.[2] The success attained by the National Advisory Committee for Aeronautics in photographing oil sprays in a manner that reveals the spread and penetration of the jets from different types of nozzles, will be followed, it is hoped, by the obtaining of like information on the magnitude and interval of that more illusive phase of solid injection to which we apply the somewhat broad term "dribbling." Pictures of jet dribbling should be worth while even though they do no more, for the time being, than lead to a more specific definition of the term.

There is much concern among many engineers over the effect of dribbling upon fuel economy. Much effort has been expended on the design of pumps to reduce dribbling. Since the end is probably the most difficult phase of injection to control, photographic evidence of the characteristics of that phase would seem to deserve equal, if not more, attention than the initial discharge.

Paper targets have revealed that for a given nozzle and pump there are certain fuel quantities and r.p.m. that give the most uniform discharge, with a smaller percentage of the injection interval consumed in nozzle-closing effects. The determination of the variations in discharge characteristics with r.p.m. should aid in the development of greater engine flexibility.

Regarding the extent to which such photographs can be used to aid in developing combustion-chamber design, an early decision may lead us astray. Much stress is laid today upon turbulence. We should like to observe how a stream of air of a density corresponding to 300 lb. abs. and 800 deg. fahr. may be able to bend or divert the spray. It would not call for much change in the equipment to connect to the spray chamber an air loop with a spring-actuated piston to alter the location of the air, or of an inert gas, in the loop and chamber during injection.

There is a growing opinion that we must get nearer to the actual operating phases in order to obtain trustworthy information bearing on engine-cylinder design. We should like to see the N.A.C.A. develop for their experimental engine a glass cylinder, or else something like Ricardo's quartz windows. Then the present photographic equipment could be applied together with suitable additions to catch a picture of the inflammation of the charge. There is a tendency among jet investigators to overlook the possibility of combustion wiping out the crest of jet before the injection is completed.

[2] 1248 Newport Ave., Detroit, Mich.

O. E. Jorgensen.[3] Our knowledge of fuel-oil sprays has been limited to what we could observe in the open air, and any one has been free to imagine what effect the greater density of the air in the compression space of a Diesel engine might have on them. The experiments recorded in the paper have removed this uncertainty and will assist experimenters in this field in visualizing more exactly and truly what actually takes place inside the cylinder, at least during the injection period.

In connection with development work on two-cycle solid-injection Diesel engines using high fuel-oil pressures, a number of observations of sprays were made last summer in Worthington Pump and Machinery Corporation's Buffalo Works, and even though these experiments were limited to the open air, some of the results obtained may be of sufficient general interest to justify mention.

Arrangements were made to motor the engine with its fuel-oil pump at engine speed (400 r.p.m.); the fuel spray valve could be fastened to a bracket at the side of the flywheel so that the spray would shoot straight across the outer cylindrical surface of the wheel and by the trace of oil left on the wheel give information on the following conditions:

*a* The time lag between the beginning of the discharge stroke and the beginning of the discharge from the spray valve, which was found largely to depend on the volume of oil contained in the pump and the discharge line.

*b* The location of the dead center in relation to the actual beginning of the injection.

*c* The actual end of the injection for any load carried by the engine, which was regulated by a hand-operated handle.

*d* The function of the fuel spray valve and fuel-oil pump, especially their ability to produce a spray starting sharply and terminating suddenly without any dripping. When the functioning had been perfected, the picture left on the flywheel was an area thickly coated with fuel oil and confined between two straight, sharp lines marking the beginning and end of the injection and located on the wheel at an angle with the center line of the spray valve which disclosed the velocity of the jet, or, as it is called in this paper, the penetration.

In one experiment the nozzle diameter was 0.00135 in., the fuel oil pressure about 5000 lb., the flywheel diameter 25 in., the speed 400 r.p.m., the fuel light Diesel oil, and no centrifugal action was employed. In this case the jet traversed the 6-in.-wide wheel in the time required for the wheel to advance 1 in., which means that the jet velocity was six times as great as the rim velocity or 260 ft. per sec. In the terms used in the paper, the penetration in 0.002 sec. is 6.2 in.

It is interesting to compare this result with those given in the paper. The nozzle was of the type used for the experiments given in Fig. 8, for which a penetration into an atmosphere of 200 lb. is found equal to $3^3/_4$ in. Fig. 9 shows the effects of density of the atmosphere and gives $3^3/_4$ in. for atmospheric pressure, but only $2^3/_4$ in. when the air pressure is 215 lb. abs. Increased in this ratio the penetration of the Fig. 8 jet into open air would be 5.1 in. as against 6.2 in. found by the flywheel method. These two values are close enough to demonstrate the merits of this method of experimentation, and had the determination of the penetration been the main object of the test it would have been an easy matter to determine it more exactly, namely, by making a correction for the spread of the fuel-oil jet, which has an effect on the lines drawn on the flywheel tending to give too high a value of the penetration.

[3] Worthington Pump and Machinery Corporation, New York, N. Y. Mem. A.S.M.E.

In closing, the writer would ask why it is that the penetration found in Fig. 9 for 215 lb. abs. pressure is not the same as the one found in Fig. 10 for fuel oil of 0.85 specific gravity, as all conditions recorded for the two experiments in that case would seem to be alike. The penetrations are respectively $3^1/_2$ in. and $4^1/_4$ in. in 0.003 sec.

P. H. Schweitzer.[4] It may not seem evident to many, but the author's paper has for its direct object methods for making oil engines lighter, safer, and more economical.

In the last twelve months we have witnessed heroic efforts and a number of failures in attempts to cross the Atlantic in an airplane. A year ago Captain Fonck's Sikorsky plane exploded when it tried to hop off with the heavy load. The plane burned and the accident took two lives. With engines using non-volatile oil instead of volatile and explosive gasoline that fatality might have been avoided. Captains Davis and Noel were killed because their plane was unable to lift safely the weight of the fuel. The French fliers Nungesser and Coli decided to omit radio from their equipment because they needed all of the lifting power for fuel. A radio sending apparatus might have saved their lives. Present-day oil engines consume about 0.4 lb. per hp-hr., while gasoline engines use more than 0.5 lb. Twenty per cent of the fuel, i.e., more than 1000 lb., could have been saved with oil engines and the spare lifting power used for radio equipment, stronger fuselage construction, etc. if the development of the high-speed oil engine had reached the stage which we hope it will reach in five or ten years from now and which will permit their safe application in airplanes.

The National Advisory Committee at Langley Field is doing more for such development than any other organization in the world, and the present paper is a fine example of their activities.

Information regarding the characteristics of oil sprays when injected into a chamber filled with high-pressure air or gases is very essential for improving the performance of injection oil engines. The Engineering Experiment Station of the Pennsylvania State College has started an investigation of oil sprays for solid-injection engines. This investigation will cover low-speed stationary engines as well as the high-speed automotive engine, and the line of attack differs somewhat from the one described in the paper, which use high-speed photography.

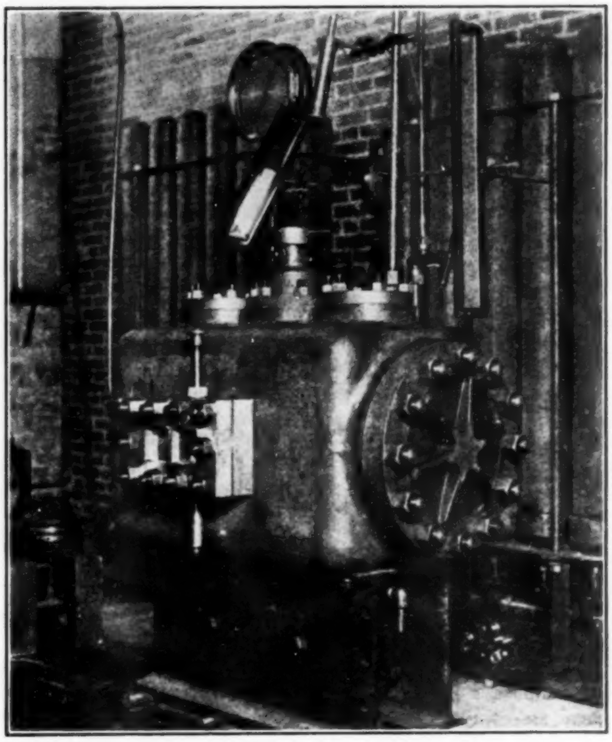

Fig. 14 Pressure Chamber for Use in Fuel-Spray Experiments

Fig. 13 gives an idea of the experimental arrangement adopted, and Fig. 14 shows the pressure chamber.

The pressure chamber is a rectangular casting with 28 × 20 × 20-in. outside dimensions and a 2 to $2^1/_2$-in. wall thickness, tested for 800 lb. hydrostatic pressure. It has two plate-glass windows 1 in. thick, one for observation and one for illumination. The observation window is provided with a window wiper for cleaning off the oil. Illumination is furnished by a 400-watt lamp.

In the study of the penetration energy visual observation is supplemented by a pendulum device (on top of the chamber) which is deflected by the impingement of the spray. The deflection of the pendulum is shown by a light beam reflected by a small mirror attached to the pendulum, and after a second

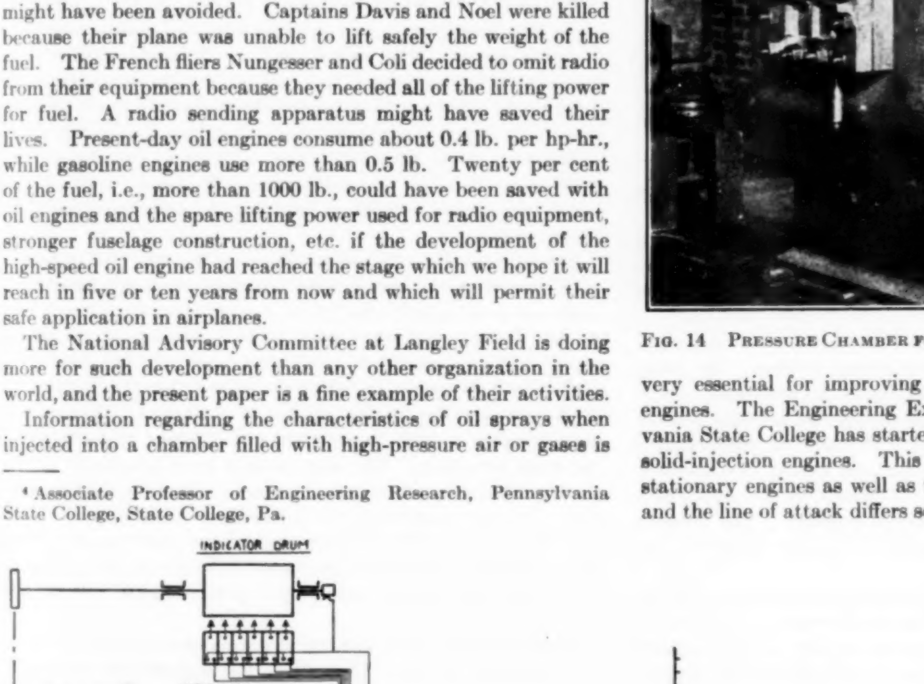

Fig. 13 Diagram of Experimental Equipment at Pennsylvania State College

[4] Associate Professor of Engineering Research, Pennsylvania State College, State College, Pa.

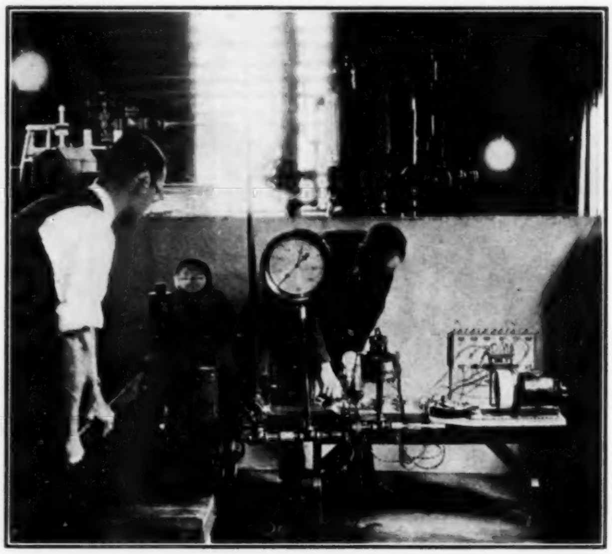

FIG. 15 PRESSURE INDICATOR AND RECORDING APPARATUS

reflection by the long 45-deg. mirror is projected to the screen visible at the right-hand side of the chamber.

The compressed-air line connects the pressure chamber with the air bottles (in the background), which are filled by a four-stage air compressor located in the next room and therefore not visible in the picture.

At the left-hand end of the pressure chamber the injection nozzles are mounted in adjustable nozzle holders. By using spacers the distance from the nozzle tip to the pendulum can be varied. Injection both by automatic and by cam-actuated nozzles is studied. The standard experimental nozzle is cam-actuated and the oil pressure is maintained uniform during the injection. For this purpose an accumulator is placed in the line which prevents a rapid variation of the liquid pressure. The pressure is produced by a hand pump capable of giving 10,000 lb. per sq. in.

In order to produce rapid single injections a control mechanism operates the lever which acts on the needle valve of the nozzle. The fuel cam, while revolving, moves axially and disengages from the roller after one revolution is completed if so desired. In this way not only continuous but intermittent sprays can be studied by one or any number of injections.

When testing automatic injection nozzles, a cam-driven power pump will be used instead of the hand pump.

To record the pressure variations in the injection line during the short time of the injection, a special indicator, Fig. 15, is used.

In preparing for this investigation we were confronted with the problem of recording pressure variations which take place in as short a time as one-hundredth of a second or less, and during which time the pressure rises to several thousand pounds per square inch and drops back almost to zero. Since no instrument seemed to answer these requirements the indicator is shown in Fig. 15, was developed and built in the college shops.

The main principle of the indicator is the use of a number of pressure-registering elements instead of a single one. Each of the six diaphragms is set for a different pressure and at the instant the pressure reaches a predetermined pressure, electric contact is made which is recorded on a rotating drum. The contact is maintained as long as the pressure exceeds the pressure for which the diaphragm is set, and during that time the corresponding spark needle on the drum punctures the paper at each spark, producing a row of holes. In this way a number of lines are produced, the length of each corresponding to the time interval during which the pressure exceeds the pressure for which the respective diaphragm is set. Using six diaphragms, which deflect at, say, 200, 400, 750, 1200, 2000, and 3000 lb. per sq. in. pressure, respectively, we obtain 12 points, 6 for the ascending and 6 for the descending curve, indicating the time at which these pressures were passed during the injection. The connection of these twelve points into a continuous curve giving a time-pressure diagram offers no difficulty. The electrical recording is practically instantaneous, and since the movement of the diaphragms is but a few thousandths of an inch, the inertia effect is negligible.

With this indicator, pressure variations of several thousand pounds within less than one-hundredth of a second have been recorded and time-pressure diagrams obtained.

EDGAR J. KATES.[5] Much interest attaches to Fig. 5, comparing a high-centrifugal spray injected into the atmosphere with the same spray injected into dense air. The reduction in penetration into dense air was to be expected, but the reduction in the spray angle could not be so positively foreseen. Until this was proved by direct experiment, many designers believed that injection into dense air would cause a spray to broaden or disperse more than in the atmosphere. Research work of this sort is exceedingly valuable for ridding the practical mind of its preconceptions.

Referring to Figs. 11 and 12 showing the effect of injection-valve design on the spray characteristics, too much importance ought not be attached to the "ratio of spray volume to oil volume." At first thought this ratio seems to be a measure of the atomization, but as a matter of fact it indicates only the size of the *periphery* of the spray, and does not show either the distribution of the oil particles in the interior or their size. It would be quite possible to have many sprays of different types but with the same periphery. One spray might have practically all the oil concentrated in the exterior surface in the form of large particles. Another might have fine particles on the exterior and larger particles inside. Still another might have particles of uniform size, uniformly distributed throughout the entire spray volume. Obviously these various sprays would perform quite differently in an engine.

There has been some criticism of the elaborate manner in which the National Advisory Committee for Aeronautics has undertaken its research work on oil sprays, but the problems involved are almost limitless and it seems impossible for the research to be made too thorough.

ALAN E. L. CHORLTON.[6] The author in opening his paper seems to have overlooked the large development in the use of injected oil in a self-ignition engine, begun by Akroyd-Stuart lately deceased, but who in his lifetime claimed to have anticipated Diesel—his patent is dated two years earlier—as particularly exemplified in such engines as those of the Lincolnshire type. A vast amount of interesting information can be drawn from development work in this field which would undoubtedly be valuable to investigators at present concerned with similar problems.

The forms of the sprays experimented with by the author do not quite convey themselves to the author in a strictly practical sense. It is essential that a spray shall start with a high degree of sharpness and cease at even a higher rate still—that is to say, that the valve shall seal itself quite tightly and extremely smartly. The percentage effect of dribbles, or loss of oil, absolutely spoils the consumption figures if they are to be good ones. It is there-

[5] Consulting Engineer, New York, N. Y. Mem. A.S.M.E.

[6] Chief Engineer, Wm. Beardmore & Co., Ltd., London, England. Mem. A.S.M.E.

fore necessary to concentrate on sharp mechanical action and not on the spray alone.

The injection pressure should mainly be set up by the orifices themselves, and not by the loading of the needle valve. The writer suggests that the oscilloscope is a good agent for examination in this respect.

THE AUTHOR. Mr. Jorgensen in his discussion mentions a nozzle diameter of 0.00135 in. I am very sure that this should be 0.0135 in. In closing he asks why there is a difference in penetration shown by Fig. 9 and Fig. 10 for what appear to be the same conditions. The reason for this difference is that the lengths of the orifices used were different in each figure. The orifice length in Fig. 9 was 0.058 in. and that used in Fig. 10 was 0.035 in. The orifice length has a considerable effect on the spray characteristics of centrifugal-type injection valves. I refer to N.A.C.A. Report No. 268, entitled "Factors in the Design of Centrifugal Type Injection Valves for Oil Engines," by W. F. Joachim and E. G. Beardsley. This contains a section devoted to the effects of ratio of orifice length to diameter on spray characteristics.

My statement in the paper that Dr. Diesel was the first to build a successful compression-ignition oil engine was based on all the information that I was able to obtain. I am glad that Mr. Chorlton corrected me as to the precedence of Akroyd-Stuart's engine developments.

# Diesel Engines for Locomotives

By R. HILDEBRAND,[1] ST. LOUIS, MO.

*Objections to the steam locomotive are made on grounds of inefficiency, the author stating that 92 to 98 per cent of the heat in the coal is being wasted, while a Diesel locomotive has an efficiency of about 33 per cent. The Diesel locomotive, however, cannot be started under full load, cannot carry any overload without excessive pressures and temperatures, and is so inflexible that an indirect drive or transmission is necessary. The principal objections to the indirect drive are cited by the author, who then makes the proposal of improving the cylinders of the steam locomotive so that they may be used either as steam or Diesel cylinders or as both simultaneously, thus retaining the advantages of both types of engine. An explanation of the working of such an engine is given, and the conditions under which the various combinations of operation are to be used are explained. Typical indicator cards for steam, for Diesel, and for combination operation are given, and the advantages of the system are explained. In closing the author answers a number of questions and objections which naturally present themselves.*

THE subject under discussion will be the outstanding strong and weak points of the steam locomotive and the existing Diesel locomotives. It will be seen that the combination of Diesel and steam power will result in an engine which is apparently superior to either of the two mentioned types.

The steam engine, in some respects, is remarkably well adapted to the requirements of the railroads. It can start under full load and can carry a heavy overload. This makes it practicable to directly drive the axles; thus a steam locomotive with this type of drive is not only very flexible, but is also a simple and cheap engine.

The principal objection to a steam locomotive is its very low efficiency. A switching engine operates with about 2 per cent, and the average main-line locomotives with 6 to 8 per cent total efficiency. Thus, from 92 to 98 per cent of the total coal burned is lost.

The Diesel engine, on the other hand, is the most economical prime mover. It has a thermal efficiency of about 33 per cent, but it is an engine which cannot be started under full load, and which cannot carry a heavy overload without encountering excessively high temperatures and pressures inside of its working cylinders. Lacking sufficient flexibility, it has not yet become practicable to drive the axles *directly* by Diesel power. All present successful Diesel locomotives use some kind of indirect drive or transmission between the Diesel and the axles. Numerous kinds of transmission have been tried, the electric drive being the most popular one. It requires, in addition to the engine, an electric generator or a hydraulic pump or a compressor, depending on the type of transmission, and a corresponding electric, hydraulic, or gas motor. The principal objections to the indirect drive are as follows:

The total weight of the locomotive should not overstep certain limits, because the existing road beds, bridges, etc. cannot stand an excessive load. In order that the total weight of the locomotive may remain within customary limits, which are about 160 lb. per hp., its engine plus its drive should not exceed a certain weight. As all indirect drives are heavy, particularly the electric type, the engine proper should not weigh more than 50 to 60 lb. per b.hp. This weight is too light for the heavy-duty service which is required by the railroads.

The term "heavy duty" means that the engine can be used for a greater length of time without being completely overhauled. This is impossible with light-weight engines, as the designer is forced to use high rotary speed, and to push the working cylinders as closely together as practical. This results in high cylinder wear and short bearings, and consequently high bearing wear.

The high wear and tear of engines of this kind is sufficiently proved by submarine engines, which also weigh 50 to 60 lb. per b.hp. For submarines, however, the initial and maintenance costs are of secondary importance, while the deciding factor for railroads is first of all the commercial result. For railroads, the high initial and maintenance costs of the present Diesel-electric locomotive, or other Diesel locomotives with indirect drive, will be a great handicap.

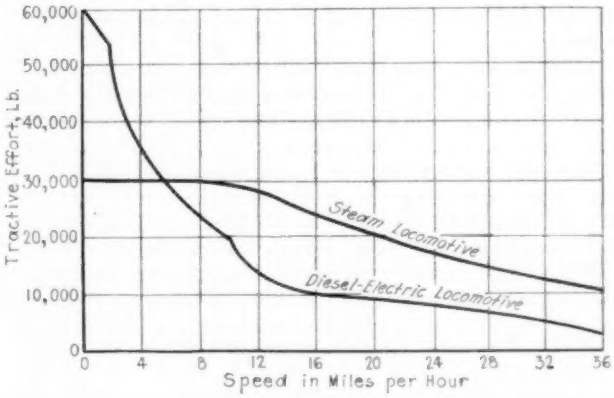

FIG. 1 TRACTIVE EFFORT OF THE DIESEL-ELECTRIC AND OF THE STEAM LOCOMOTIVE

Furthermore, the indirect drive, whether it is electric, hydraulic, or gaseous, has a low mechanical efficiency. For instance, the electric transmission has about 65 to 85 per cent mechanical efficiency, depending on the load and speed.

Also undesirable are the peculiar speed-tractive-effort characteristics of locomotives using Diesels as prime movers which drive by means of any of the indirect power transmissions. These characteristics differ much from those obtained with steam locomotives.

This is illustrated in Fig. 1, which shows the tractive effort of the Diesel-electric and of a steam locomotive. The former has a very favorable tractive effort during starting, but it drops off very rapidly when the speed increases. Thus the Diesel-electric locomotive is well adapted for switching because it can quickly accelerate a heavy train. However, for main-line engines the steam locomotive furnishes a much more desirable tractive effort at higher speeds.

The above-mentioned strong and weak points of the present Diesel locomotives are fundamental. These being facts, it appears that the present Diesel, in spite of its very desirable thermal efficiency, is a prime mover which leaves much to be desired for main-line service.

With due respect to all the accomplishments in Diesel loco-

[1] Chief Engineer, Diesel Department, Fulton Iron Works Co., St. Louis, Mo.

Contributed by the Oil and Gas Power Division and presented at the Annual Meeting, New York, December 5 to 8, 1927, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

motives, it is the author's personal opinion that for main-line locomotives the present Diesel, in connection with any of the existing indirect drives, is not the final solution of the problem. It appears to be a move in the wrong direction to completely abandon the present steam locomotive, which has proved so successful during the last one hundred years, and which adapts itself remarkably well to the requirements of the railroads besides being very simple and cheap. It seems to be logical to combine, at least for main-line purposes, the Diesel and steam power, to adhere to the direct drive, and to take advantage of the high thermal efficiency of the former and the great flexibility and adaptability of the latter.

### The Diesel-Steam Locomotive

What the author proposes is not to abandon but to improve the steam locomotive with its direct drive by changing its working cylinders so that they may be used either as a Diesel or as a steam engine, or simultaneously as a Diesel-steam engine. The combination of the Diesel and steam power could be called the Diesel-steam engine. However, to distinguish the engine which the author proposes from the existing well-known "Still" engine, which is also a Diesel-steam engine, the author's engine will be called hereafter the D-H (Diesel-Hildebrand) engine or locomotive.

During starting, only steam will be used. Fig. 2 shows a starting card which is identical with that of a uniflow steam engine. Starting with steam, the D-H locomotive will have same powerful starting ability as the existing steam locomotive.

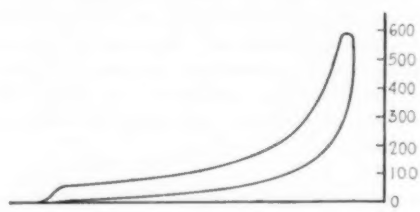
When the engine runs with normal speed and the *average* load, Diesel power only will move the train, and its indicator card will resemble that of Fig. 3. The locomotive while using Diesel power only will operate with a thermal efficiency which is in the neighborhood of 33 per cent and with a mechanical efficiency of about 84 per cent, as the axles are directly driven, and the engine will be of the double-acting two-cycle type. These are efficiencies which none of the existing Diesel locomotives possess.

While climbing steep grades, the D-H locomotive will use Diesel plus steam power. When steam is used in addition to Diesel power the steam will be admitted into the cylinders after the combustion of fuel is substantially completed, and after the gases are expanded to a pressure which about equals the steam pressure. The indicator card while using Diesel and steam power will appear similar to that shown in Fig. 4. The cut-off chosen in Fig. 4 admits just sufficient steam so the auxiliary steam power (shaded area) increases the Diesel power by 100 per cent.

The admission of steam into the power cylinders will begin when the load begins to exceed the *average* one, i.e., when the normal Diesel rating of the engine is reached and overstepped. The steam will then carry the load above that which can be carried by Diesel power. Thus the Diesel power will be used to its fullest extent, and the cut-off of the steam will be chosen to carry the overload.

To fully comprehend the power requirements of a locomotive reference may be made to the power requirements of an automobile. When automobiling, it comparatively seldom occurs that the engine is used to its fullest capacity. After climbing a hill, down again it goes, using little or no power. When passing villages, crossing bridges, short curves, etc. the speed and consequently the power must be reduced. Thus, the *average* power demand on the engine is comparatively low and fluctuates between wide limits. As in automobiling, so in railroad service, the *average* demand on the engine is only in the neighborhood of, say, 50 to 75 per cent of the maximum, depending upon the service and the nature of the road. With working cylinders of just sufficient volume to develop enough Diesel power to meet the said *average* power demand, the D-H locomotive will operate as a pure Diesel most of the time.

As the power cylinders will be dimensioned for the *average* power demand, the D-H engine will have the highest possible thermal efficiency while running under the average load. This thermal efficiency, at the *average* power demand, will be decidedly higher than that now obtained with any Diesel locomotives because their Diesel engines must be dimensioned to suit the maximum power demand, which is undesirably large for the average load.



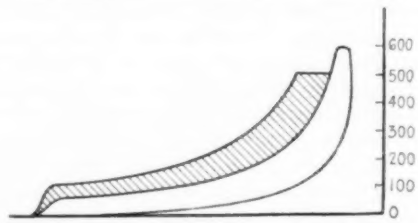


Fig. 2 Indicator Card of D-H Locomotive Under Starting Conditions

Fig. 3 Indicator Card of D-H Locomotive Operating Under Full Diesel Power

Fig. 4 Indicator Card of D-H Locomotive Using Both Diesel and Steam Power

Admission of the steam into the Diesel cylinder, and mixing it with the hot gases therein, will prevent dangerous overheating of the power cylinders because the steam, even if superheated, will have a cooling effect on the hot combustion chambers. The higher the load, the greater will be the quantity of steam admitted, and the more effective will be the internal cooling of the combustion chamber.

The mixing of the steam with the hot gases inside of the power cylinders will result in a heat exchange between the steam and the gases. The hot gases will be cooled to a certain extent, as just mentioned, and the entering steam will be heated (superheated). Thus there will be no loss of heat because all the heat contained in the Diesel gases remains in the cylinder. However, adding steam will increase the heat carried away by the exhaust, thereby reducing the thermal efficiency, although the steam consumption per steam horsepower-hour is a very favorable one. A thermodynamic calculation shows that the steam consumption of the D-H locomotive will be at least as low as that of the compound steam engine when it operates at its most favorable cut-off. This will be the case while the D-H locomotive operates at its most unfavorable cut-off, i.e., when it carries a 100 per cent overload over its Diesel rating. On request the author will gladly furnish these calculations, which

are here omitted because they would make this paper undesirably long.

The explanation for this favorable steam consumption is to be found in the fact that no steam whatever will condense when it enters the power cylinders. On the contrary, as stated, the steam will superheat when it mixes with the hot Diesel gases. The fact is that the steam will still be superheated when it is exhausted into the atmosphere.

From the above it appears, when comparing the D-H locomotive with a locomotive having large cylinders of sufficient capacity to meet the maximum demand by Diesel power, that the thermal efficiency of the D-H locomotive is higher at loads up to the average and lower at loads above the average. Thus, it can be expected that the thermal efficiency of the two compared

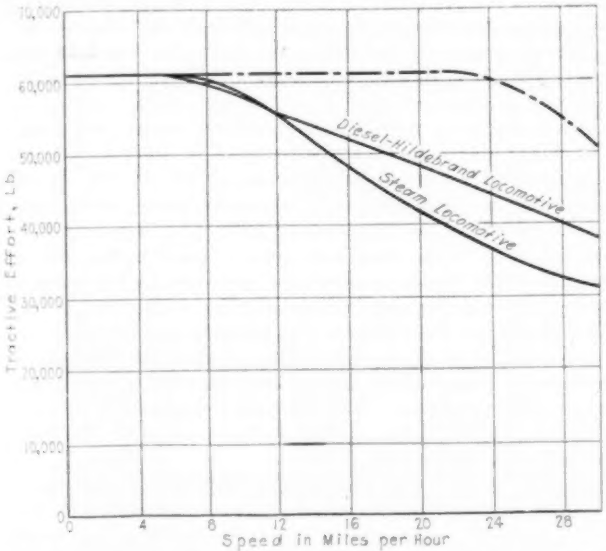

Fig. 5 Tractive Effort of Freight Steam Engine and D-H Locomotive Using Combined Diesel and Steam Power

locomotives is about at par. However, the D-H locomotive will have a much higher mechanical efficiency and also the advantage that it eliminates the indirect drive, and is well adapted for main-line service.

### Comparison of Diesel-Steam Locomotive with Still Locomotive

Here it may be of interest to compare the D-H locomotive with the Still locomotive. The latter type of locomotive is under construction in England and France while stationary Still engines have been in actual service for some time and have proved satisfactory. The Diesel-steam locomotive of the Still type drives the axles directly by means of one set of reduction gears, eliminating the disadvantages of the indirect drive. This is a distinct feature of the Still locomotive, and its results will be watched with keen interest by the railroads.

It will be remembered that the Still is a double-acting engine. Its head end is used exclusively for developing Diesel power and its crank end is used for developing steam power. Therefore the Still is a single-acting Diesel and a single acting steam engine. The Diesel economy is confined to the head end, and the overload-carrying capacity is confined to the crank end. The D-H engine is also double-acting, but it develops Diesel power (high efficiency) and steam power (high overload-carrying capacity) on both sides of the piston. Thus the D-H locomotive with the same cylinder volume as the Still locomotive will have about twice the starting and overload-carrying capacity. The D-H locomotive will therefore adapt itself better to the requirements of railroads than the Still locomotive.

Furthermore, the steam in the Still engine expands in the cool and unsuited crank ends of the working cylinders. With the exception of starting or climbing steep grades, the steam ends of the working cylinders of the Still engine will use short cut-offs which, in connection with cool cylinders, are bound to result in a high steam consumption per steam horsepower-hour. In the D-H locomotive the steam expands under the most favorable conditions, i.e., in hot Diesel cylinders. In consequence, its steam consumption is exceptionally favorable, and it decreases with decrease of cut-off. From this it appears that the steam economy of the D-H locomotive will also be higher than that of the Still locomotive. It will also be of interest to compare the D-H locomotive with the existing steam engine. We shall assume a D-H locomotive of 1400 Diesel hp. at a speed of 24 miles per hour; and we shall assume a freight steam engine of the 2-8-2 type with 27-in. by 32-in. cylinders, and a maximum tractive effort of about 60,000 lb. We shall further assume that the boiler capacity of the D-H locomotive is 60 per cent of the boiler capacity of the freight steam engine. Fig. 5 shows the tractive efforts of the freight steam engine and that of the D-H locomotive when using combined Diesel and steam power. Fig. 5 further shows, by a dash-and dot line, the tractive effort which the D-H locomotive would have provided its boiler capacity equaled the boiler capacity of the steam freight engine.

### Questions as to Practicability of Diesel-Steam Locomotive Answered

Probably several questions will have arisen in the reader's mind; these will be answered as follows:

1 Will the steam which mixes with the products of combustion cause an undesirable chemical effect (corrosion) on the cylinder walls?

In an ordinary Diesel, the products of combustion contain a considerable amount of steam (caused by the hydrogen and hydrocarbons in the fuel oil) which does not affect the cylinder walls whatever.

Another proof that the steam and the products of combustion in the proposed D-H locomotive will not cause difficulties is furnished by the performance of the Still engine. In this engine, while the piston travels, gases will blow by the piston into the steam space because no piston holds perfectly tight, and many leak badly. This brings the steam part of the cylinder liner in contact with the gases. According to the author's knowledge this has caused no piston and liner difficulties, although the crank end of the cylinder liner in the Still engine will be wet because it is comparatively cool.

The most convincing proof that the admission of steam to the working cylinder of the Diesel will not be harmful are the experiments of Professor Hopkinson[3] in which water was injected into the power cylinder of a producer-gas engine to eliminate the external cooling. The water injection lasted from 30 deg. before to 30 deg. after the crank passed through the firing dead center. The author wishes here to quote Professor Hopkinson's own words: "It (the engine) is giving no trouble at all and has been working regularly for two years, the total time of running being 5000 hours. Anthracite coal is used in the producer, and the coal contains a considerable portion of sulphur, yet there has been no trace of corrosion."

The internal-combustion boiler furnishes a further proof that steam and the products of combustion can be mixed and that this mixture will do no harm to cylinder liners and pistons.

[3] A New Method of Cooling Gas Engines, by Prof. Bertram Hopkinson, *Engineering*, 1913, p. 152.

Reference may be made to a paper read by O. Brunler at a meeting of the Institution of (English) Locomotive Engineers, January 14, 1927. An extract appeared in *The Railway Engineer*, of March, 1927, page 97. In this boiler the combustion takes place in immediate contact with the water, the flame being submerged, and the products of combustion passing through the water. The boiler does not produce pure steam but a steam-gas mixture.

If the internal-combustion boiler can be operated in the manner described, and if water can be injected into a cylinder

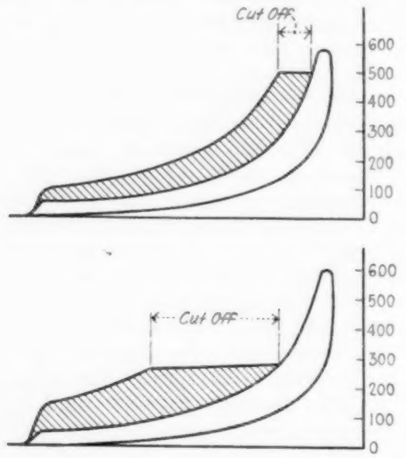

FIG. 6 INDICATOR CARDS SHOWING ADVANTAGE OF HIGH-PRESSURE BOILERS FOR THE D-H TYPE LOCOMOTIVE

of an internal-combustion engine, and if the Still engine is practical, then it is unquestionable that highly superheated steam may be admitted into a hot Diesel cylinder without causing difficulties. There will be no chemical reaction because the highly superheated steam, while expanding together with the hot Diesel gases, will not condense to water. The sulphur dioxide ($SO_2$) contained in the products of combustion cannot change into sulphuric acid ($H_2SO_4$) unless water is present, which, however, will not be the case in the D-H locomotive. The exhaust temperature of the steam-gas mixture, even under the most unfavorable conditions, will be above the point of condensation.

2 Why is the steam to be expanded in the Diesel cylinders and not in separate cylinders?

As the steam will have to do the starting, separate steam cylinders would be of large dimensions in order to furnish the needed starting force. For economy's sake the Diesel should generate as much power as possible (except when starting), leaving little or nothing for the steam cylinders to do. These cylinders would therefore not be doing useful work most of the time but would cause friction losses. It would be uneconomical to generate a small amount of steam power in large cylinders, i.e., to operate them with very short cut-offs. If, however, the steam expands in hot Diesel cylinders, a high economy will be attained, even if only a small amount of steam is needed. Thus for the sake of economy separate cylinders are not desirable. Furthermore, additional cylinders would increase the weight, the unbalanced reciprocating masses, and the first cost; they would complicate the locomotive, and there would hardly be room for them, the Diesel cylinders requiring all the room available.

3 What will be the boiler pressure?

Since the working cylinders must be designed for 550 to 600 lb. initial pressure, it is highly advisable to use also a high boiler pressure, say, 500 lb. gage. Fig. 6 will illustrate this. Both cards show an auxiliary power of just 100 per cent, but the cut-off is much shorter and consequently the economy much greater with the auxiliary power medium of 500 lb. than with the low pressure shown.

4 Will not such a high boiler pressure cause difficulties?

It should not if the boiler is designed for such a pressure. In stationary practice, boiler pressures of 300 to 400 lb. are quite common; also 500 lb. is frequently used. Even 1200-lb. pressures have been successfully tried. All these high-pressure boilers are of the water-tube type. Similar boilers may be installed within the space and weight limits of a D-H locomotive as the boiler capacity required is only about 60 per cent of that which is now used in connection with standard steam locomotives.

5 All high-pressure boilers have small drums and consequently small water contents with only a very limited amount of heat stored up in the water. Will this heat, in connection with the combustion in the boiler, furnish sufficient steam to start and to accelerate the train?

While it is true that the tractive effort required to start a train is great, yet the average engine speed during the starting period is small; consequently, the corresponding horsepower is small. This explains why the limitations on the boiler capacity of the present steam locomotives are mostly felt at higher speeds, while during starting there is ample boiler capacity but not always sufficient adhesion between the wheels and the rails. Therefore a small boiler will be sufficient to start the train and to accelerate it up to a speed of about four miles per hour. After that speed is reached, the Diesel begins to fire and relieves the boiler.

Here it should be mentioned that the D-H locomotive will begin to fire at a lower speed than the ordinary Diesel engine because the former uses superheated steam and the latter cold high-pressure air as a starting medium. Superheated steam heats the cylinders, while the expansion of cold air has a chilling effect which makes starting difficult.

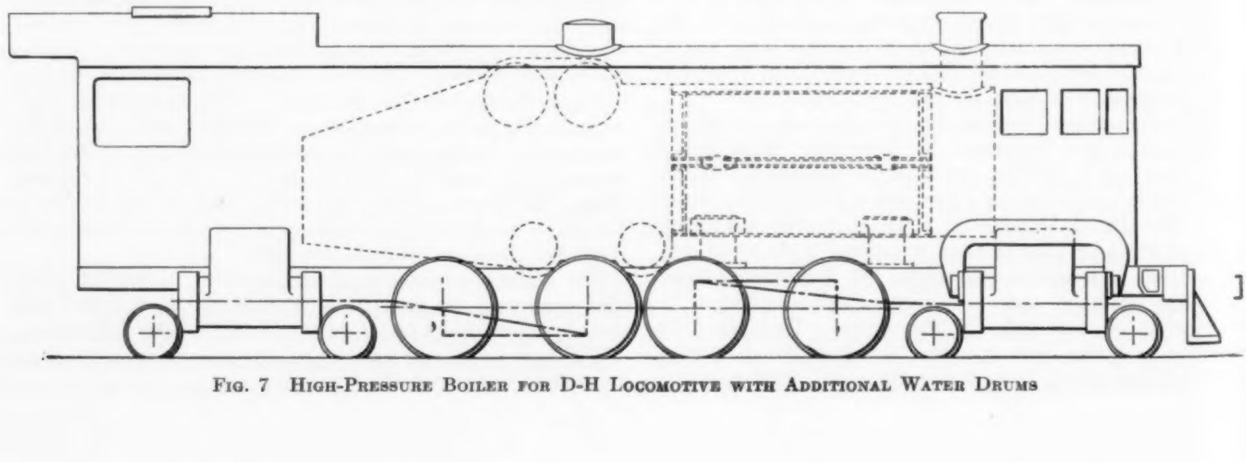

FIG. 7 HIGH-PRESSURE BOILER FOR D-H LOCOMOTIVE WITH ADDITIONAL WATER DRUMS

It should also be considered that the steam consumption, as soon as the firing of the Diesel begins, greatly diminishes not only because Diesel power is added, but because all condensation of the entering steam is positively prevented. Thus, it can be expected that the D-H locomotive will need considerably less steam to start and to accelerate the train than the ordinary steam locomotive, which latter has a comparatively high steam consumption for the power which it develops during the starting period.

There may be conditions when a boiler with a large water volume is desirable, as for instance in mountainous regions. In order to obtain, when conditions demand it, a large water volume, a few additional water drums may be attached to the boiler. A high-pressure boiler with additional water drums is shown in Fig. 7.

6 Will not the cost of maintaining the boiler be a considerable item?

The rate of combustion has a deciding influence on the maintenance of a boiler. While it is true that the boiler of the D-H

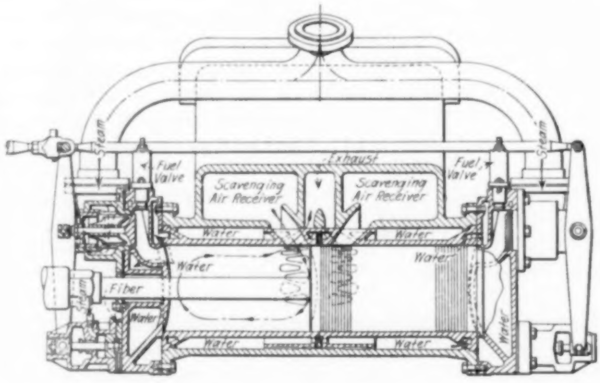

FIG. 8 LONGITUDINAL SECTION OF CYLINDER SHOWING LOOP SCAVENGING SYSTEM

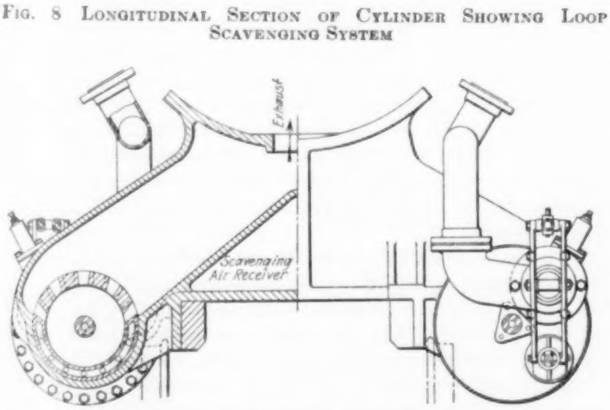

FIG. 9 CROSS-SECTION OF CYLINDER SHOWING LOOP SCAVENGING SYSTEM

locomotive will be kept permanently under full steam pressure to be ready at all times to furnish auxiliary power, steam will nevertheless be used very sparingly, and seldom up to the full boiler capacity. Using Diesel power most of the time, and steam power only intermittently, the cost of maintaining the boiler will be less than that experienced with the present steam locomotives with their high rates of evaporation.

7 What kind of fuel will be used for the boiler?

The most convenient fuel will be the same as that used for the Diesels. If oil or coal dust is used, the fire in the boiler can be instantaneously increased when starting or while climbing a steep grade, provided a small ignition flame burns all the time. Of course, ordinary coal may be used for the boiler. The commercial more than the engineering point of view will decide this question. Here again it should be kept in mind that the locomotive will not burn much fuel in the boiler, because, as stated before, it will run as a pure Diesel most of the time.

8 Why will Diesels of the solid-injection type be used?

It is advisable to use them because injection air would cause too great a chilling effect in the combustion chamber. Consequently, if the Diesel were of the air-injection type, it would require higher speed before the firing would take place than if it were of the airless-injection type.

9 What scavenging-air system will be used?

The loop scavenging system will be found most convenient for locomotive purposes because it permits a long stroke and the arrangement of the exhaust and scavenging ports on the same cylinder side. This arrangement also provides convenient passages for the exhaust and scavenging air. It leaves the lower or bearing halves of horizontal cylinder liners free of ports. This will result in a better cylinder lubrication and a better wearing of the liners and pistons than if the lower cylinder halves were equipped with ports. The loop scavenging system shown in Figs. 8 and 9 has the exhaust and air ports arranged in the upper cylinder half. It has the good feature that its effective stroke (total stroke minus length of ports) is favorable. Also the well-known M.A.M. loop scavenging system will come into consideration; however, here the effective stroke is shorter than in the system shown in Figs. 8 and 9.

10 What kind of valve gear will be used?

The Walschaerts, or any other established reversing gear, may be used. The valve gear has to control only the steam inlet with a variable cut-off. The exhaust and the scavenging air are controlled by the ports. This makes a favorable valve gear.

11 How will the steam inlet valve be made to open just when the gases are expanded to a pressure substantially equal to the steam pressure?

Figs. 8 and 9 will make this clear. These show a preliminary design of a working cylinder and part of the valve gear. The cylinder greatly resembles a uniflow steam cylinder, while the combustion chamber resembles the well-known "A" type Diesels of the former American Diesel Engine Co., which engines have now been in operation for about eighteen years with a record of good combustion.

The valve shown is equipped with a piston at its outer end. The steam pressing on the valve head and its piston, always tends to close the valve and to hold it tight against its seat. The fulcrum of the valve lever is fastened to a small piston, on which the steam presses.

The valve gear tends to open the steam valve slightly ahead of the dead-center position. This (constant) lead is necessary because the locomotive will operate as a uniflow steam engine while starting. When Diesel plus steam power is used, the initial pressure inside of the cylinder rises above the steam pressure. This high pressure will hold the steam valve so tight on its seat that the valve lever fails to open it on account of its yielding fulcrum. The fulcrum will yield until the steam in the cylinder is sufficiently expanded, i.e., until the force to open the steam valve is sufficiently reduced. Then, and not before, will the steam valve open quickly due to the movement of the valve gear and the return movement of the fulcrum by its steam-loaded piston. Selecting a suitable size of the fulcrum piston, the steam valve will open in proper time to obtain a card substantially as shown in Fig. 4. When no steam is used, the steam throttle will not be closed, but the steam on the pistons attached to the fulcrums of the valve levers will be turned off. This will prevent the steam valves from opening.

12 Are the high initial pressures, which are characteristic of the Diesel cycle, permissible in railroad engineering?

To avoid excessive forces, four small cylinders instead of two large ones may be used, as shown in Fig. 7. These small cylinders will drive the axles directly, and their forces will not exceed the piston forces now obtained with ordinary steam locomotives. Consequently, the piston rod, crosshead, connecting rod, pins, and axles will be of the same size as now used in railroad practice.

Instead of using four cylinders, only three or two may be used if they drive through one set of reduction gears as shown in Fig. 10. There is sufficient room to arrange three cylinders within the available space. Using a reduction gear, which only very slightly lowers the mechanical efficiency, a favorable piston speed and a convenient stroke-bore ratio can be chosen.

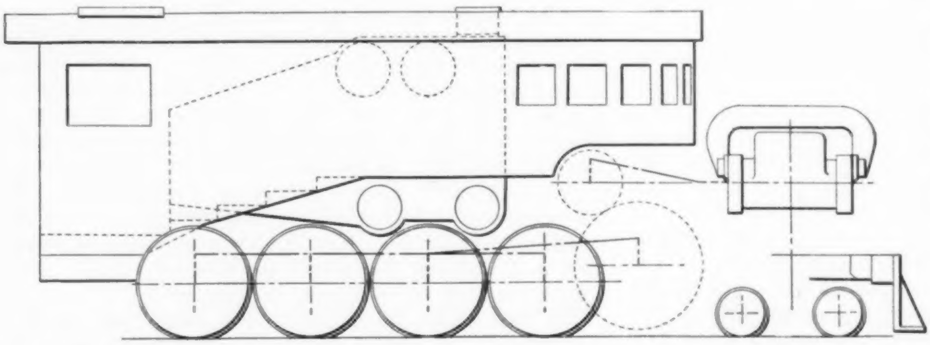

FIG. 10 ARRANGEMENT FOR DRIVING D-H LOCOMOTIVE THROUGH REDUCTION GEARS

13 Are not three or four small cylinders less efficient than two large ones?

It is one of the good features of the Diesel that small cylinders give practically the same thermal efficiency as large ones. So with steam, when it expands in hot Diesel cylinders where no condensation will take place, the cylinder size is of minor importance.

14 Will a three- or four-cylinder locomotive, with its greatly increased reciprocating masses, run just as smoothly as one with only two cylinders?

Using three cranks, the reciprocating masses are balanced more effectively than with only two cranks. When using four cylinders (two on each side, see Fig. 7) and opposed piston travel, perfect balancing of the masses can be obtained, which is impossible if only one cylinder on each side is used.

15 Is it practical to instal a "booster engine" as is done in the standard steam locomotive for raising the tractive effort while starting?

The installation of a booster engine in a D-H locomotive is just as easily accomplished as in a standard steam locomotive because the booster engine may be steam driven.

16 Will it not be quite complicated for the engineer to operate the engine as outlined above?

The whole control on the locomotive will be accomplished by two levers. One will operate the reversing gear in the usual manner. The other lever, when moved into the starting position, will permit steam to enter the cylinders. While this lever is held in the starting position, no fuel will be delivered to the working cylinders. When the control lever is turned into the first notch (i.e., when the Diesel begins to fire) the steam is turned off, and a small amount of fuel will be delivered to the cylinders. Advancing the lever to the next notch increases the fuel supply until the fuel delivery will correspond to the normal Diesel rating of the engine. Advancing the lever still further will begin to admit steam to the cylinders and will increase the fuel delivery until the maximum Diesel rating is reached. The engineer, with this arrangement, can use steam only during starting and when the fuel supply is reached which corresponds to the normal Diesel rating. There is no danger that the D-H locomotive will be operated by steam power alone because it will not have sufficient boiler capacity to be operated satisfactorily.

17 What are the principal disadvantages of the D-H locomotive as compared with the existing engines?

The D-H locomotive has no disadvantages when compared with the steam locomotive. In fact, both types compare very well so far as initial cost, weight, tractive effort, simplicity, and manner of operation are concerned. Their fundamental difference is in the overall efficiency, which will be high with the D-H locomotive and which is very low with the steam locomotive.

The D-H locomotive requires a boiler. This may be considered a disadvantage, while in reality it is a more desirable means for obtaining the needed load on the driving wheels than an indirect drive and other auxiliaries required in connection with the present Diesel locomotives. This refers to main-line engines. It is the boiler with its stored-up energy and with its combustion which is ready at any moment to furnish auxiliary power to the Diesel when starting and when climbing steep grades. It is the boiler which protects the Diesel from being overheated. It is the boiler which enables the engine to furnish tractive efforts which, at all speeds, will be equal to or higher than those of the present steam locomotives. It is the boiler which makes the D-H locomotive adaptable to main-line purposes. On the other hand, it is the indirect drive of the present Diesel locomotive which complicates the engine, causes high initial cost, great total weight, too light an engine for heavy duty, great reduction of the total mechanical efficiency and undesirable tractive efforts at higher speeds. Thus, it is the indirect drive which makes the present Diesel locomotive undesirable for main-line service.

It is unfortunate that the D-H locomotive like the present steam engine must first have its boiler heated in order to be ready for service, and that it will not be smokeless unless it uses fuel oil for its boiler. This, however, is of secondary importance compared with the great advantages which the boiler furnishes.

Minor considerations for or against a certain type of locomotive should not cloud the broad viewpoint from which the merits of the different engines should be judged. The present Diesel locomotives are very desirable switching engines. In this respect they will satisfy the need of the railroads. For main-line service the railroads still depend on the uneconomic steam engine. There is little hope that the present Diesel will make a desirable main-line engine for reasons which are fundamental for all internal-combustion engines, as set forth above.

There are about 70,000 steam locomotives in operation in the United States alone; many of them are main-line engines. There is an urgent need for higher economy not only from the viewpoint of the railroads but also from the viewpoint of national economy. Any suggestions to fill this need should receive proper consideration. How the obtaining of a higher commercial efficiency will be accomplished is of secondary importance.

## Discussion

A. Lipetz.[3] The author's proposition of a direct-driven Diesel steam locomotive is of great interest, especially at present when the Still locomotive in England has already been completed and is undergoing tests. If experience with the Still locomotive should prove that the proposition of a combination of Diesel and steam for railway traction is practicable, we may hope to see the D-H locomotive built in this country. However, there are several points to be taken into consideration in connection with such a locomotive, and the remarks which follow are not made in any spirit of criticism but rather with the idea of assisting in further development of the locomotive.

It would be a mistake in considering the use of steam in a locomotive to treat it from the point of view of power instead of tractive effort. The author's remark that "with working cylinders of just sufficient volume to develop enough Diesel power to meet the said average power demand, the D-H locomotive will operate as a pure Diesel most of the time," is somewhat misleading. A direct-driven Diesel locomotive becomes a constant-torque locomotive instead of a constant-power locomotive as in the case of intermediate transmission. The constant-torque locomotive must be designed to correspond not to the average but to the minimum torque, or a torque very close to minimum; otherwise, for smaller tractive efforts the Diesel engine will be considerably underloaded and its economy reduced. As the torque variation in a locomotive on account of railroad conditions varies from 1:4 to 1:6, the addition of steam power to Diesel power, which will be required, may go up to 3 to 5 times that of the Diesel. This would turn a Diesel-steam locomotive into a steam locomotive with the addition of Diesel cylinders working all the time, with both oil and steam, contrary to the author's supposition that the locomotive will operate as a pure Diesel most of the time. The efficiency of such a locomotive will correspondingly drop and may not be over 10 to 12 per cent as an average, representing an improvement over a steam locomotive which may not justify the complication and the use of oil when coal is available.

Further, among the limitations imposed upon a locomotive, the maximum piston thrust must be taken into consideration. With the present steels in use, the dimensions of the crankpins in a direct-driven freight locomotive are such that the driving wheels must be larger than they should be for tractive purposes only. If calculations are made on the basis of the maximum permissible piston thrust, the cylinder dimensions cannot exceed for our present conditions 16 in. in view of the high ignition pressure in the Diesel cycle. This would call for at least four cylinders for a medium-size locomotive, and possibly for more than four for larger locomotives. Moreover as the rapid change of pressures in the Diesel cycle, especially at high speeds, gives the effect of explosions, it is very probable that the dimensions of pins, bearings, axles, frames, etc. will have to be increased, or if this should be impossible, the dimensions of the cylinders will have to be further reduced. If now one considers that a two-cycle Diesel engine, as suggested in the paper, cannot give over 60 to 65 lb. per sq. in. mean effective pressure, whereas for starting at least 200 lb. would be necessary for the smaller cylinders, and for running conditions on continuous grades about 160 lb., it becomes evident that the addition of steam power will have to be very substantial, ranging from 200 to 300 per cent of that obtained from the Diesel cycle.

Fig. 5 shows that the tractive effort of a D-H locomotive is higher than that of a steam locomotive, but it does not indicate the fact that while in the steam locomotive any tractive effort below the maximum can be easily obtained by shortening the cut-off and rendering the locomotive more economical, in a Diesel locomotive the opposite is the fact, namely, the efficiency of the locomotive will drop with the decrease of tractive effort obtained from the Diesel cycle. Tests made with the 4-10-2 Diesel locomotive with gear transmission recently built in Germany for Russia, have shown that while at full power the total overall efficiency of the locomotive was 29.3 per cent, it dropped to 8-12 per cent when the load was low,[4] and this may happen on the road quite often.

The author states that Professor Hopkinson's tests in cooling Diesel engines by injecting water into the cylinders instead of jacket cooling have proved that there can be no bad chemical effect from the mixture of steam and gases on cylinder walls. However, this expedient, which has been suggested and tried by various experimenters (Capitaine, Banki, et al.), has never become generally accepted, and all our internal-combustion engines are cooled by outside jackets. The reference, therefore, is not very convincing. Nor can the writer consider as very pertinent the author's reference to the Brunler internal-combustion boiler, as this device is only in its preliminary stage and no practical every-day results with the use of steam and the products of combustion in engine cylinders have so far come to our knowledge. We do not, therefore, know whether this mixture will not affect cylinder liners and pistons in the long run.

In conclusion the writer would say that the distinction which the author draws between his proposition and the Still locomotive is not as pronounced as he thinks. The steam ends of the Still cylinders are fairly hot because they are very close to the internal-combustion ends. Moreover the Still pistons have no cooling and are designed in such a way as to depend upon the cooling by steam on the opposite side. Thus the steam is in turn heated by the combustion gases of the Diesel side and consequently the steam is also highly superheated—possibly not so high as the Hildebrand engine, but sufficiently high to prevent any condensation and to permit good thermal utilization.

The author's assertion that the starting effort in his case would be double that of the Still engine is not exactly to the point because the Still locomotives were designed in such a way as to provide sufficient starting effort. In the two-cycle engine designed by the Schneider Company of Creusot, France, provisions are made for starting by steam in both ends of the cylinders. In the four-cycle design where the total volume of the cylinders is comparatively larger, steam is admitted only to the steam ends as this is sufficient for starting and a larger tractive effort would simply cause the driving wheels to slip. There is, however, one essential difference between the Hildebrand and Still engines, which lies in the fact that the Still engine makes use of the waste heat from the steam jacket and exhaust gases, and steam is generated only in so far as it is necessary for making good use of the waste heat. The normal action of the Still engine is therefore always Diesel and steam, the steam costing nothing, whereas in the Hildebrand engine the normal action of the locomotive is with the Diesel engine only, and any steam which has to be used must be generated in the boiler with a corresponding consumption of fuel. In the Still engine the burners are used only for starting and on very heavy grades, whereas in the Hildebrand engine, the writer is inclined to believe, the burners in the firebox will have to be used most of the time.

The solution offered by the author in answer to No. 11 is very ingenious. The simultaneous action of gas and steam valves is very nicely worked out. The author's proposition as a whole is of great practical value and interest, and the writer believes that

[3] Consulting Engineer, American Locomotive Co., Schenectady, N. Y., and non-resident Professor of Locomotive Engineering of Purdue University, Lafayette, Ind., Mem. A.S.M.E.

[4] *Railway Mechanical Engineer*, vol. 101, no. 5, p. 272, Fig. 3.

trials and development work with an engine of this sort in this country should be welcomed.

HERMANN LEMP.[5] The oil locomotive has come to stay and will prove to be the one outstanding advance in railroading where complete electrification is not justified by density of traffic or other compelling motives for its adoption. Any serious attempt, therefore, to give to the oil locomotive the flexibility of the steam locomotive while retaining the high thermal efficiency of the internal-combustion engine must be welcomed.

The proposition of the author is such an attempt and appears to be novel as far as the mingling of high-pressure steam and the Diesel cycle is concerned. The writer has no apprehensions regarding the procedure suggested by the author, having in connection with Mr. Chatain started Diesel engines by hot steam in lieu of compressed air several years ago, and at one time seriously considered the use of an oil-fired flash boiler as a starting means in place of an air compressor. He has further introduced atomized water into the air suction of a solid-fuel-injection engine without deleterious results. While the possibility of intermingling the two cycles is admitted, the efficiency is doubtful and remains to be proved.

The building and maintenance of a water-tube or flash boiler giving 500 lb. per sq. in. for locomotive service is, however, not so simple a proposition as to be brushed lightly aside. It is exactly the boiler of the present steam locomotive which is its weakest link, and which more than anything else limits the availability of the locomotive to—say, at its best and when oil fired—50 per cent of continuous service. Therefore, to still maintain a boiler of 60 per cent the capacity of a regular steam locomotive does not impress the writer as very desirable. A boiler of that capacity will still demand water stations, cinder pits, etc., all of which a pure oil internal-combustion locomotive does not require.

The fear expressed by the author that for railroads the high initial and maintenance costs of the present Diesel-electric locomotives with indirect drive will be a great handicap, is not born out by actual experience.

The maintenance of a steam locomotive varies from 15 to 30 cents per locomotive-mile, while on an average a number of oil-electric locomotives of the A.L.G.E.I.R. type in service in the United States for the past three years show that in spite of the handicap of introducing a new product into new hands and service organizations the maintenance varies from 10 to 15 cents per locomotive-mile, which figure is expected to be reduced to 10 cents per mile.

The first cost of the oil-electric locomotive is offset by its greater availability over the steam locomotive.

A steam locomotive of the conventional design requires a heavier roadbed than, say, an electric locomotive of the same weight on account of the added dynamic loading of rail and the vertical component of the connecting-rod thrust. This amounts to from 50 to 100 per cent. Furthermore, the adhesion is much less than when the drivers are propelled by electric motors. That the weight of the most successful oil-electric locomotive is at present about 250 lb. per hp. and therefore greater than 160 lb. per hp. is admitted, but even with this handicap the fuel economy in hauling of freight and passengers is so far ahead of that of a steam locomotive, varying anywhere from 300 to 400 per cent, that the handicap is not seriously felt.

It must be remembered that this steam-locomotive weight of 160 lb. per hp. does not include the weight of the tender loaded with fuel and water, while the weight of the oil-electric locomotive does include both. When this weight is added to that of the steam locomotive and both are compared on the basis of maximum sustained horsepower, we find that the weight of the steam locomotive is between 220 and 230 lb. per hp. or only 20 lb. less than for oil-electric locomotives designed for main-line work. Switching locomotives are much heavier.

The electric transmission permits distribution of the weights over numerous axles so that as far as the effect on the roadbed is concerned it may be forgotten. In the second place, it must not be overlooked that improvements in the design of oil engines of the solid-fuel-injection type are constantly going on and engines of 25 lb. per hp. are already available, which with increased rotary speed will also reduce the weight and cost of the electric transmission.

History will repeat itself as with the development of the gasoline engine. Fifteen years ago the General Electric motor-car engines of 500 r.p.m. were considered high-speed. Today 1200 r.p.m. is accepted as practical, and in automobile and aviation engines 2000 to 3000 r.p.m. is coming more and more into use.

The writer is unable to agree with the author's statement that the characteristics of an oil-electric locomotive and a steam locomotive are fundamentally different as shown in the tractive-effort curves of Fig. 1 of the paper. The locomotives therein compared are evidently of different powers. The steam locomotive has approximately twice the horsepower of the oil-electric. The steam locomotive cannot make use of the full horsepower at slow speed, and only reaches its full power toward the full speed. The oil-electric locomotive, on the contrary, uses its full power over nearly its full range. Hence we are able to do the slow-speed yard shifting (when high speeds are not only undesirable but not practical) with an oil engine of approximately half the horsepower of the steamer.

The Chicago & Northwestern Railway is now using three 60-ton oil-electric locomotives to do yard shifting. Each of these locomotives of 300 hp. working continuously from Monday morning till Saturday night with three 8-hour-shift crews replaces two steam locomotives of 600 hp. each. Actual experience has shown that the three locomotives during 23,084 hours have given a 97 per cent availability and 17,833 hours of actual service, there being no assigned work on Sundays and holidays, which time is included in the 23,084 hours.

The author concedes the possible use of electric transmission for yard shifting, but doubts its adaptability to main-line work. Referring to Fig. 1, it is evident that by changing the gearing of the motor drive the tractive effort at the start may be lessened and higher speeds made possible, and particularly so when the same horsepowers are used in either case. On the contrary, it is the writer's belief that the real field of the oil-electric locomotive will be heavy main-line work where its low fuel consumption and greater availability are the chief economic factors.

Multiple high-speed oil-engine generator units make for reliability of operation, lower costs through mass production, single-crew operation of multiple power plants, and finally a simplicity of control self-adjustable to all load conditions which is hard to achieve through any other transmission means.

In connection with main-line work, an article appeared in *Railway Age* of Nov. 5, 1927, describing a run made on October 13 by a 100-ton oil-electric locomotive, geared for high speed, over the Erie Railroad, from Hornell, N. Y., to Meadville, Pa. The train was run by Erie Railroad officials through two divisions, requiring two engineers. Distance, 183.7 miles; trailing load, four passenger coaches; total load, 280.5 tons. The train ran on express schedule between the two stations, making six station stops of three minutes each. Maximum speed, 56 m.p.h., average speed 33.4 m.p.h., average load factor on oil engines, 49.9; maximum load factor on oil engines, 78.8. Total gallons

[5] Consulting Engineer, Locomotive Department, Ingersoll-Rand Co., New York, N. Y.

of fuel consumed, 134 (at 5 cents per gal.); total gallons of lubricating oil consumed, 2 (at 50 cents per gal.); total water consumed, negligible; total cost of fuel and lubricating oil for run, $7.70 or per 1.05 cents per car-mile.

The significant thing of this trip was the fact that two steam engineers, who never before were aboard an oil-electric locomotive, took charge and with only five minutes of instructions operated the train (without further help) on a steam-road schedule through their respective divisions.

The citing of this actual main-line high-speed performance, the first in America with an oil-electric locomotive, was prompted by the author's apparent disbelief in electric transmission. In that attitude he is one of many engineers, and out of this praiseworthy engineering competition the most suitable oil locomotive will be evolved. Personally the writer will watch with interest the advent of the English Still locomotive, which he understands will come to test sometime next spring, and hopes that the author will someday see the realization of his endeavors.

In the meanwhile oil-electric locomotives of from 2400 to 3000 hp. are serious projects under construction and will be factors in the race for supremacy in railroad operation.

P. H. Schweitzer.[6] In the first part of the paper the author enumerates some objections to the Diesel locomotives using an indirect transmission. The writer agrees with most of them. The statement that the Diesel engine is inferior in flexibility to the steam engine includes two different things: first, the Diesel engine cannot be run economically or at all at a speed materially different from its normal speed; second, the Diesel engine cannot be overloaded to any appreciable degree. So far as the locomotive is concerned, the first deficiency of the Diesel engine can be corrected by some form of variable-speed transmission, but not the second. If we are concerned with the torque alone the writer knows of nothing better than the electric transmission. Because of its high mechanical efficiency at all speeds the tractive efforts obtainable are very high, the drawbar horsepower being almost constant. Referring to Fig. 1, he would ask the author on which basis the comparison has been made. If the steam and the Diesel-electric locomotive are of equal drawbar horsepower, their tractive efforts at normal speed should be equal. But if the tractive effort of the Diesel-electric from 16 miles up is always less than half of that of the steam locomotive, the writer would not call them corresponding sizes.

Weight and first cost are the only objections against the electric drive so far as transmission of power is concerned. However, if a Diesel locomotive had a perfect transmission it would still lack the surplus power available to a steam locomotive of the same rating for climbing steep hills or accelerating a train quickly. Such extra power can only be obtained from a power accumulator.

The steam engine has a power accumulator in the boiler. Other means would be a compressed-air tank or electric accumulators. If with a Diesel engine we wish to equal the maximum drawbar horsepower of a steam locomotive, we have two alternatives: either install a Diesel engine of a size which is capable of delivering, say, 100 per cent more power than the average load would require, or provide some form of power accumulator. The author chooses the second alternative and gives two reasons therefor: first, the combination he proposes is less expensive to build; and second, it is less expensive to run.

The writer has not at hand sufficient data to contest the first statement, but he does question the second. Referring first to the fuel economy, the author states that the thermal efficiency at the average power demand will be decidedly higher than now

[6] Associate Professor of Engineering Research, The Pennsylvania State College, State College, Pa.

obtained with any Diesel locomotives because their Diesel engines must be dimensioned to suit the maximum power demand, which is undesirably large for the average load. The writer cannot agree with this because one of the characteristics of the Diesel engine is that its thermal efficiency on partial load nearly equals and sometimes exceeds that on full load. The reason is that the indicated thermal efficiency actually increases as the load decreases. A good Diesel locomotive, if run at half-load all the time, would have a fuel consumption less than 10 per cent higher than that of a locomotive engine of half the size running all the time on full load. This difference hardly amounts to anything. As to the effect on the engine, the writer would prefer to run an engine continuously on half-load than continuously on full load. The upkeep cost would probably be less, not to speak of the additional upkeep cost of the boiler.

The electric transmission has proved to be good, but it would be rather expensive and heavy for a 3000-hp. main-line locomotive. The writer wonders if by some arrangement the Diesel power could not be split, having, say, 2000 hp. in direct drive and 1000 hp. coupled with an electric transmission. The starting torque of a 1000-hp. d.c. motor would give plenty of tractive effort at low speed to accelerate a heavy train quickly. Near normal speed the (geared) direct drive would do most of the work, but electric transmission for about one-third of the total power would always be available to assist in taking grades and starting trains from standstill.

If experience should prove that electric or all other kinds of indirect drives now being tried are either mechanically or economically infeasible, the arrangement that the writer has called the accumulator system might offer the "solution." The Kitson-Still and Diesel-Hildebrand systems both have a steam boiler, which is just the thing some engineers would like to eliminate from the locomotive. Comparing the two systems, the author's proposal is more ingenious. The expanding of combustion gases and steam in the same cylinder, though daring, seems to be perfectly feasible. The writer sees no reason why the presence of steam should affect the combustion or the cylinder walls unfavorably. The parts that might give difficulties are the very-high-pressure boiler and the steam valve in the cylinder head.

However, the writer has heard good arguments for eliminating the steam boiler altogether, i.e., replacing it with a compressed-air tank. Such a modification of the Kitson-Still system was proposed by Mr. Child of the Baldwin Locomotive Company. In a similar modification for the Hildebrand system, compressed air would be admitted into the cylinder instead of steam after the combustion of the fuel was substantially completed, and the result would be not much different. There would be an air compressor for 500 lb. pressure and a compressed-air tank of sufficient capacity, but the boiler would be eliminated. The question is which is the less desirable.

Harte Cooke.[7] In general with a locomotive there are a few factors which are vital, namely, cost, weight, and tractive-effort curve.

The author's arrangement requires a complete Diesel engine with coolers, etc., so that the locomotive can operate as a Diesel engine when it is approximately up to speed. For starting it requires a complete steam-locomotive equipment with moderate-sized boiler, with the exception of the steam cylinders, using steam in the Diesel cylinders for starting.

Now it would seem that the steam-locomotive arrangement for starting with its tender carrying water and coal, would cost and weigh more than the electrical equipment used in connection

[7] Engineer, McIntosh & Seymour Corp., Auburn, N. Y., Mem. A.S.M.E.

with the Diesel engine. Also under railroad conditions, it is necessary to run at whatever speed the conditions impose at any particular time, and if this speed is a few per cent lower than the maximum speed permissible with the Diesel cylinders, the Diesel output would be less than it would be with Diesel-electric.

It may be that the extra Diesel-electric power to give a total power of the combined steam and Diesel locomotive would weigh less than the boiler with the fuel and water which would be required, or near enough to the same weight so that the higher tractive effort at starting and lower maintenance and lower fuel cost would make the Diesel locomotive more desirable.

R. Eksergian.[8] The author's proposal to increase the m.e.p. of the indicator card, particularly at the lower speeds, by the use of steam where the torque demand is large and thus to do away with the present costly and heavy transmissions, is one worthy of careful consideration and study for all engineers interested in expanding the utility of the Diesel locomotive for railway service. Assuming that the use of steam on the same side of the piston as for the oil combustion can be worked out satisfactorily, the proposed D-H type of engine is distinctly superior to the Still engine both in weight and steam economy.

However, the mechanical features of the two proposed designs from a locomotive aspect offer certain difficulties which the writer here wishes to point out in a very rough way.

For locomotive performance, good thermal performance is entirely secondary to weight efficiency and flexibility in torque variation. The starting requirements necessitate a large torque at starting, while the performance at speed requires maximum horsepower capacity per pound of weight. In addition, the arrangement of wheelbase and trucks is very important for proper tracking, minimum flange wear, etc.

It is well known that increasing the speed of any type of prime mover reduces its weight, though usually at the cost of higher maintenance. The author's first scheme, though eliminating the transmission, materially increases the weight of the engine if we take its effect on the frames, axles, etc. into consideration. With the jackshaft scheme the engine speed is increased, but at the expense of a jackshaft and its gearing.

In the direct drive proposed we at once run into the same difficulties that have been already experienced with the use of high-pressure steam in steam locomotives. That is, good expansion ratios from a very high pressure to a low pressure give a high ratio of peak to mean pressure. The mean pressure is effective in work performance, but the design of the machinery on the other hand is dependent entirely on the peak pressure.

This condition on limited-cut-off steam engines has already caused considerable difficulties in regard to space limitations and also a marked increase in the weight of the machinery, thus limiting the available boiler capacity when applied to our larger locomotives. To get a good expansion ratio and take advantage of the higher pressures, and also to reduce the ratio of peak to mean pressure in any one cylinder and thus reduce the weight of machinery, particularly on the limited-weight driving axles, the writer's company has recently developed a three-cylinder compound locomotive operating at 350 lb. steam pressure. This locomotive has developed 4500 i.hp. or 3700 drawbar hp. at the remarkable weight efficiency of 100 lb. per i.hp.

If we consider the preliminary proportioning of cylinders for the D-H locomotive under straight Diesel performance at maximum horsepower and corresponding speed, we find the ratio of peak to mean pressure excessive as compared with steam locomotives.

Further, since the ratio of starting to speed torque at maximum horsepower for satisfactory road performance should not exceed 2 to 2.3, we shall find that the same cylinders already proportioned for Diesel performance, when operating by steam in starting, will require very early cut-offs as compared with ordinary steam locomotives. It is therefore apparent that to meet the peak pressure for Diesel performance will require very large piston loads, necessitating large axles, heavy frames, and limited-size wheel centers.

In the performance of a locomotive a very severe requirement is that of developing large horsepowers at relatively low speeds, i.e., from 50 to 80 r.p.m. This condition brings a maximum demand on the boiler, because the engine efficiency is at its poorest, due to the meeting of maximum-torque requirements. With the proposed D-H locomotive, the Diesel power is either nil or, if in operation, relatively low due to the low r.p.m., so that the boiler capacity must be fairly large.

Therefore the practicability of this locomotive, aside from the cylinder performance, depends essentially upon whether the increased weight of machinery will permit sufficient boiler capacity to meet the above requirements, and at the same time meet the limited axle loadings and weights now demanded in large motive power.

In the jackshaft drive we encounter some very difinite limitations which would require a multiplicity of unit to meet the tractive-force requirements. It is known (see discussion by writer on the "Zoelly Turbine Locomotives," Trans. A.S.M.E., vol. 46, 1924), that 180,000 lb. adhesive weight is approximately the extreme limit for one jackshaft drive. To meet modern power tractive requirements would therefore require two jackshaft units. We have, of course, the same power demands and boiler requirements as before, but due to the higher speed of the engine and the fact that it is self-contained, a reduction in the weight of the engine may more than compensate for the two jackshafts. The cost, however, would probably be greater, due to the necessity of two separate units.

W. A. Pownell.[9] Although at present the average main-line steam locomotive has an overall thermal efficiency of 6 to 8 per cent, some of the more modern types of locomotives making use of all economy developments and devices have a somewhat higher efficiency. The steam-turbine locomotive, of which there are already a few in service, promises a thermal efficiency of around 16 per cent, and this probably represents nearly the maximum that may be expected from the steam locomotive for some time to come. The Diesel locomotive offers a thermal efficiency of about 33 per cent, or practically twice that of the best that may be expected of the steam locomotive. It is the writer's understanding that the author's Diesel steam locomotive will have a combined thermal efficiency which may average possibly 25 per cent, this average of course depending on the percentage of time that the locomotive is worked all-Diesel, all-steam, or steam-Diesel.

A. I. Lipetz in a paper read before the A.R.A. Mechanical Division at the 1927 meeting at Montreal stated that the Still engine used in marine service gave on tests thermal efficiencies of 37.1 and 36.4 per cent, respectively.

It seems to the writer that the comparison between the steam and Diesel-electric locomotives shown in Fig. 1 may not be exactly fair to the Diesel, since in this case the Diesel is probably of considerably lower horsepower than the steam locomotive with which it is compared, and the Diesel-electric tractive-power effort would therefore be considerably less than that of the steam locomotive as the speed increased.

The author's locomotive is based on the assumption that the

[8] Engineer, Baldwin Locomotive Works, Philadelphia, Pa., Mem. A.S.M.E.

[9] Mechanical Engineer, Wabash Railway Co., Decatur, Ill.

average demand on the present locomotive as it moves a train over the road is only 50 to 75 per cent of the maximum, depending on the service and nature of the road. This is true in general, although there may be some classes of service, such as time freight service or heavy freight trains that move over a low-grade line without much interference, where the average demand comes somewhat closer to the total available power of the locomotive. As a matter of information the writer submits the curve of Fig. 11 which shows the cylinder horsepower of a modern locomotive, developed over a 100-mile run in heavy freight service over a district having 0.4 per cent ruling grade. This curve was taken from actual dynamometer records, and the engine used had available boiler horsepower of 2760. In this case the average cylinder horsepower was about 75 per cent of the available horsepower.

Inasmuch as our modern practice of using superheated steam practically takes care of cylinder condensation, the writer does not see that the fact that the steam would expand in hot Diesel cylinders would be any additional advantage from this standpoint. However, on the other hand, if the hot Diesel cylinder will take care of cylinder condensation, it might be possible to do away with superheating the steam.

It is stated in the paper that steam and products of combustion

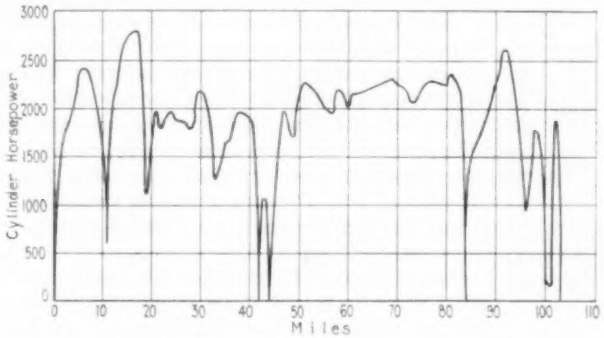

FIG. 11 CYLINDER HORSEPOWER DEVELOPED BY A MODERN LOCOMOTIVE OVER A 100-MILE RUN IN HEAVY FREIGHT SERVICE

of the Diesel can be mixed and do no harm to the cylinder liners and pistons. It may not be an analogous case, but most car drivers find that automobile engines seem to work better when there is a light rain or heavy fog, and there have been several devices on the market for injecting water into the manifold of the automobile engine. However, it is the writer's understanding that this practice has been discouraged on account of the expected dissolving effect of the mixture on the metal in the cylinders.

In the author's arrangement it is stated that the Diesel is to begin to operate when the speed of the locomotive reaches 4 m.p.h. With a 63-in.-driver locomotive, which is a very common size for modern freight engine, this would mean only $21^1/_3$ r.p.m., which seems rather low for Diesel-engine operation.

One incidental problem which is not mentioned in the paper is that of suitable draft for the fire of the steam boiler. Modern locomotives use induced draft produced by a jet of steam through the exhaust-nozzle tip, and which at the same time is responsible for more or less back pressure on the pistons of the engine. It would be rather impracticable to produce draft by this same method with a combined Diesel-steam locomotive, and the writer understands it would not be advisable to put this back pressure on the pistons. The alternative is the production of draft with an induced-draft fan, which, while it has been tried out to some extent in Europe and experimentally in this country, has not yet been successfully developed. This is of course an incidental problem, but one which will have to be given careful consideration.

If the initial cost of the D-H locomotive will, as stated in the author's answer to question 17, be approximately the same as that of a steam locomotive of equal capacity, it will overcome one of the principal objections that have been raised so far to the Diesel-electric locomotive, namely, its high initial cost.

If the D-H engine will give at least twice the thermal efficiency of the present steam locomotive, as seems probable, it will certainly result in a very large fuel saving, and one that will justify the interest and support of transportation men in the development of this steam-Diesel type of locomotive.

EDGAR J. KATES.[10] Although the author expects to use only Diesel power in the locomotive cylinders when pulling the train at normal speed and average load, it seems likely that in an engine as commercially built and practically used, steam will be admitted to the cylinders for a considerable portion of the running time.

In this case it becomes necessary to study fully the effect that the introduction of large amounts of steam will have on the Diesel cycle. The author mentions that there will result a heat exchange between the steam and the gases, that the hot gases will be cooled to a certain extent, and that the entering steam will be superheated. This, in the writer's opinion, might result in the hot gases being cooled something like 1000 deg. fahr., in which case it would seem that the Diesel efficiency would be seriously reduced because of the temperature degradation. A complete thermodynamic calculation on this point would be enlightening.

C. A. JACOBSON.[11] This paper, the writer believes, is the first one that has been discussed in this country on the direct-drive locomotive. He disagrees with the author that light-weight engines will not wear. If we take solid-injection engines of 50 lb. weight, they will be found to wear very much better than anything that is used in the steam locomotives which are at present in use on the railroads. Of course, this Diesel-steam process has not been tried so we are not sure that it will work out satisfactorily and undoubtedly there will be a great deal of development work required to perfect it.

The geared arrangement would be the most suitable as it would allow the most advantageous arrangement on the locomotive as far as weight distribution is concerned, with the separation of pressure and stress generated from the wheels from those generated by the engine, and it would also allow better ratios, so that a lighter engine could be built. Even on a direct-drive locomotive it would be unnecessary to add weight such as a boiler, as there would be more weight than was required. That would depend entirely upon the type of service in which the locomotive was placed. A passenger-steam locomotive may run down to 100 lb. per hp.

There is a decided disadvantage with the author's scheme, and very likely this will be true of the Kitson-Still locomotive. It will not be smokeless by any means. At the present time that is the chief reason for adopting a Diesel locomotive. Around New York City probably every such locomotive has been bought on that account. In other cases, of course, the reason has been branch-line operation. Smoke would even be very serious in main-line operation. Clean operation is probably one of the best reasons for the adoption of the locomotive, aside from its economy.

It may be of interest to note that the first gear-drive locomotive has been in regular operation since January 1, 1927.

[10] Consulting Engineer, New York, N. Y., Mem. A.S.M.E.

[11] American Crusher & Machinery Co., New York, N. Y.

One of the high officials of the German State Railways who recently returned from Russia has stated that there was no maintenance except what was required on the ordinary steam locomotive such as brakes. He stated that, in his opinion, the type was one of the best designed for main-line work, and it is expected that the German State Railways will place orders with the German licensees for a number of them. The Japanese State Railways have just placed an order for 15 of these locomotives, and very soon in this country there will be an opportunity to see one which was built by Krupp in Germany.

Mr. Lipetz said something about the efficiency of the mechanical gear-drive locomotive being as low as 12 to 13 per cent at times. That is true of any locomotive; when it is running on a partial load its efficiency is probably very low compared with its maximum. The electric drive would probably have a maximum transmission efficiency of 75 per cent at one load and speed, but at others it might be very poor. That has to be taken into account with any type of locomotive.

It seems to the writer that one of the chief things to get away from is the idea that a Diesel engine should only run at a mean effective pressure of 70 or 80 lb. We impose no such limit when we build a truck engine or an aviation engine, but build it so that it will give the highest horsepower output that can be possibly gotten out of it. The same thing should be true in a locomotive. A test was made in Europe with the four-cycle mechanical-injection type with the normal m.e.p. at 85 lb., and at that rate the fuel consumption was 0.37 lb. per hp. When the maximum mean effective pressure was 120 lb. the exhaust was just barely visible. The corresponding fuel consumption was 0.4 lb. for that increase of 50 per cent in the mean effective pressure and capacity of that engine, there was no difference as far as smoke was concerned, and the fuel economy was still very good. That increase in fuel consumption would be a very minor thing in locomotive operation where the periods of maximum power output would be comparatively small, and the majority of the time the power required would be very much less than the maximum.

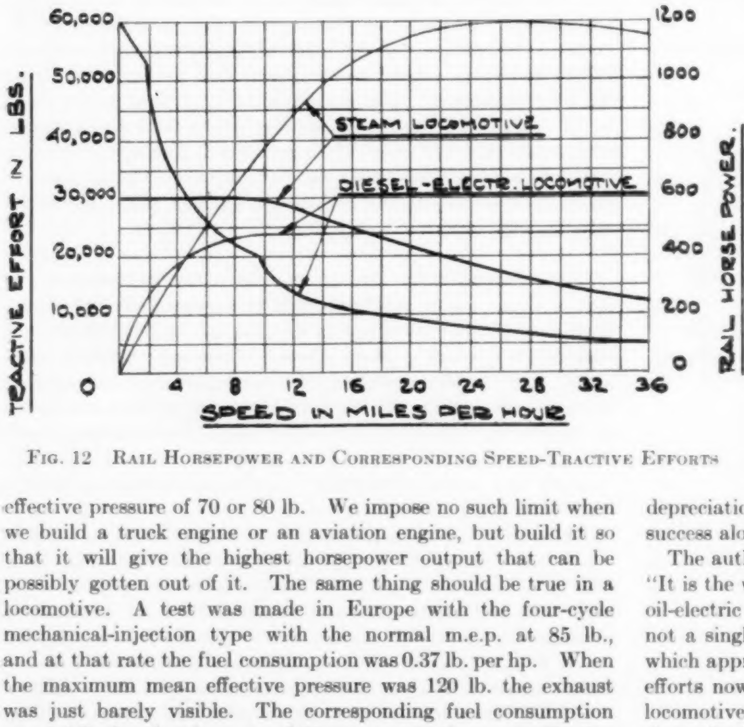

Fig. 12 Rail Horsepower and Corresponding Speed-Tractive Efforts

The Author. The whole discussion has not set forth a single argument which would make the proposed D-H locomotive questionable. A careful reader of the paper will find therein adequate replies to many of the remarks made during the discussion. Some of them are not sufficiently to the point to justify dealing with them. However, there are some which need a reply.

There is a fixed relation between rail horsepower and tractive effort at a given speed which is expressed by the following equation:

$$\text{Rail horsepower} = T \times 88S/33{,}000 = 0.00266\ TS$$

Here $T$ signifies the tractive effort in pounds, and $S$ the speed in miles per hour (one mile per hour equals 88 ft. per min.). The prime mover, whether it is a constant-torque or a constant-speed engine, must deliver the equivalent rail horsepower to obtain a given speed-tractive effort.

Fig. 12 shows the rail horsepower and the corresponding speed-tractive efforts. At the point where the curves of the latter intersect, both engines will develop the same horsepower. At lower speed the Diesel-electric, at higher speed the steam engine, develops the most horsepower and consequently the higher tractive effort.

Mr. Lemp states: "In reference to Fig. 1, it is evident that by changing the gear of the motor drive, the tractive effort (of the Diesel-electric locomotive) at the start may be lessened and higher speeds made possible." Generally speaking, when using a constant-speed engine, changing gears can only increase the speed at the expense of tractive effort. For the tractive efforts at the higher speeds in Fig. 1 to equal those of the steam locomotive it would require a larger Diesel developing not 480 but 1200 rail hp.

Right here is the difficulty. The present main-line locomotive of customary size (27-in. × 32-in. cylinders) develops at higher speeds about 2400 rail hp. and weighs, when loaded, about 160 tons or 133 lb. per rail hp. On the other hand, let us take the 600-b.hp. Ingersoll-Rand Diesel-electric locomotive: Its weight is 100 tons, or 330 lb. per b.hp., or 390 lb. per rail hp. These figures show what the designer of the Diesel-electric locomotive is up against. If he wishes to install 2400 or even 4000 rail hp. (equal to 2850 or 4750 b.hp.) to obtain the tractive effort which the present steam locomotives at higher speeds develop (without overstepping their weights), he is compelled to use Diesels about as light as those for airships. This, however, is not practical as their first cost and their inherent high wear and depreciation are prohibitive, because for railroads commercial success alone counts.

The author cannot at all agree with Mr. Lemp when he states, "It is the writer's (Mr. Lemp's) belief that the real field of the oil-electric locomotive will be heavy main-line service." So far not a single main-line locomotive exists anywhere on the globe which approaches the rail horsepower and corresponding tractive efforts now developed by the present heavier type of main-line locomotives at higher speeds. He cites an article in the *Railway Age* referring to a test on a Diesel-electric locomotive pulling four passenger coaches. What are four coaches with a handful of passengers compared to a heavy freight train several city blocks long moving at a fairly swift speed? Besides, M. B. Richardson pointed out in reference to Mr. Lemp's statement that "that test was made primarily for branch-line service and not for main-line service."

Mr. Lemp questions the reliability of a boiler carrying 500 lb. pressure. Here the author wishes to mention that the following locomotives are at present under course of construction which use much higher boiler pressures than he intends to:

Swiss Locomotive Works, Buchli type, boiler pressure 800 lb.; engine speed 1000 to 1200 r.p.m. geared down to a jackshaft.

The Swiss Locomotive & Machine Co. is testing at present a locomotive using 875 lb. boiler pressure.

Schwartz & Co.'s Berlin Works, 2500-hp. engine; boiler pressure, 1500 lb.

Referring to the remarks made by Mr. Lipetz: The author cannot agree when he claims that "it would be a mistake to consider the use of steam in a locomotive to treat it from the point of view of power instead of tractive effort." Power and speed-tractive effort stand in a fixed relation to each other, as the above equation shows. The engine builder is accustomed to speak of "horsepower;" the railroad man of "speed-tractive effort;" but both terms are interchangeable.

Mr. Lipetz errs when he says that a constant-torque locomotive must be designed to correspond to the minimum torque, for otherwise the engine will be considerably underloaded, and its economy reduced for small tractive efforts. Most of the power plants, those of Diese electric locomotives included, operate with low *average* load factors. Why does Mr. Lipetz's suggestion not extend to the Diesel-electric locomotive and have its engine designed for a low load factor? Of course the suggestion cannot be realized in practice in either case because the engine must be of sufficient size to meet the maximum load.

Mr. Lipetz believes that the maximum piston forces of the D-H locomotive will exceed those of the present steam locomotive. This will not be the case, as a careful investigation has shown. He assumes that the highest mean effective pressure obtainable in double-acting two-stroke-cycle engines is only 60 to 65 lb. per sq. in. This is not the case. The figures just mentioned refer to continuous load and represent a very conservative rating. The author is informed that mean effective pressures of 80 lb. per sq. in. have been reached without difficulty. Here it should be kept in mind that the term "tractive effort" refers to the maximum of what the engine can furnish. This being the case, much higher mean effective pressures, and consequently smaller power cylinders, can be used than Mr. Lipetz assumes.

Mr. Lipetz's statement that in a steam locomotive any tractive effort below the maximum renders the engine more economical, is not quite correct. A locomotive at a given speed has a most favorable cut-off; below this the economy drops off rapidly.

Mr. Lipetz's statement that in a Diesel locomotive the efficiency decreases with diminished tractive effort is correct with a locomotive driven by straight Diesel power. This, however, is not the case in the D-H locomotive. On the contrary, the economy increases until about half the maximum tractive effort is reached, which corresponds to about the normal load obtainable by straight Diesel power. Below this the efficiency remains first nearly constant (a characteristic of the Diesel cycle), and then begins to fall off more noticeably.

When Mr. Lipetz refers to the Still engine, pointing out that the piston top tends to superheat the steam, it should be mentioned that this is probably more than counterbalanced by the fact that the steam end of the cylinder has an extremely undesirable shape. That the steam consumption in the Still engine cannot be favorable may be judged from *Power*, vol. 64, page 730. Here a 2500-hp. marine Still engine is referred to, making use of the exhaust gases and the heat supplied to the water jackets. An economizer and a 27-in. vacuum are used, and yet only 14 per cent of the total power output is delivered by the steam unit. The D-H locomotive will have a much better steam consumption, and it will make use of the waste heat of the engine in a manner somewhat similar to that of the Still locomotive.

The author feels certain that Mr. Eksergian is not correct when he assumes that the weight of the D-H locomotive, shown in Fig. 7, will be materially higher than that of a steam engine of equal tractive effort. Here it should be considered that the boiler capacity needs to be only a fraction of that of the steam locomotive.

The author is fully aware that a direct-connected straight Diesel would give an undesirable ratio of peak to mean crankpin forces. This is one reason why he proposes the combination of Diesel and steam power and intends to proportion the cylinders for only 50 per cent straight Diesel. Mr. Eksergian says, "If we consider the preliminary proportioning of cylinders for the D-H locomotive under straight Diesel performance at a maximum horsepower and speed, we find..." The conclusions drawn on this assumption are not to the point in regard to the D-H locomotive.

Professor Schweitzer should be commended for his disinterested and unbiased remarks. He admits that, at average load, the D-H locomotive on account of its better load factor will consume about 10 per cent less fuel than a straight Diesel locomotive. The author would ask whether 10 per cent is not worth saving in addition to the considerable losses encountered by the generator and motors which alone amount to 15 to 35 per cent, depending on the load.

The author wishes to thank Mr. Pownell for furnishing a chart of an actual dynamometer record on a 100-mile run, having 0.4 per cent ruling grade, showing an average cylinder horsepower of about 75 per cent over the maximum.

It is true that superheating the steam in a steam locomotive reduces cylinder condensation, but it does not prevent it completely as does the D-H locomotive.

Mr. Pownell questions that the firing of the power cylinders will take place at a speed as low as four miles per hour. This depends on the heat at the end of the compression stroke. Using airless fuel injection and steam for starting eliminates the refrigeration effect which the use of air has in ordinary Diesels, making the D-H locomotive start much easier.

Referring to Mr. Jacobson's remark, it is a well-known fact that nearly all Diesels of medium and larger sizes are rated much below their maximum capacity. The reason is not that the Diesel could not be successfully operated at continuous higher loads, but that the average engineer under the average plant conditions will do very much better if his Diesel is not loaded to the utmost. The maintenance cost will be lower. Larger Diesels should not be compared with automobile and aviation engines because here the stresses are harder to deal with than in smaller cylinder sizes. This makes supercharging practical for smaller Diesels but questionable for larger ones.

In conclusion, the author would say that the D-H locomotive is a typical heavy-duty main-line engine. It does not deviate radically from customary practice as the straight Diesel locomotive does. Using a much smaller boiler but a greater number of cylinders, its weight and its crankpin forces will be within customary limits. Adding a fuel-injection pump and a scavenging-air blower will not materially affect its simplicity but will permit the introduction of the Diesel cycle and will completely eliminate all cylinder condensation. This will increase the efficiency over the steam locomotive a few hundred per cent, and will maintain its flexibility and its favorable tractive efforts at higher speeds.

The D-H locomotive will require some development work, but there is no question in the author's mind relative to its success, its revolutionizing effect on the railroads, and its importance relative to national economy. He expresses his hope that he will succeed in obtaining financial assistance which will enable him to prove by actual demonstration the value of the D-H locomotive.

# Efficiencies of Otto and Diesel Engines[1]

By F. O. ELLENWOOD,[2] ITHACA, N. Y., F. C. EVANS,[3] NEWPORT, DEL., AND C. T. CHWANG,[4] WASHINGTON, D. C.

*This paper gives primarily the results of calculations for the ideal Otto and Diesel engines in which the working substance is a mixture of real gases. The results are presented in the form of convenient tables and curves that may be readily used by any engineer in the determination of the engine efficiencies of internal-combustion motors operating under the various conditions existing today. The general method of procedure is fully explained and the necessary equations are given.*

*The paper also considers the factors involved in the establishment of "real-mixture standards" on which to base the performance of Otto and Diesel engines, and compares the results obtained by somewhat different conceptions. The use of higher and lower heating values of the fuel in the various calculations involved is discussed, and the tables and curves for the 65 cases considered give the results for both values.*

*The importance of using engine efficiencies to express performance is stressed, and five illustrative examples indicate that some of the best internal-combustion motors have already been so well designed and built that they give the excellent result of engine efficiencies as high as 76 per cent.*

FOR SOME years engineers have realized the importance of knowing the laws governing the variable specific heats of gases at high temperatures in order that they may make more satisfactory calculations of the ideal cycles of internal-combustion motors than was possible by the so-called "air standard" method formerly in use. The experimental data relating to these specific heats are not all in close agreement, but Goodenough and Felbeck[5] have recently assembled this information and presented equations that the authors accept as representing the most reliable values available to date. If engineers agree on the specific heats of gases, the chief uncertainty regarding the solution of problems based on the ideal Otto and Diesel cycles has been removed. However, there still remain certain points about which there may be differences of opinion.

This paper, therefore, has the following objects:

1 To discuss the factors involved in the determination of the ideal Otto and Diesel cycle efficiencies that may be used as logical standards;

2 To give the results of calculations for the ideal engines using various compression ratios and fuel mixtures, when considering the variable specific heats, but not dissociation; and to show the significance of these results in expressing the performance of internal-combustion engines;

3 To compare these results with those in which dissociation has been considered;

4 To present a few fairly typical illustrations of the efficiencies of modern engines.

---

### Ideal Otto and Diesel Cycles Defined

The ideal Otto engine herein considered is one in which the cycle is completed under the following conditions:

(*a*) There is no transfer of heat to or from the mixture while in the cylinder.

(*b*) There is no leakage, fluid friction, or mechanical friction in this engine.

(*c*) The mixture at the beginning of compression is assumed to be a gas having atmospheric pressure and a temperature of 200 deg. fahr.

(*d*) The compression and expansion ratio $r$ is equal to $(100 + c)/c$, where $c$ represents the clearance of the engine in per cent of piston displacement. The value of $c$ is to be chosen the same as it is in the actual engine with which the ideal is being compared.

(*e*) The mixture in the cylinder during compression is composed of air, fuel, and residual gases. The air-fuel ratio is chosen for the ideal engine to be the same as that obtained by test of the actual engine with which comparison is to be made, *provided the actual engine has at least sufficient air to permit complete combustion of the fuel. If the actual engine is operated with a deficiency of air, the air-fuel ratio in the ideal engine is then taken as just sufficient to afford complete combustion of all of the fuel.* The weight of residual gases cannot be calculated accurately, but it is assumed to be sufficient to fill one-half of the clearance volume when reduced to the pressure and temperature previously assumed at the beginning of compression.

(*f*) No dissociation is considered; in other words, all combustion is assumed to take place at constant volume, and the corresponding rise in the temperature of the products of combustion is just sufficient to account for the lower heating value of the known weight of fuel used per cycle.

For the ideal Diesel engine, conditions (*a*), (*b*), and (*c*) are assumed to hold as given for the Otto, while (*d*) is modified by having the expansion ratio less than the compression ratio due to the injection of fuel at constant pressure during part of the stroke, (*e*) is changed by eliminating the fuel from the mixture during compression, and (*f*) assumes that combustion occurs at constant pressure as the liquid fuel is injected.

The reason for considering the ideal engine to have at all times at least sufficient air to burn completely all of the fuel used is that, in the opinion of the authors, only by such a procedure can the heating value of the fuel be fairly used as a base on which the efficiency is measured. The mere fact that in certain types of Otto engines it may be desirable, for purely commercial or personal reasons, to operate an engine without sufficient air to burn the fuel, does not necessarily méan that the ideal engine is one through which part of the fuel is considered to pass without any possibility of complete combustion. The modern automobile engine is often operated with a deficiency of air in order to give a more flexible motor and at the same time yield its maximum power per unit of piston displacement. Fundamentally, however, this engine is still a heat engine, and it seems to the authors that in calculating the energy available from each unit of fuel it should be assumed that all of the fuel is to be completely burned, as is done with all other ideal heat engines. If any engine fails to burn its fuel completely, it certainly seems reasonable to expect its engine efficiency to be reduced thereby, and that is exactly what happens when the ideal is always considered to have at least sufficient air for complete combustion.

After establishing the conception of an ideal engine in which there is never a deficiency of air, the question of dissociation is next in order. The effect of dissociation on the efficiencies of the ideal cycles involving no deficiency of air is small, and it is therefore questionable whether such a refinement is warranted in the calculation of such ideal cycles, because of the following uncertainties involved:

*a* The amount of dissociation occurring within the cylinder of the real engine and the proper laws to use in considering dissociation in the corresponding ideal engine;

*b* The specific heats of the mixture in the cylinder at various temperatures;

*c* The composition and temperature of the mixture (including dilution) in the cylinder at the beginning of compression in the actual engine; and

*d* The composition and heating value of the fuel used.

Dissociation usually does not affect the efficiency of the ideal Diesel engine to as great an extent as it does that of the Otto engine, because dissociation is decreased by low temperature and the Diesel engine is commonly operated with a large percentage of excess air so that the maximum temperatures involved are less than in the Otto engine.

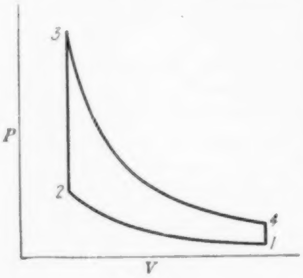

FIG. 1

## EQUATIONS USED

Since the ideal cycles are to be calculated for a mixture of gases whose composition varies with the compression ratio, fuel used, and air-fuel ratio, it is necessary to determine the equations for the specific heats of each mixture before and after combustion. The specific heats of a mixture of gases can be represented in terms of the absolute temperature $T$ by the equations

$$c_v = M + BT + CT^2$$

and

$$c_p = M' + BT + CT^2$$

where $M'$, $M$, $B$, and $C$ are constants for each gas mixture. As an illustration, consider the mixture of three gases with the respective weights $w_1$, $w_2$, and $w_3$, the same subscripts also being used to indicate the constants of each constituent. Then for this mixture

$$M = \frac{w_1M_1 + w_2M_2 + w_3M_3}{w_1 + w_2 + w_3} \ldots\ldots\ldots\ldots\ldots [1]$$

$$B = \frac{w_1B_1 + w_2B_2 + w_3B_3}{w_1 + w_2 + w_3} \ldots\ldots\ldots\ldots\ldots [2]$$

$$C = \frac{w_1C_1 + w_2C_2 + w_3C_3}{w_1 + w_2 + w_3} \ldots\ldots\ldots\ldots\ldots [3]$$

$$M' = \frac{w_1M'_1 + w_2M'_2 + w_3M'_3}{w_1 + w_2 + w_3} \ldots\ldots\ldots\ldots\ldots [4]$$

Also for $w$ pounds of this mixture having an absolute pressure of $p$ lb. per sq. in. and a volume of $V$ cu. ft., the constant $R$ is such that

$$\frac{144pV}{wT} = R = 778\,(c_p - c_v) = 778\,(M' - M) \ldots\ldots [5]$$

The mixture in the Otto- and Diesel-engine cylinders always contains some residual gases during compression. Therefore both the fuel mixture and the products mixture will contain a certain amount of $CO_2$, which means, according to Goodenough and Felbeck, that the gas constants will be different above and below 2900 deg. fahr. abs. Let the subscript zero be attached to the gas constants to be used with values of $T$ less than 2900. The actual values of the constants for the constituent gases, as used in the calculations, are given in Table 1. By the aid of the values given in this table and Equations [1] to [5], inclusive, the constants for the mixtures involved in each case were calculated and the results are clearly shown in the other tables.

TABLE 1 GAS CONSTANTS FOR CONSTITUENTS OF MIXTURES

| | $M'$ | $M$ | $B(10)^6$ | $C(10)^9$ | $R$ |
|---|---|---|---|---|---|
| $C_6H_6$ (Benzene) | 0.0513 | 0.0258 | 40.77 | 0 | 19.80 |
| $C_7H_8$ (Toluene) | 0.0435 | 0.0219 | 34.60 | 0 | 16.80 |
| $C_8H_{10}$ (Xylene) | 0.0377 | 0.0190 | 30.00 | 0 | 14.55 |
| $C_8H_{18}$ (Gasoline) | 0.3358 | 0.3184 | 33.29 | 0 | 13.53 |
| $O_2$ | 0.2166 | 0.1545 | 0 | 3.750 | 48.26 |
| $N_2$ | 0.2474 | 0.1765 | 0 | 4.283 | 55.12 |
| $H_2$ | 2.9762 | 1.9916 | 33.07 | 0 | 766.03 |
| $H_2O$ | 0.4624 | 0.3522 | −1.532 | 23.48 | 85.72 |
| CO | 0.2474 | 0.1765 | 0 | 4.283 | 55.12 |
| $CO_2$, $T < 2900$ | 0.1625 | 0.1174 | 8.864 | −13.64 | 35.10 |
| $CO_2$, $T > 2900$ | 0.2772 | 0.2321 | 0.9545 | 0 | 35.10 |

As soon as the specific-heat equations are known, it is then possible to calculate the values of internal energy and enthalpy (or heat content) of any mixture having a known temperature, or vice versa. Equations [6] to [13], inclusive, which follow, are used for this purpose.

Specific Heat at Constant Volume, $c_v$

$$\text{If } T < 2900, \quad c_v = M_0 + B_0T + C_0T^2 \ldots\ldots\ldots [6]$$

$$\text{If } T > 2900, \quad c_v = M + BT + CT^2 \ldots\ldots\ldots [7]$$

Specific Heat at Constant Pressure, $c_p$

$$\text{If } T < 2900, \quad c_p = M'_0 + B_0T + C_0T^2 \ldots\ldots\ldots [8]$$

$$\text{If } T > 2900, \quad c_p = M' + BT + CT^2 \ldots\ldots\ldots [9]$$

Specific Internal Energy, $i$

$$\text{If } T < 2900, \quad i = \int_0^T c_v dT = M_0T + \frac{B_0T^2}{2} + \frac{C_0T^3}{3} \ldots\ldots [10]$$

$$\text{If } T > 2900, \quad i = i_{2900} + \int_{2900}^T c_v dT$$

$$= (M_0 - M)2900 + \frac{B_0 - B}{2}\,(2900)^2 + \frac{C_0 - C}{3}\,(2900)^3 + MT + \frac{BT^2}{2} + \frac{CT^3}{3} \ldots [11]$$

Specific Enthalpy (or heat content), $h$

$$\text{If } T < 2900, \quad h = \int_0^T c_p dT = M'_0T + \frac{B_0T^2}{2} + \frac{C_0T^3}{3} \ldots\ldots [12]$$

$$\text{If } T > 2900, \quad h = h_{2900} + \int_{2900}^T c_p dT$$

$$= (M'_0 - M')\,2900 + \frac{B_0 - B}{2}\,(2900)^2 + \frac{C_0 - C}{3}\,(2900)^3 + M'T + \frac{BT^2}{2} + \frac{CT^3}{3} \ldots [13]$$

First consider the ideal Otto engine, for which the lines 1–2 and 3–4 of Fig. 1 represent on the pressure-volume diagram the isentropic compression and expansion curves, respectively, of a definite weight of working substance. It is not necessary to consider the suction and exhaust strokes for the ideal engine because it is assumed that there is no fluid friction, and consequently the area of the diagram would not be affected by them. The line 2–3 represents the rise in pressure of the products mixture due to

combustion, which is considered as taking place at constant volume and without any transfer of heat to or from the working substance. The line 4–1 represents the extremely rapid drop in pressure of the products mixture remaining in the cylinder while the piston is at the end of the stroke after the exhaust valve opens at 4 and lets most of the gases rush out to the atmosphere. This exit of exhaust gases does no work on the piston, and the effect of it on this diagram is the same as though all of the gases had been cooled at constant volume from 4 to 1.

The relation between temperature and volume of a mixture, having variable specific heats, when undergoing an isentropic compression or expansion is now required. The temperature $T_1$, the ratio of compression, $r = V_1/V_2$, and $w$ pounds of a certain mixture are assumed for the case under consideration.

TABLE 2 GAS CONSTANTS FOR EXPANSION MIXTURE IN OTTO ENGINE

| Fuel | | Lb. air per lb. fuel | Per cent air | $M$ ($T > 2900$) | $M_0$ ($T < 2900$) | $B(10)^5$ ($T > 2900$) | $B_0(10)^5$ ($T < 2900$) | $C(10)^9$ ($T > 2900$) | $C_0(10)^9$ ($T < 2900$) | $R$ |
|---|---|---|---|---|---|---|---|---|---|---|
| Gasoline $C_8H_{18}$ | | 15.2 | 100 | 0.2026 | 0.1808 | 0.0485 | 1.556 | 5.150 | 2.550 | 54.10 |
| | | 16.7 | 110 | 0.2000 | 0.1799 | 0.0440 | 1.427 | 5.060 | 2.674 | 54.06 |
| | | 18.2 | 120 | 0.1980 | 0.1792 | 0.0403 | 1.312 | 5.002 | 2.852 | 54.05 |
| | | 20.5 | 135 | 0.1950 | 0.1785 | 0.0357 | 1.173 | 4.910 | 2.950 | 53.99 |
| | | 22.8 | 150 | 0.1927 | 0.1778 | 0.0320 | 1.058 | 4.838 | 3.069 | 53.97 |
| "90%" Benzol | $C_6H_6$ 73% | 13.48 | 100 | 0.1985 | 0.1717 | 0.1470 | 1.994 | 4.195 | 1.015 | 52.09 |
| | $C_7H_8$ 23% | 16.18 | 120 | 0.1943 | 0.1717 | 0.1240 | 1.680 | 4.226 | 1.558 | 52.32 |
| | $C_8H_{10}$ 4% | 20.22 | 150 | 0.1901 | 0.1719 | 0.1002 | 1.358 | 4.220 | 2.060 | 52.69 |
| Blast-furnace gas | CO (Vol.) 28% | 0.744 | 100 | 0.1971 | 0.1590 | 0.2975 | 2.934 | 3.064 | −1.486 | 48.82 |
| | $H_2$ (Vol.) 3% | 0.893 | 120 | 0.1952 | 0.1600 | 0.2690 | 2.710 | 3.151 | −1.030 | 49.32 |
| | $CO_2$ (Vol.) 10% | 1.042 | 140 | 0.1935 | 0.1608 | 0.2584 | 2.516 | 3.223 | −0.657 | 49.63 |
| | $N_2$ (Vol.) 59% | .... | .... | .... | .... | .... | .... | .... | .... | .... |

Then with $I$ representing the internal energy, $Q$ the quantity of heat added during a process, and $A = 1/778$, it follows from the common energy equation that $dQ = dI + APdV$.

But from the relation $PV = wRT$, and remembering that $dQ = 0$ for an isentropic process, it must be true that

$$0 = dI + A\frac{wRTdV}{V}$$

But for $T < 2900$, $dI = wc_vdT = w[M_0 + B_0T + C_0T^2]dT$

$$\text{Hence} \qquad \left[\frac{M_0}{T} + B_0 + C_0T\right]dT = -A\frac{RdV}{V}$$

Then integrating between the limits $T_1$, $V_1$ and $T_2$, $V_2$ yields the following equation between $T$ and $V$:

$$M_0 \log_e \frac{T_2}{T_1} + B_0(T_2 - T_1) + \frac{C_0}{2}(T_2^2 - T_1^2)$$

$$= -AR\log_e\frac{V_2}{V_1} = AR\log_e\frac{V_1}{V_2} \qquad [14]$$

Let $K = 2.3026 = \dfrac{\log_e N}{\log_{10} N}$.

$$\text{Then } KM_0 \log\frac{T_2}{T_1} + B_0(T_2 - T_1) + \frac{C_0}{2}(T_2^2 - T_1^2) = KAR\log r$$

or

$$\log\frac{T_2}{T_1} + \frac{B_0}{KM_0}(T_2 - T_1) + \frac{C_0}{2KM_0}(T_2^2 - T_1^2) = \frac{AR}{M_0}\log r \qquad [15]$$

With the constants $M_0$, $B_0$, and $C_0$ for the fuel mixtures obtained from the tables of calculated results given later, the temperature at the end of compression $T_2$ is now found by means of Equation [15] for each case having $T_1$ and $r$ known.

After obtaining $T_2$ for the fuel mixture, the value of the specific internal energy $i_2$ at the end of compression is next obtained by means of Equation [10]. Then the work done by a unit weight of this mixture during compression is

$$\text{Work}_{1,2} = i_1 - i_2 \qquad [16]$$

From this equation, which will always yield a negative value since $i_2$ is greater than $i_1$, it is apparent that it is not the absolute value of the internal energy that is involved but only the difference of two internal energies, both of which must be measured above the same zero value, which is arbitrarily chosen.

For the rest of the cycle the problem deals with the products mixture. Here it should be noted that the internal energy of a fuel mixture at a given temperature and volume is not necessarily the same as the internal energy of the products mixture at the same temperature and volume. Consequently the next step in the solution is to find the internal energy of the products mixture $i'_2$ at the temperature $T_2$. This is done by using Equation [10] with the proper constants for the products mixture. The values of $i_2$ and $i'_2$ are given in the table for each set of calculations. Then by adding to $i'_2$ the energy evolved by the combustion of $w_f$ pounds of fuel per pound of mixture, the internal energy of the pound of mixture at the end of combustion is found. When the heating value of a fuel is determined experimentally, it is done by measuring the amount of heat abstracted from the products of combustion and not from the original mixture. Consequently

$$i_3 = i'_2 + w_f(\text{L.H.V.}) \qquad [17]$$

The lower heating value of the fuel should be used for this purpose because the temperatures at 2 and 3 are both far above the saturation temperature corresponding to the partial pressure of the water vapor formed by the combustion of any hydrogen in the fuel.

For the isentropic expansion the equation used is similar to that just developed for the compression curve, but it is complicated by the fact that in general two sets of gas constants are involved because the extremes of temperature usually lie both above and below 2900 deg. Assuming this condition to hold, the equation giving the temperature-volume relation for the expansion line 3–4 may be derived thus:

Let $T_d(=2900)$ and $V_d$ represent respectively the absolute temperature and volume of the products mixture at the dividing point $d$ between the equations of the two portions of the expansion line. Then above 2900,

$$M\log\frac{T_3}{T_d} + \frac{B}{K}(T_3 - T_d) + \frac{C}{2K}(T_3^2 - T_d^2)$$

$$= AR\log\frac{V_d}{V_3} \qquad [18]$$

and below 2900,

$$M_0\log\frac{T_d}{T_4} + \frac{B_0}{K}(T_d - T_4) + \frac{C_0}{2K}(T_d^2 - T_4^2)$$

$$= AR\log\frac{V_4}{V_d} \qquad [19]$$

Now, by adding Equations [18] and [19], there is obtained

$$\left[(M_0 - M)\log T_d + \left(\frac{B_0 - B}{K}\right)T_d + \left(\frac{C_0 - C}{2K}\right)T_d^2\right]$$

$$+ M\log T_3 - M_0 \log T_4 + \frac{BT_3 - B_0T_4}{K} + \frac{CT_3^2 - C_0T_4^2}{2K}$$

$$= AR\log\frac{V_4}{V_3} \qquad [20]$$

For any given mixture, the portion of Equation [20] that is enclosed by the brackets becomes a constant (since $T_d = 2900$) and consequently the solution of this equation to find $T_4$ is somewhat shorter than might be expected. However, in all of these equations of isentropic processes the solution involves the use of trial values of the unknown temperature until the equation is satisfied for the given ratio of expansion or compression.

After obtaining $i_3$, the value of $T_3$ is found by means of Equation [10] or [11]. Usually $T_3$ is above 2900 and consequently Equation [11] is used. Then by knowing the expansion ratio, $V_4/V_3$, the temperature $T_4$ is found by using Equation [20]. Next, the internal energy per pound of product mixture $i_4$ is obtained for the temperature $T_4$, and the work done by this mixture during its isentropic expansion is

$$\text{Work}_{3,4} = i_3 - i_4 \qquad [21]$$

Since the ideal cycle involves no fluid or mechanical friction the net work done by each pound of mixture in the ideal Otto engine is therefore

$$\text{Work}_i = i_3 - i_4 + (i_1 - i_2) \qquad [22]$$

The efficiency of this ideal engine is

$$e_i = \frac{\text{Work}_i}{w_f \times (\text{heating value of the fuel})} \qquad [23]$$

In this expression $w_f$ represents the weight of fuel used per pound of mixture.

The question of whether the higher or lower heating value should be used for this efficiency is debatable to the same extent as it is when determining the thermal efficiency of the actual engine. Since there is such a difference of opinion on this point among the engineers of the world, the efficiencies have been calculated for both the higher and lower values and the results are clearly indicated in the tables and curves. However, it should probably be stated again at this point that in Equation [17] the lower heating value should be used regardless of what value is used in Equation [23], because there is no possibility that the higher heating value is available to increase the temperature of the products of combustion above the temperature at the end of compression.

For the ideal Diesel engine the solution is carried out in a somewhat similar manner to that just outlined for the Otto. However, there are certain modifications that need to be observed on account of the fact that a definite weight of liquid fuel is injected after compression and is assumed to burn at constant pressure instead of constant volume. It should perhaps be emphasized here that in the actual engine it is only necessary to atomize the fuel finely (not vaporize) and mix it thoroughly with the air before it will ignite or burn readily. Tests show this to be true, and to assume that the fuel must be vaporized before injection in the ideal Diesel seems to the authors to be basically wrong and unnecessary.

Let Fig. 2 represent the $P$-$V$ diagram of this ideal engine. After assuming $T_1$, and finding the gas constants for the compression mixture (consisting of air and residual gases only), the values of $T_2$, $i_1$, and $i_2$ may be determined for the given compression ratio, as previously explained for the Otto. The work done by $w_c$ pounds of this compression mixture is found from the equation

$$\text{Work}_{1,2} = I_1 - I_2 = w_c(i_1 - i_2) \qquad [24]$$

The work done on the liquid fuel in pumping it into the cylinder of the actual Diesel engine is a very small fraction of the work done in compressing the air required for its combustion, and in the ideal Diesel the work done on the liquid fuel is still less because it is assumed there is no fluid or mechanical friction. As a matter of fact, for the ideal engine the work done on the liquid fuel is so small that it affects the net work of the cycle less

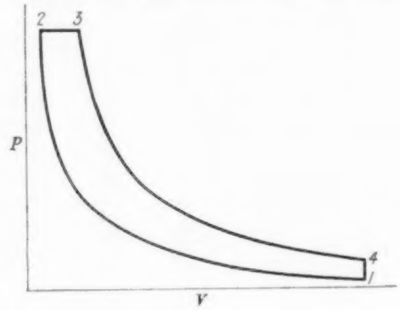

Fig. 2

than one part in 4000, and is therefore properly considered a negligible quantity in these calculations.

For the case of air injection of the fuel, it is not necessary to make any special calculations for the work of compression of the air in the corresponding ideal engine. This is because the work of compression in the ideal engine includes that required for the injection air if the correct air-fuel ratio is used. It is true that the actual engine must employ injection-air pressures much higher than the compression pressure, but this is due chiefly to fluid friction and the necessity of rapid injection, and consequently whatever loss is incurred by this extra pressure must appear in the reduced engine efficiency.

While $w_f$ pounds of the fuel are injected into the cylinder and burned at constant pressure, the work done by the resulting $(w_f + w_c)$ pounds of product mixture is

$$\text{Work}_{2,3} = AP_3V_3 - AP_2V_2 = (w_f + w_c)AP_3\overline{V}_3 - w_cAP_2\overline{V}_2 \qquad [25]$$

where $\overline{V}$ indicates specific volume.

During the isentropic expansion of the products mixture from 3 to 4, the work done is

$$\text{Work}_{3,4} = I_3 - I_4$$

$$= (w_r + w_c)(i_3 - i_4) \qquad [26]$$

By combining Equations [24], [25], and [26] and remembering that for any mixture the specific enthalpy is defined by the equation, $h = i + AP\overline{V}$, it follows that the net work for $(w_f + w_c)$ pounds of product mixture is

$$(w_f + w_c)(i_3 - i_4) + (w_f + w_c)AP_3\overline{V}_3 - w_cAP_3\overline{V}_3 + w_c(i_1 - i_2)$$

$$= (w_f + w_c)(h_3 - i_4) - w_c(i_1 - h_2)$$

Hence the net work in B.t.u. per pound of product mixture becomes

$$\text{Work}_i = (h_3 - i_4) - \left(\frac{w_c}{w_f + w_c}\right)(i_1 - h_2) \qquad [27]$$

Therefore the efficiency of the ideal Diesel engine is

$$e_i = \frac{(h_3 - i_4) - \left(\dfrac{w_e}{w_f + w_e}\right)(i_1 - h_2)}{w_f \times (\text{heating value in B.t.u. per lb.})} \quad \ldots\ldots [28]$$

In order to calculate the values needed in Equation [28], there are several points to be noted. As soon as the temperature at 2 is obtained the specific enthalpy $h_2$ of the compression mixture may be found by using Equation [12]; then, by the same equation but with different constants, it is necessary to find $h_2'$

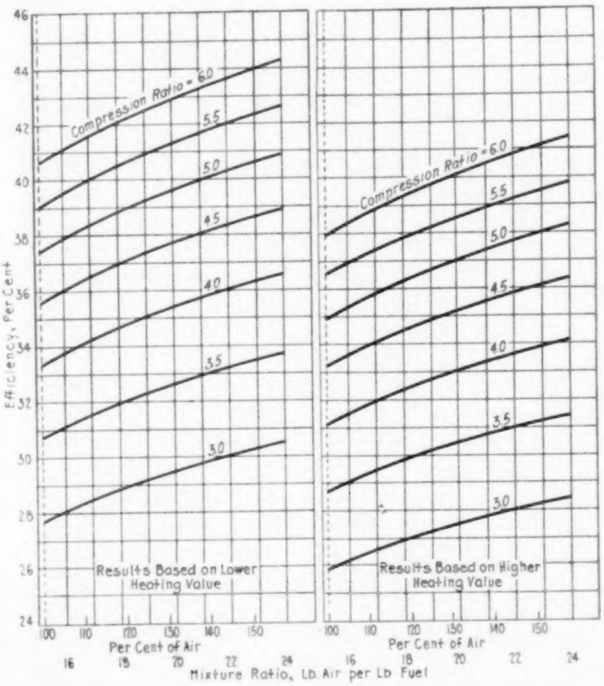

Fig. 3 Efficiency of Ideal Otto Engine Using Gasoline

the specific enthalpy of the product mixture at this same temperature, $T_2$. The calculation of $h_2'$ is essential because the experimental determination of the heating value of a fuel at constant pressure simply shows the amount of heat abstracted from the products mixture in order to cool it to its original temperature, the pressure being constant. Hence, if the lower heating value (L.H.V.) of the fuel is known, it follows that

$$h_3 = h_2' + w_f(\text{L.H.V.}) \quad \ldots\ldots [29]$$

From Table 8 it may be noted that $h_2'$ is appreciably different from $h_2$. After $h_3$ is found the corresponding temperature $T_3$ is obtained by using Equation [13].

Before $T_4$ can be found the ratio of expansion $V_4/V_3$ must be obtained. Since the pressure of $w_2$ pounds of the compression mixture at 2 is the same as $w_3$ pounds of the product mixture at 3, it follows that

$$V_3 = \left(\frac{w_3R_3T_3}{w_2R_2T_2}\right) V_2 \quad \ldots\ldots [30]$$

But $V_4 = V_1 = rV_2$, where $r$ represents the compression ratio. Therefore

$$\frac{V_4}{V_3} = \left(\frac{w_2R_2T_2}{w_3R_3T_3}\right) r \quad \ldots\ldots [31]$$

Then by using Equations [20] and [31], $T_4$ is obtained and consequently $i_4$ may be found from Equation [10] if $T_4$ is less than 2900 deg. and from Equation [11] if $T_4$ is greater than that value.

## Results of Calculations and Their Significance

By using the method just outlined for the Otto and Diesel cycles, the results, as shown in Tables 3, 4, and 5, were obtained. Special effort has been made to make clear the meaning of each column by means of suitable names as well as by the symbols used in the formulas. The term "100 per cent air" means that amount necessary to supply just sufficient oxygen to burn the fuel completely, and "120 per cent air" means 20 per cent more than is necessary for this purpose.

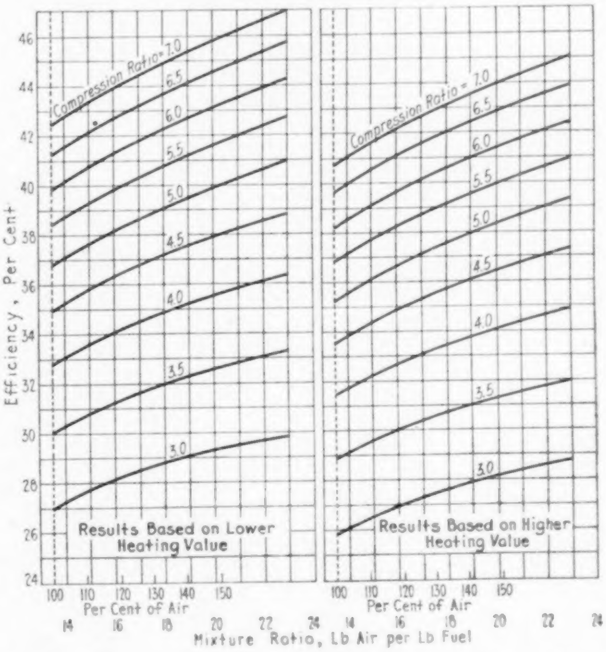

Fig. 4 Efficiency of Ideal Otto Engine Using "90 Per Cent" Benzol

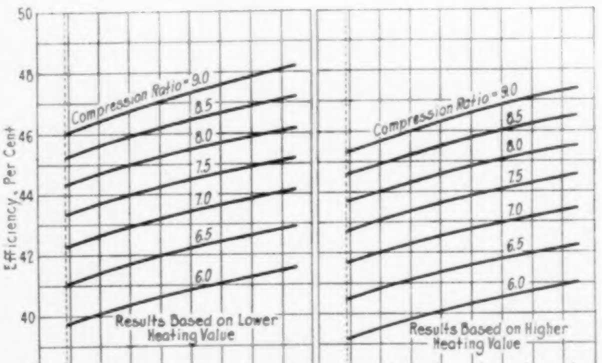

Fig. 5 Efficiency of Ideal Otto Engine Using Blast-Furnace Gas

For the Otto engine, using gasoline, 90 per cent benzol, and blast-furnace gas, the results are also given in Figs. 3, 4, and 5, respectively. The efficiencies were plotted against the mixture ratio, because this set of axes gives the best distribution of the curves in a given space.

The curves for each of the three fuels are similar and are only displaced from each other by a maximum difference of slightly more than 2 per cent for any given compression ratio and the

TABLE 3 CALCULATED RESULTS FOR IDEAL OTTO ENGINE WITH GASOLINE[1] AS FUEL

[1] Lower heating value = 98 B.t.u. per cu. ft. or 1300 B.t.u. per lb. Higher heating value = 99.5 B.t.u. per cu. ft. or 1318 B.t.u. per lb.
Composition by volume 28 per cent CO, 3 per cent $H_2$, 10 per cent $CO_2$, 59 per cent $N_2$.
Composition by weight 27.2 per cent CO, 0.2 per cent $H_2$, 15.2 per cent $CO_2$, 57.4 per cent $N_2$.

same percentage of air. For the gasoline and "90 per cent benzol" the curves are almost identical when taken for the same weight of air per pound of fuel and for the same compression ratio. In all cases the efficiency is increased by a high compression ratio and a high percentage of air.

The ideal cycle efficiencies are drawn for both the higher and lower heating values of the fuel because sometimes one and sometimes the other is needed, for the present at least, when used as the proper standard with which the thermal efficiency of an actual engine may be compared. The engineer knows that he cannot build an internal-combustion engine that does not waste some energy to the water jacket, some to mechanical and fluid friction, and sometimes an excessive amount to the exhaust. (The term fluid friction refers to the resistances that must be overcome in getting the working substance in and out of the cylinder.) Naturally the designer and owner of an engine desire to know to what degree they have succeeded in eliminating these combined losses. The only way to do this is to determine the ratio that is now called by the A.S.M.E. Test Code on Definitions and Values the "engine efficiency." This term seems to be an excellent one because it represents a ratio that tells exactly how well the actual engine succeeds in converting the available energy of the fuel into useful work at the brake. This available energy, as previously explained, can never be based logically on anything but the lower heating value for the internal-combustion motor. However, both the ideal and actual engine may be arbitrarily charged with the higher heating value by any engineer who desires to base his thermal efficiency upon it. Consequently the two heating values may be involved in expressing engine performance, and there result the following equations:

Engine efficiency

$$= \frac{\text{Brake thermal effy. of actual engine based on L.H.V.}}{\text{Ideal cycle efficiency based on L.H.V.}} \quad [32a]$$

$$= \frac{\text{Brake thermal effy. of actual engine based on H.H.V.}}{\text{Ideal cycle efficiency based on H.H.V.}} \quad [32b]$$

$$= \frac{\text{Fuel required by ideal engine, lb. per hp-hr.}}{\text{Fuel used by actual engine, lb. per b.hp-hr.}} \quad [32c]$$

As an illustration of the application of these equations, consider the following typical example:

Assume an Otto engine with a compression ratio of 5, using 0.5 lb. of gasoline per b.hp-hr., and 10 per cent more air than that required for complete combustion of the fuel. Consider the two heating values of the fuel to be as given at the bottom of Table 3. From this table it may be seen that case No. 12 fulfils the required conditions, and that the efficiencies of the ideal engine are 38.2 and 35.7 per cent for the lower and higher heating values, respectively. Then from Equation [32*a*],

$$\text{Engine effy.} = \frac{2545/(0.5 \times 18{,}830)}{0.382} = \frac{0.27}{0.382} = 0.708$$

also from Equation [32*b*],

$$\text{Engine effy.} = \frac{2545/(0.5 \times 20{,}150)}{0.357} = \frac{0.253}{0.357} = 0.708$$

This same result will also be obtained by using Equation [32c], but it can not be found in quite such a direct manner. Thus for case 12, Table 3, it is observed that the net work per pound of mixture is 361.5 B.t.u. and this mixture is made up of 16.7 lb. of air and 2.18 lb. of residual gases per pound of fuel. Consequently the net work per pound of fuel in the ideal engine would be

$$361.5(16.7 + 2.18 + 1) = 7190 \text{ B.t.u.}$$

Hence the fuel required by such an engine would be

$$\frac{2545}{7190} = 0.354 \text{ lb. per hp-hr.}$$

Then from Equation [32*c*],

$$\text{Engine efficiency} = \frac{0.354}{0.5} = 0.708$$

It should be particularly noted that each of the three results for the engine efficiency is the same regardless of which heating value is chosen as the base on which the thermal efficiency is calculated, an important point for this method of measuring performance.

This measure of the performance of an internal-combustion engine is, in the opinion of the authors, one of the best to use in most of our engineering and public discussions. Why should the layman be continuously confronted with highly technical terms which he does not understand and which are positively misleading to him? He may never understand either thermal or engine efficiency, but when either one is presented to him he instinctively thinks of how near it is to 100 per cent. Thus he thinks that an engine that has a thermal efficiency of 30 per cent is a very poor example of the mechanical engineer's art, whereas if he is told that the engine efficiency is 75 per cent he naturally feels that the machine is a much better one. This is especially true if this layman has purchased from the same mechanical engineer a water wheel whose only "efficiency" is given as 85 per cent. As a matter of fact, the portion of the available energy that has been utilized by the actual internal-combustion motor or water wheel is an excellent measure of performance for both the engineer and the layman, because it indicates at once what the possible margin of future improvement actually is, while the thermal efficiency does not. In the past, the lack of sufficient reliable data regarding variable specific heats has been a serious difficulty in the way of obtaining the available energy, but now this question seems to be fairly well answered. Consequently, is there any good reason why engine efficiencies and fuel consumption per brake horsepower-hour should not be used as the chief means of expressing the performance of internal-combustion engines?

The results of calculations for the Otto cycle using gasoline, with 100 and 120 per cent air, have been plotted in Fig. 6 with the compression ratios as abscissas. There has also been added to these figures the curves which represent the results obtained by solving the familiar equation for the efficiency, $e = 1 - (1/r)^{\gamma - 1}$ where $\gamma$ represents the ratio $c_p/c_v$ of the specific heats of the working substance. Thus if $\gamma$ be taken as 1.4 this equation will

yield the efficiency curve marked "cold-air standard," because this value of $\gamma$ is only true for air when at the relatively low temperature of from about 0 to 400 deg. fahr. Since the average temperature in the Otto engine is far above these values, it is not surprising to see the curves representing the efficiencies based on this value lying far above the more reliable ones in this same figure. In this latter group are drawn in heavy lines the curves showing the efficiencies obtained by calculations involving the variable specific heats of the mixture corresponding to that in the actual engine. These curves may therefore, it seems to the authors, very properly be designated as those based on the "real-mixture standard."

In Fig. 6 there are also the curves giving the efficiencies calculated by the equation, $e = 1 - (1/r)^{\gamma - 1}$, in which the value of $\gamma$ is chosen to give efficiencies that agree fairly well with the real-mixture standard. This simply means determining a suitable average value of $\gamma$ for the entire cycle corresponding to hot air instead of cold air, and consequently it seems logical to the authors to refer to these curves as "hot-air standards." It is seen from Fig. 6 that with $\gamma = 1.295$, the resultant curve is in fairly close agreement with the one representing the real-mixture standard based on the lower heating value of gasoline with a small amount of excess air. For the compression ratios above 4, a value of $\gamma = 1.29$ will be in better agreement with this real-mixture standard for 100 per cent air.

When the higher heating value of gasoline is used, the curves in Fig. 6 show that a value of $\gamma$ = 1.265 or 1.27 would be more suitable. It may be observed that the shape of the efficiency curve for the real-mixture standard is slightly different from those of the air standards.

For blast-furnace gas the results are given in Fig. 7, which shows the same general characteristics as those discussed for gasoline. It will be noticed at once that for this fuel the difference between the two efficiencies based upon the two heating values becomes slight because the amount of hydrogen involved in blast-furnace gas is so small. With $\gamma = 1.28$ the hot-air standard is seen to agree very closely with the real-mixture standard based on the higher heating value and 100 per cent air, while for the same standard on the lower heating value, the agreement is close if $\gamma$ is chosen as 1.275.

For the ideal Diesel engine the results obtained by calculations of the efficiencies for the real-mixture standard with petroleum oil are given in Table 8, and also in Fig. 8. These efficiencies are higher than for the Otto solely because they have been calculated for higher compression ratios and with more air per unit weight of fuel than was done for the Otto. A basic advantage of the Diesel engine over the Otto, as far as thermal economy is concerned, is due to the fact that the former can operate satisfactorily with very much higher compression ratios and a higher air-to-fuel ratio than the latter. The Diesel engine so seldom operates without considerable excess air that it was not considered worth while to calculate the ideal efficiencies for less than 20 pounds of air per pound of fuel, or in other words, for about 40 per cent excess air. On the other hand, when the Diesel is running at very light loads the air-fuel ratio is extremely high

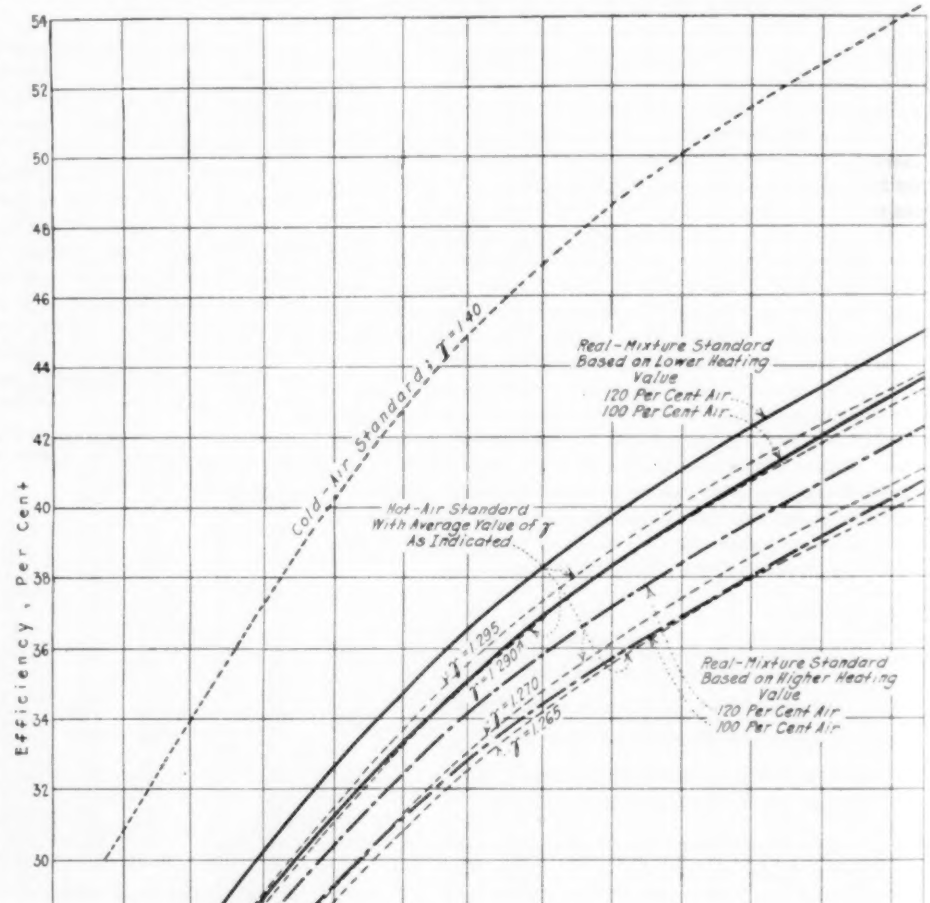

Fig. 6 Effect of Different Standards on the Efficiencies of the Ideal Otto Engine Using Gasoline

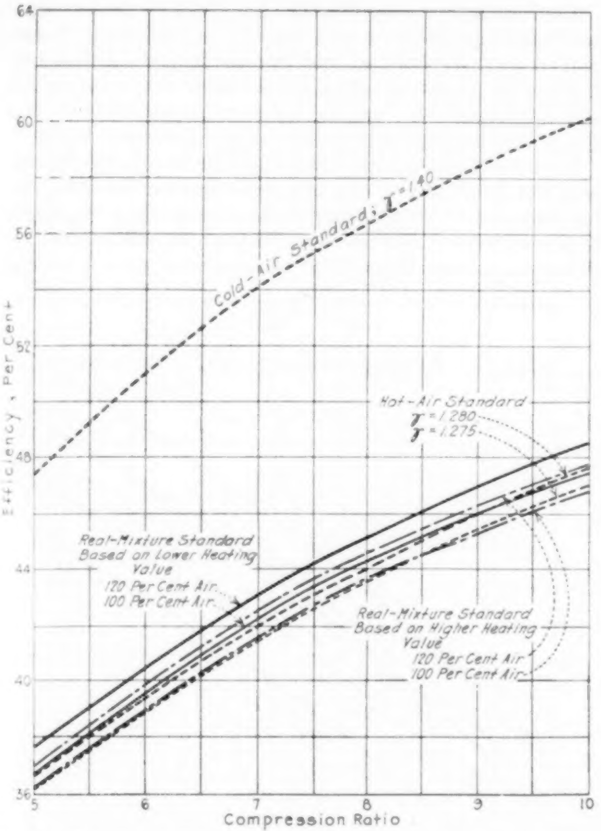

FIG. 7 EFFECT OF DIFFERENT STANDARDS ON THE EFFICIENCIES OF THE IDEAL OTTO ENGINE USING BLAST-FURNACE GAS

and the calculations were, therefore, carried to 100 pounds of air per pound of fuel, which corresponds to nearly seven times as much air as is required for complete combustion.

In the Diesel, for any given compression ratio a large proportion of air to fuel simply means early cut-off of the fuel injection and consequently a greater expansion of the products of combustion. This greater expansion is the primary reason for the marked increase in the ideal cycle efficiency shown in Fig. 8, as the air-fuel ratio becomes larger. A secondary reason is that with the greater weights of air used per unit weight of fuel the

[1] Composition by weight, 86 per cent C, 13 per cent H, 1 per cent N; lower heating value = 18,250 B.t.u. per lb., higher heating value = 19,480 B.t.u. per lb.

higher will be the average value of $\gamma$ during the expansion, and consequently the smaller becomes the temperature $T_4$ for a given expansion ratio, just as in the Otto. Of course it is desirable to have $T_4$ as low as possible in order to reduce the energy lost to the exhaust.

It was not considered worth while to plot the results for the Diesel in any form other than that given in Fig. 8 because it is believed this will be found to be the most convenient arrangement for general use. The performance test of a Diesel engine should give the specific fuel consumption and the corresponding air-fuel ratio. The compression ratio is known for any given engine, consequently the engine efficiency may be readily found by the aid of Fig. 8 and Equation [32].

### Mean Effective Pressures

If it be desired to determine the mean effective pressure of the ideal Otto or Diesel engine for any of the 65 cases calculated, it may be readily done in the following manner. From the appropriate table of calculated results read the net work $\text{Work}_i$ accomplished by the ideal engine in B.t.u. per pound of product mixture. Then the piston displacement, P.D., necessary to handle this pound of product mixture depends upon the constant $R_1$ for the compression mixture, the initial pressure $p_1$, the initial absolute temperature $T_1$, the ratio of compression $r$, and the weight of compression mixture $w_1$ required for each pound of product mixture. Referring to Fig. 2, it follows that the piston displacement in cubic feet required per pound of product mixture is

$$\text{P.D.} = V_4 - V_3 = V_1 - V_2 = V_1\left[1 - \frac{1}{r}\right]$$

$$= \frac{w_1 R_1 T_1}{144 p_1}\left[1 - \frac{1}{r}\right] \qquad [33]$$

Consequently the mean effective pressure of the ideal engine in pounds per square inch is

$$p_m = \frac{778 \times \text{Work}_i}{144\ \text{P.D.}} = \frac{778 \times \text{Work}_i(p_1)}{w_1 R_1 T_1\left[1 - \dfrac{1}{r}\right]} \qquad [34]$$

In this equation the value of $p_1$ should be chosen to agree with the atmospheric pressure at the time and place at which the actual engine is being tested, and $T_1$ should equal the assumed value for the ideal cycle calculations. Under these conditions the engine efficiency is also equal to the ratio of the brake m.e.p. of the actual engine to that of the corresponding ideal.

### Comparison with Results of Goodenough and Baker

After the calculations given in this paper for the ideal Otto and Diesel cycles had been almost completed, there became available the valuable bulletin[6] by Goodenough and Baker, entitled "A Thermodynamic Analysis of Internal-Combustion-Engine Cycles." Since this bulletin deals largely with the same questions that are treated in this paper, and since the same specific-heat equations are used in both cases, a brief discussion of the main points of difference in the conceptions of the ideal cycles and in the results obtained from the calculations will be given.

[6] Bulletin No. 160, University of Illinois, 1927.

The assumptions regarding the ideal cycles for the two sets of calculations are not alike with regard to air deficiency, dissociation, initial temperature, and the amount of residual gases. Also, for the Diesel, Goodenough and Baker have considered the fuel to be completely vaporized before entering the cylinder, while the authors have assumed the fuel to be injected as a liquid.

From Fig. 9 it may be seen that the difference in the efficiencies obtained from the two sets of calculations for the Otto varies from about 1.5 to 2 per cent, for the case in which the air used is 100 per cent of that necessary to support combustion. The difference becomes less and less as the air-fuel ratio is increased

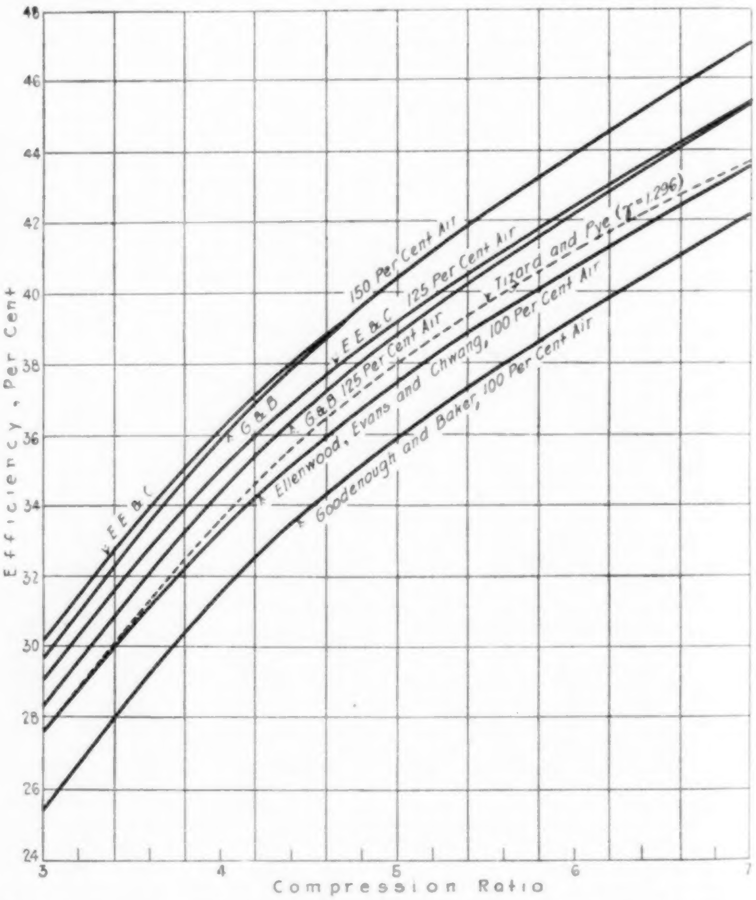

Fig. 9 Comparative Results for the Otto Engine Using Gasoline (Lower Heating Value)

until it is negligibly small at 150 per cent air, as shown by the two upper curves. For cases involving a deficiency of air the comparison cannot be made because this paper does not include them for reasons already given.

In Fig. 9 there is also shown by the broken line the curve of efficiencies obtained by using the equation $e = 1 - (1/r)^{\gamma - 1}$ where $\gamma$ is taken as equal to 1.296. This represents the equation proposed by Tizard and Pye[7] to replace the old air standard. It also represents their results of calculations of the ideal Otto-cycle efficiency in which the mixture has 25 per cent more air than is necessary for complete combustion, this being the mixture that usually gives the maximum thermal efficiency of an actual engine. According to their calculations the same result is obtained for this mixture regardless of whether dissociation is considered in the ideal cycle.

[7] See *The Automobile Engineer*, Feb., 1921, p. 58.

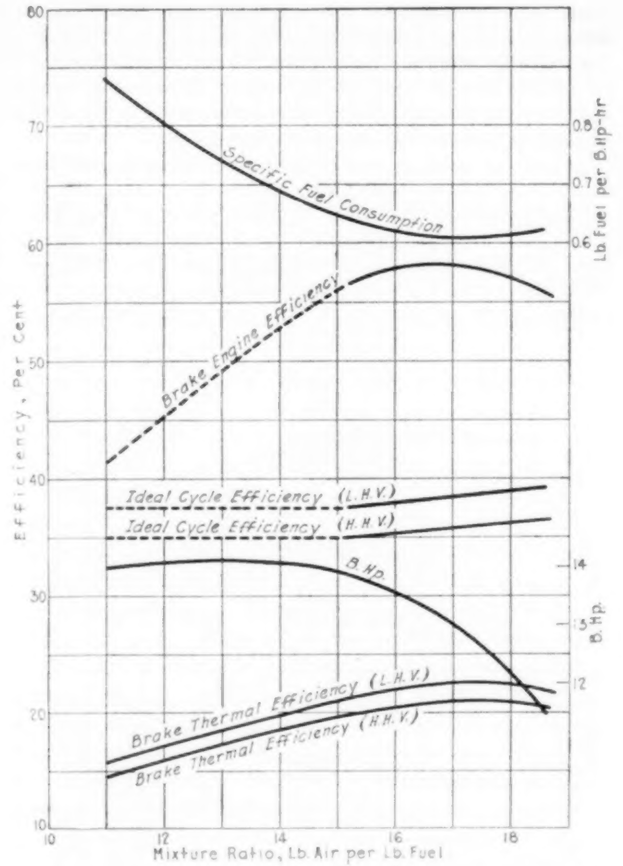

FIG. 10 85-PER CENT LOAD CURVES OF MARINE OTTO ENGINE

(Universal; 4 cylinders, $3^{1}/_{4}$ in. × $4^{1}/_{2}$ in.; compression ratio, 5; fuel, gasoline; speed, 1120 r.p.m. Data from student tests in Mechanical Laboratory, Cornell University.)

The results as given in Fig. 8 for the Diesel cannot be compared strictly with those of Goodenough and Baker because they used a different fuel. However, this would not account for nearly all the difference in the efficiencies, which amounts to about one per cent with 40 lb. of air per lb. of fuel, and becomes appreciably larger for the lower ratios of air to fuel, probably largely because the effect of dissociation is then so much greater. Possibly some of the difference is also due to the fact that they considered the fuel injected as a vapor instead of a liquid.

In this comparison it should also be pointed out that in this paper all results have been calculated on the assumption that the temperature of the mixture in the ideal engine at the beginning of compression is 200 deg. fahr., or in other words, $T_1 = 660$. It is realized that, strictly speaking, this temperature should be based on the compression ratio, the air-fuel ratio, and the temperature of the mixture entering the cylinder of the actual engine. All these factors make it difficult to select a suitable constant value of $T_1$ or to derive a logical equation for finding it. Goodenough and Baker have attempted the latter, and probably their value of $T_1$ is somewhat superior to the one used in this paper. However, from calculations made by the authors, it was found that a variation of 100 degrees in $T_1$ would cause a difference in the efficiency of only about 0.5 per cent, and this amount of variation in $T_1$ for the two sets of calculations was not approached in the Otto and exceeded slightly in the Diesel only at the very high compression ratios. Consequently it may be concluded that the selection of $T_1$ is not one of the most important factors in the calculations.

For actual engines operating with a deficiency of air there is involved the interesting technical question of what constitutes the mixture in the ideal engine on which to base the engine efficiency. Goodenough and Baker have considered the ideal engine for this case to use a mixture in which there is a deficiency of air, but at the same time the heat supplied is assumed to be that corresponding to complete combustion. This conception results in a low efficiency for the ideal engine and a correspondingly high value for the engine efficiency. On the other hand, the authors believe, for reasons given in the first part of this paper, that engines running under these conditions should be compared with an ideal that has sufficient air to support complete combustion. Here is an important technical point about which there may be considerable difference of opinion among engineers. This question does not come up for the Diesel because it seldom, if ever, operates with a deficiency of air.

Goodenough and Baker, also Tizard and Pye, gave no results based on the higher heating value and the authors of this paper would do likewise if they considered only their own preference. Even though the A.S.M.E. specifies in its present test codes that the higher heating value should be used in determining the thermal efficiencies of internal-combustion motors, such a procedure is not altogether logical, in the opinion of many members, and to the authors this question seems to be one worthy of further consideration by the Society.

### PERFORMANCE OF MODERN ENGINES

Probably most engineers in the past have not fully appreciated how important it is to determine the air-fuel ratio when making a thermal-economy test of an internal-combustion engine, or

perhaps in many instances the extra cost involved in making the more complete test has prevented it. In any case, in looking over the literature one has considerable difficulty in finding data including this important ratio.

The five sets of test results that are presented in graphical form in Figs. 10 to 14, inclusive, will serve to show the application of the ideal cycle efficiencies to determine the engine efficiencies under the various conditions as given. The test data were obtained from the sources indicated in the captions, and the engine efficiency has been calculated by using Equation [32].

In Figs. 10 and 11 are shown the performance curves of two small Otto engines running at constant speed, but with wide

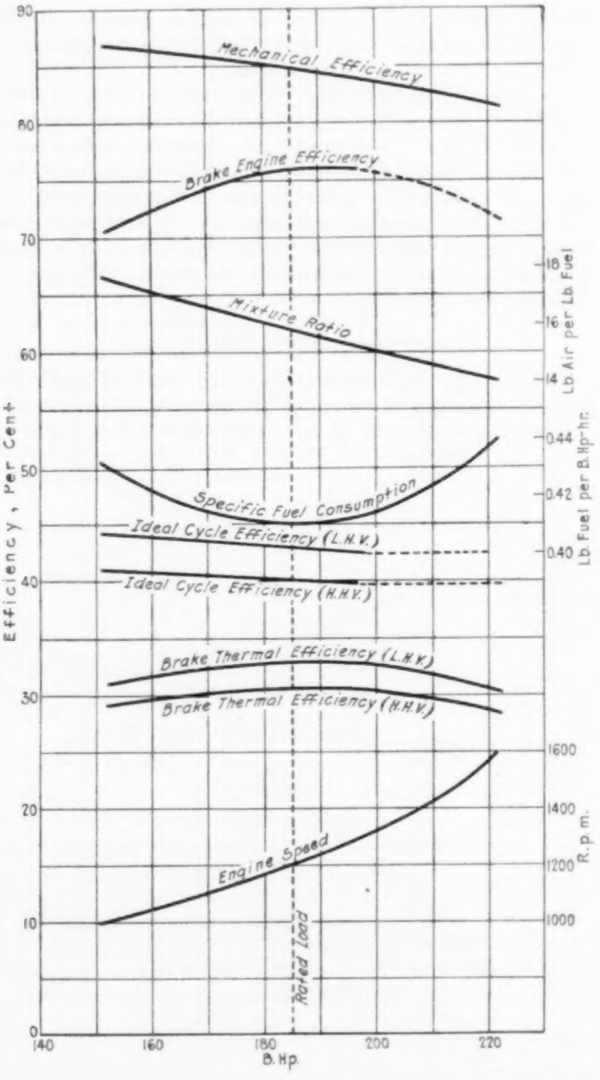

FIG. 12 PERFORMANCE CURVES OF 185-HP. AIRPLANE ENGINE

variations in air-fuel ratio, which are therefore plotted as abscissas. It is interesting to note from both of these figures how much more sensitive to a change in this mixture ratio are the engine and thermal efficiencies than is the power output. Thus in Fig. 10 the maximum power is seen to be 14.1 hp. for a mixture of 13 to 1, and the power is decreased only to 13 hp. for a mixture of 17 to 1, or this change in the air-fuel ratio causes a 7.8 per cent loss in power. At the same time the engine efficiency rises from 0.49 to its maximum value of 0.58, an increase of 18.4 per cent, and the brake thermal efficiency rises from 0.185 to 0.225, an increase of 21.6 per cent. The thermal and engine efficiencies do not increase in exactly the same proportion because the ideal cycle efficiency is not constant over this mixture range.

In both of these figures the curves representing the ideal

[Maybach; 6 cylinders, 6.5 in. × 7.09 in.; compression ratio, 5.9; fuel, 20 per cent benzol, 80 per cent gasoline. Test data from Report 134, United States National Advisory Committee for Aeronautics (1922).]

cycle efficiencies and the engine efficiencies are drawn with a broken line for those mixture ratios in which there is a deficiency of air, because it is desired to call special attention to this region concerning which there may be debatable ground as to the proper method of procedure.

The small marine engine whose performance curves are shown in Fig. 10 has given these same results on many different runs, as everything was under careful control. The motor could not be run at full load at this speed without serious detonation because it was cooled with steam at a temperature of 212 deg. fahr. This speed used was that which gave its maximum torque instead of maximum power.

In Fig. 12 and 13 are shown the results of tests of two airplane engines, operated with changes in both speed and mixture ratio.

Both of these tests were made in the altitude chamber of the U. S. Bureau of Standards, because full power was not supposed to be developed at sea level with these high compression ratios. Each one gives exceptionally high thermal and engine efficiencies, but this is especially true of the B.M.W. machine, whose maximum engine efficiency is, as may be seen from Fig. 12, slightly over 76 per cent.

In Fig. 14 are given the performance curves of a marine Diesel over its entire range of speed. These test data were obtained by the Marine-Oil-Engine Trials Committee of the Institution of Mechanical Engineers after very extensive tests. In their report they considered the ideal engine to have a constant efficiency of 52 per cent, whereas in Fig. 14 the variable

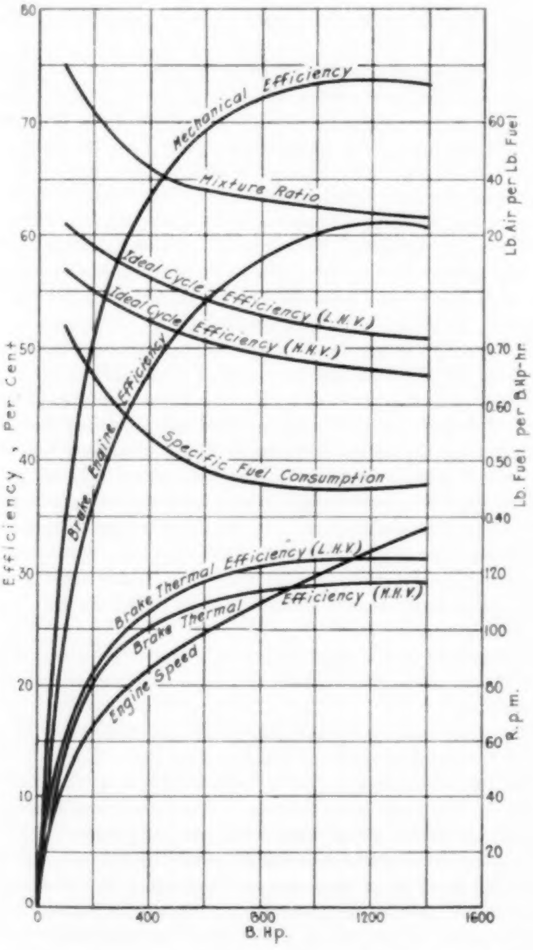

Fig. 14 Performance Curves of 1250-Hp. Marine Diesel Engine

(Richardsons-Beardmore-Tosi Director Valve; 6 cylinders, 4-cycle, 24.41 in. × 38.39 in.; compression ratio, 13; fuel, Anglo-Persian Diesel oil. Data from *Engineering*, vol. 118, p. 750.)

efficiencies of the real mixture standard are shown, and the corresponding curve for the engine efficiency was calculated by the authors as given in this figure.

Comparing the results of this marine Diesel test with those of the airplane Otto engine as given in Fig. 12, it is seen that the maximum thermal efficiency of this Otto engine is slightly better than the Diesel and the mechanical efficiency of the Otto is far superior. The combination of the lower mechanical efficiency and the higher cycle efficiency of the Diesel gives it an appreciably lower engine efficiency. Considerably better brake thermal efficiencies than those given in Fig. 14 are reported in *Engineering*[8] for both solid- and air-injection types of Diesels. These efficiencies are 34 and 36.7 per cent, respectively, for these two engines, but the air-fuel ratio and the compression ratio are not given, consequently the engine efficiency can not be determined.

## General Conclusions

The evidence presented in this paper and in those already published by other authors, indicates, to some extent at least, the difficulty and complexity of determining accurately the amount of energy available for the production of work in an internal-combustion motor. It also shows the necessity of making a few assumptions which may give rise to some difference of opinion among engineers. However, the final results obtained by different authors are for most cases in close agreement, and they all show very clearly that the "cold-air standard" with $\gamma = 1.4$ is too far from the truth to be further considered.

The results of the calculations of Goodenough and Baker, Tizard and Pye, and the authors are in close agreement except for those cases involving a deficiency of air, for which there is considerable divergence due to the different conceptions of what constitutes the mixture in the ideal engine and what is the proper method of treating dissociation in it. Considering the complexity of the problem, the final results obtained by different authors are, for most cases, in sufficiently close agreement to justify the hope that some of them, or a combination of them, may be accepted as standards by the A.S.M.E., or that at least they will serve to promote additional study and interest in the subject.

For the ideal Otto engine, in which no dissociation and no air deficiency are involved, the efficiencies calculated by the authors are given in Figs. 3, 4, and 5, for the fuels gasoline, benzol, and blast-furnace gas, respectively. For the Diesel using petroleum oil the results are shown by Fig. 8. The characteristics of these fuels were chosen to represent average values, and the results given in these curves may therefore be used for calculating actual engine efficiencies. In all of these curves the range of the compression ratio is more than sufficient for present practice. For all cases the ideal cycle efficiency is increased materially by a large air-fuel ratio and a high compression ratio, the fuel used being only of secondary importance. Thus for a compression ratio of 6 and just the right amount of air to afford complete combustion, the Otto gives efficiencies of 0.405, 0.398, and 0.397, on the lower heating values, for gasoline, benzol, and blast-furnace gas, respectively.

The efficiencies of the ideal engine are given for both the higher and lower heating values of the fuels because both are needed as standards at present. By using the same heating value for the ideal and actual, the engine efficiency will always be independent of individual preference in this matter. This advantage combined with the basic conception of the term, makes it one of the best measures of performance of an internal-combustion engine.

## Acknowledgments

Credit is due to Professors W. N. Barnard, G. B. Upton, and A. C. Davis, all of the Sibley School of Mechanical Engineering, for their many helpful suggestions and criticisms. Professor Davis also kindly furnished the test data on the Universal marine motor.

To C. O. Mackey, instructor in Sibley, and M. C. Tate, M.E., Cornell, 1927, grateful acknowledgment is made for their very able assistance in making the calculations and curves.

## Discussion

Lionel S. Marks.[9] The writer is in entire agreement with the authors of this paper on the desirability of finding and standardizing some method of stating the engine efficiencies of internal-combustion engines. With steam engines and turbines the engine efficiency or, as we used to call it, the Rankine efficiency can be determined with no more uncertainty than is involved in the comparatively small errors in existing steam tables. With internal-combustion engines, however, there are several important uncertainties. In order to calculate the ideal efficiency, two things are necessary: (1) to define the cycle and (2) to know the physical properties of the working substance. In defining the cycle it is necessary to know the weight of the residual gases in the clearance space so as to be able to determine the weight and composition of the substance going through the cycle. Unfortunately, any exact knowledge of the weight of clearance gases is impossible without a knowledge of the mean temperature in the clearance at the beginning of the admission stroke. In the absence of such knowledge it is necessary to make some assumption, and the authors have assumed two temperatures, one at the beginning and one at the end of the admission stroke. Neither of these assumptions has any special validity. Other calculators in this field have made different assumptions. Second, with respect to the physical properties of the working substance, it is impossible to regard our present knowledge of specific heats at high temperatures as of great accuracy. Our knowledge of the chemical equilibrium of $CO_2$ and $H_2O$ in explosive mixtures at the maximum temperature is far from satisfactory. With these two uncertainties it is obvious that no accurate calculation of ideal cycle efficiency is possible.

Two other investigations have been made in this field in the recent past, and all three sets of investigators have had available the same experimental data for the determination of specific heats and dissociation. Comparing their results for a compression ratio of 5 with the Otto cycle, no excess air, and with benzine as fuel, their calculated efficiencies vary by 3 per cent in absolute efficiency or a variation of 9 per cent in comparative values. An engine which showed 70 per cent engine efficiency according to Ellenwood, would show 79 per cent efficiency according to Tizard and Pye. And this is not all. Further investigations on specific heats and dissociation may quite easily yield new values of these quantities which may change engine efficiencies as calculated by these three sets of investigators by 3 or 6 per cent. In other words, the engine efficiencies calculated from the cycle efficiencies given in this paper may quite easily be from 10 to 15 per cent wrong.

Under these circumstances it does not seem to the writer that the time is ripe for the official adoption by the A.S.M.E. of any such set of ideal efficiencies as those calculated in the paper. It will always be desirable for those engaged in research in this field to calculate engine efficiencies, but it should always be on the basis of the best information available at the time.

An argument might, the writer thinks, be made for the use of an air-cycle standard which is different both from the cold-air cycle which has been adopted generally up to the present time and also from the hot-air standard as defined in this paper. The specific heat of air at high temperatures is known more accurately than the specific heats of $CO_2$ and $H_2O$, and there is no dissociation when air only is present. In place of using the cold-air standard which has been in general use and which has no justification other than the simplicity of the calculations involved, an air standard might be adopted which would take into account the change of specific heat of air with temperature. This is something quite different from the hot-air standard of the paper. It would be an arbitrary standard that would have the advantage of being nearer to the true ideal efficiencies than the customary air cycle and would actually give correct values for Diesel engines at the lower limit of power, that is, with no fuel injected. For Otto cycles it could not be approached closely because of the non-explosibility of mixtures with a large excess of air.

G. A. Goodenough.[10] This paper is a welcome contribution. If the "air standard" as a measure of efficiency is to be discarded, as it undoubtedly should be, a body of data on the ideal thermal efficiencies of internal-combustion motors must be provided. The paper gives results that supplement the data which have already been furnished by Tizard and Pye, and by Goodenough and Baker.

The subject of engine efficiency is admirably covered. All that is said in this connection may be endorsed without reservation. It seems, however, that the authors have introduced a contradiction in their assumption as to the efficiency of an engine operating with a deficiency of air. As stated, the engine efficiency should indicate the success of the designer and builder in reducing the various losses inherent in the engine. Deficiency of air results in a loss of efficiency; but this loss should be charged to the operator, not to the engine. In other words, it seems only fair that the effect of insufficient air should be reflected in the thermal efficiency rather than in the engine efficiency.

It is gratifying to note that the authors have an opinion relative to the use of the high and low heats of combustion. They point out that only the low value can enter into Equation [17]; likewise with Equation [29]. In the calculations that involve dissociation the heats of combustion of CO and $H_2$ are also used, and these must invariably be the low values. In no phase of the analysis of a cycle can the higher heat of combustion possibly enter into the calculation. It is only in the final step, the determination of the efficiency, that the high value functions. By an arbitrary edict of the power test codes committee, the high value here usurps the place that rightfully and logically belongs to the low value.

It might be well if the terms "high" and "low" were replaced by "gross" and "net," which are used by some of the English authorities.

The discrepancies between the tabulated efficiencies and those given by Goodenough and Baker are noted. They are due, of course, to the different systems of analysis and to slight differences in the basic assumptions. The Goodenough and Baker analysis took account of dissociation, and as a result the efficiency values are somewhat lower under certain conditions. But leaving out the effect of dissociation, there remains a small discrepancy that needs explanation. A close examination of the results given in Tables 3 and 8 of the paper discloses two reasons why the E. E. and C. values should be higher than the Goodenough and Baker values. These are: (1) the amount of residual gas carried in the charge; and (2) the interpretation of L.H.V. in Equations [17] and [29].

The authors say that the residual gas cannot be calculated accurately, hence they make the convenient assumption that this gas fills one-half the clearance volume under certain conditions. With this assumption they find in case 11 the weight of residual to be 1.96 lb. per lb. of fuel. In the same case Goodenough and Baker find 0.535 lb., or less than one-third as much. Perhaps an accurate calculation is not possible, but even a rough estimate favors the smaller figure.

In Table 3, case 11, the gas constant of the fuel mixture is

[9] Professor of Mechanical Engineering, Harvard University, Cambridge, Mass. Mem. A.S.M.E.

[10] Professor of Thermodynamics, University of Illinois, Urbana, Ill. Mem. A.S.M.E.

given as 51.57, and a rough calculation shows that the constant for the mixture of products is about 54. Taking 51.6 and 54, and the values of $T_3$ and $T_4$ given in Table 3, the pressure at point 4 is found to be

$$p_4 = 14.7 \times \frac{54}{51.6} \times \frac{3521}{660} = 82.3 \text{ lb. per sq. in.}$$

In the first phase of the exhaust the pressure drops from 82.3 lb. to 14.7 lb. simply because the greater part of the cylinder contents has passed out. The temperature of the part going out is somewhat reduced on account of throttling, but this reduction does not extend to the part remaining in the cylinder, which, under the ideal conditions assumed, remains practically at a temperature of 3521 deg. The slight drop in temperature due to work of expansion is negligible. The fraction that remains in the cylinder is therefore 14.7/82.3. In the second phase of the exhaust, the piston pushes out of the cylinder $^4/_5$ of this amount. The total amount of charge (per pound of fuel) at point 3 is $1 + 15.2 + M = 16.2 + M$, where $M$ denotes the weight of the residual. There remains in the cylinder at the end of the exhaust stroke

$$\frac{1}{5} \times \frac{14.7}{82.3}\left(16.2 + M\right) = 0.0357\ (16.2 + M)$$

Hence $$M = 0.0357\ (16.2 + M)$$

or $$M = 0.604 \text{ lb.}$$

This result is for $T_1 = 660$; Goodenough and Baker obtain $M = 0.535$ with $T_1 = 638$.

Has the amount of residual any effect on the efficiency? To answer this question, the efficiency for this case was recalculated: (1) with the residual found by Goodenough and Baker; (2) with the residual given by Table 3. Dissociation was neglected in both cases. The results, along with those already given, are as follows:

| | $T_1$ | $T_2$ | $T_3$ | $T_4$ | Efficiency, per cent |
|---|---|---|---|---|---|
| E. E. and C. | 660 | 1124 | 5116 | 3521 | 37.38 |
| Residual 0.54 lb., no dissociation | 638 | 1081 | 5363 | 3740 | 37.18 |
| Residual 1.96 lb., no dissociation | 638 | 1081 | 5106 | 3516 | 37.60 |
| G. and B., with dissociation | 638 | 1081 | 5053 | 3736 | 35.97 |

The efficiency is thus increased about 0.4 per cent by taking the increased residual.

It may be conceded that the assumption of E. E. and C. agrees fairly well with the conditions in the actual engine. But it appears hardly logical to assume ideal conditions for three of the phases of the cycle and then abandon the ideal for the real in the fourth phase.

A second reason for the discrepancy lies in a difference of the interpretation of the combustion process 2–3 in the two cycles; this process involves the heat of combustion of the fuels. Let the authors' L.H.V. be denoted simply by $L$; then $L_v$ denotes heat of combustion at constant volume, and $L_p$ that at constant pressure. By the definition of heat of combustion,

$L_v$ = total internal energy of factors — total internal energy of products.

$L_p$ = total enthalpy of factors — total enthalpy of products.

The restriction is imposed that the final temperature of the products shall be the same as the initial temperature of the factors. The fuel factor may be taken as 1 lb.; then $L_v$ and $L_p$ are heats of combustion per pound. From the preceding definitions, $L_v$ and $L_p$ depend upon the temperature at which the process is conducted; the $L_v$ for $T = 1500$ may be, and generally is, quite different from the $L_v$ for $T = 500$.

The total internal energy of a gas mixture (denoted by $I'$) is

$$I' = I_0 + I$$

in which $I$ denotes the thermal energy as given by Equation [10], and $I_0$ denotes the energy the mixture would have at absolute zero; in reality the chemical energy. Consider now the process 2–3 of the Otto cycle. No work is done, and the process is assumed to be adiabatic; hence

$$I'_2 = I'_3$$

Let subscripts $m$ and $p$ be used to denote the initial and products mixture, respectively; and subscripts 2 and 3 to denote states 2 and 3. Then the preceding equation becomes

$$I_{0m} + I_{2m} = I_{0p} + I_{3p}$$

The difference $I_{0m} - I_{0p} = L_0$, the heat of combustion at absolute zero; hence

$$I_{3p} = I_{2m} + L_0$$

or in the notation of Equation [17],

$$i_3 = i_2 + w_f L_0$$

If the authors had used this formula, they would have been saved the calculation of the $i'_2$ values. However, taking Equation [17], what particular value of L.H.V. is implied? The equation

$$I'_{2m} = I'_{3p}$$

may be changed to

$$I'_{2m} - I'_{2p} = I'_{3p} - I'_{2p} = I_{3p} - I_{2p}$$

The first member is $L_{v2}$, the heat of combustion at temperature $T_2$, and the second member is the difference which was used in Equation [17]. Hence the L.H.V. in Equation [17] should properly be the heat of combustion at temperature $T_2$, and this will vary with $T_2$. From an examination of Table 3, it appears that the authors have used throughout the constant value $L_v = 18{,}830$. The effect, however, is almost negligible except at the highest values of $T_2$. For example, in case 18 the value of $I_3$ becomes 1119.0 instead of 1117.2.

The Diesel cycle presents a different picture. The relations are somewhat more complicated because the fuel and compressed charge are kept separated up to the state 2. Let the subscript $a$ refer to the mixture of air and residual gas that is compressed from state 1 to state 2. The energy equation for the adiabatic process 2–3 is (taking 1 lb. of oil)

Work $_{2-3}$ = energy of gas $a$ in state 2 + energy of oil—energy of products in state 3

or

$$Ap\,(V_3 - V_2) = I_{oa} + I_{a2} + i_{o(\text{oil})} + i_{(\text{oil})} - I_{op} - I_{p3}$$

If the work of injection is included, the effect is to change $i_{(\text{oil})}$ to $h_{(\text{oil})}$. But

$$I_{a2} + ApV_2 = H_{a2} \qquad I_{p3} + A_{p3}V_3 = H_{p3}$$

and $$I_{oa} + i_{o(\text{oil})} - I_{op} = L_0$$

The equation becomes, therefore,

$$L_o + h_{(\text{oil})} + H_{a2} = H_{p3}$$

Here, again, a constant is added to $H_2$, the enthalpy of the initial mixture, *not* to the enthalpy of the products mixture. The calculation of $h'_2$ is quite superfluous. The symbol $h_{(\text{oil})}$ stands for the enthalpy of the oil at the temperature it has when injected.

Not knowing the characteristics of petroleum oil, we assume that they follow somewhat closely those of kerosene.

For the latter fuel, Goodenough and Felbeck's figures show that the sum $L_0 + h_{(oil)}$ is about 1.2 per cent greater than the value of $L_p$ at ordinary temperature. Hence, we assume for petroleum oil $L_0 + h_{(oil)} = 18{,}250 \times 1.012 = 18{,}470$ B.t.u. per lb.

With this value of the constant, and with other data from Table 8, the following results are obtained.

| Case No........ | | 45 | 52 | 57 | 61 | 65 |
|---|---|---|---|---|---|---|
| $h_3$ (revised) | = | 1244.3 | 860.1 | 737.2 | 682.5 | 650.3 |
| $h_3$ (Table 8) | = | 1276.3 | 877.2 | 749.1 | 690.4 | 657.5 |
| Difference, per cent | | 2.6 | 2.0 | 1.6 | 1.15 | 1.1 |

The effect, of course, of a larger value of $h_3$ is a higher temperature $T_3$ and larger volume $V_3$. The area of the ideal indicator diagram is thereby increased, and with it the efficiency.

Taking no account of dissociation, it appears that the E. E. and C. values for ideal efficiency will be higher than the Goodenough and Baker values for both Otto and Diesel cycles. In the case of the Otto cycles, the reason lies chiefly in the difference between the amount of residual gas assumed. In the case of the Diesel cycle this factor has slight effect and the discrepancy lies chiefly in the difference between the two interpretations of the combustion process 2–3.

The effect of dissociation is easily explained. Referring to Table 2 of Bulletin No. 160, case No. 9 shows at the point 4, $x_4 = 0.9756$, $y_4 = 0.995$. This means that unburned CO and $H_2$ are present in the exhaust. From the data on p. 34 of the bulletin it is found that the chemical energy thus thrown away is 1.3 per cent of the chemical energy of the gasoline. From the calculation previously shown, $T_4$ with dissociation is 3736 deg. and without dissociation is 3740 deg. The thermal energy $I_4$ is nearly the same in the two cases. If it were exactly the same, the difference in efficiency would be precisely 1.31 per cent. Actually it is 1.21 per cent. The decrease of efficiency due to dissociation becomes significant when the end temperature $T_4$ is higher than 3300 or 3400 so that an appreciable amount of unburned gas is thrown into the exhaust. With 100 per cent or more air, $T_4$ will be high (1) when the air supply is a minimum, and (2) when the volume ratio $r$ is small. Inspection of Fig. 9 shows that these are the conditions that give the greatest discrepancies between the two sets of curves.

John B. Baker.[11] The objection to the air standard is that it is a standard impossible to attain. In establishing a new standard we must make sure that our standard is not working a hardship on the engine being compared. It would appear that assumption $e$ of the authors imposes a condition which has no physical significance. Why should we compare an engine which is running on an air deficiency with an ideal which specifies the theoretical amount of air necessary for complete combustion? If we are comparing an engine with deficient air to such a standard there seems to be no justification for changing our standard when an excess of air is used. If a steam engine is supplied with steam with a quality of 95 per cent we do not charge the engine with the heat which the steam might have had had it been saturated.

In the publication of Goodenough and Baker on the same subject the method of analysis was extended to the case of insufficient air. This analysis considers the dissociation of the products of combustion. It is true that with a large excess of air the maximum temperatures reached are lower and the consequent dissociation is negligible. With less air, however, this phenomenon of dissociation becomes the dominating factor. With insufficient air for complete combustion we can conceive of the dissociation of the primary products of combustion until equilibrium is attained between CO, $CO_2$, $H_2$, and $H_2O$. It may be true that the primary products are not $CO_2$ and $H_2O$, but at any rate the equilibrium is attained.

In this analysis the heat of combustion for the complete combustion of the fuel enters, but a considerable portion of this heat is used to form the large quantities of CO and $H_2$ present. This appears in Equation [21] of the reference quoted. The actual heat supplied is not then the heat value for complete combustion as inferred in the present paper.

E. A. Allcut.[12] A number of attempts have been made to establish a standard cycle for the internal-combustion engine to occupy a position similar to that held for many years by the Rankine cycle in steam-engine practice. The old "air cycle" is defective as an ideal because it neither takes into account variations in specific heat, which become serious at high temperatures, nor changes in the composition of the working fluid which take place during the cycle. With so many variable factors many tables must necessarily be prepared, as in the present paper, and the labor involved in computing them is great. Such labor, moreover, is wasted to some extent, unless the tables and curves come into reasonably general use, and it would seem that the present state of knowledge in this subject is sufficiently accurate to permit the compilation of a series of tables and curves similar to the steam tables, so that efficiency ratios of engines of different types may readily be compared. For that work the present paper might well serve as a basis. Professor Marks has deprecated that suggestion, and the writer is sorry to be unable to agree with him for the reason that had we waited until we reached the present state of knowledge in the preparation of steam tables, we should not have made anything like the amount of progress in steam engineering that we actually have made.

The writer is in general agreement with the methods of calculation employed, but before any authoritative tables or curves can be drawn up as standards it will be necessary to consider very carefully what factors shall be included in the standard efficiency and what characterized as unavoidable losses. For instance, the writer wishes most emphatically to dissent from the general attitude of the authors on calorific values and particularly to certain statements, one of which is as follows: "This available energy, as previously explained, can never be based logically on anything but the lower heating value for the internal-combustion motor." (Page 7.) This seems to be a decidedly retrograde step, particularly in view of the fact that the most recent test codes used in America, England, France, and Germany have all expressed in no uncertain terms the desirability of using the higher heating value as a basis for all efficiencies. The word "logical" in this connection was particularly ill chosen, as anything less logical than the lower heating value could hardly be conceived. If it be maintained, as it has been, that no internal-combustion engine can reject its heat at temperatures lower than 212 deg. fahr., why fix on this as a standard? The argument applies equally well to 300 or 400 deg. fahr. Even if 212 deg. be arbitrarily selected (and there is nothing logical about that) there is still the heat of the liquid and the sensible heat of the gases below 212 deg. which are still included as losses, although they come within exactly the same category as the latent heat which is not so included, if the lower calorific value be used. Consider the case of the combination of a gas producer and gas engine. Is the gas maker to be penalized because the engine, which he does not design, and over which he has no

[11] University of New Mexico, Albuquerque, N. M. Jun. A.S.M.E.

[12] Associate Professor of Mechanical Engineering, University of Toronto, Toronto, Ont., Can. Mem. A.S.M.E.

control, is unable to use all the heat in the fuel supplied? The higher value is used with solid fuels, why not with liquid? A further practical point is that many liquid-fuel calorimeters give the higher value alone and the lower can only be obtained by calculation from the analysis, which few engineers are able to perform and which is not always available from other sources.

If it be argued that the latent-heat loss is inevitable and is the most important factor in the exhaust loss, the same argument could be used for omitting the frictional loss in the engine, or a portion of it, as this is equally inevitable and just as important. By excluding these and a few other necessary losses, efficiency ratios of 100 per cent might be realized and the designer could then sit back complacently.

It follows from this that both on logical and practical grounds the case for the use of the higher value is overwhelming, and the writer deprecates any attempt to revert to the lower value as a basis.

These and other similar points must be thrashed out thoroughly before any cycle or method of calculation can be established, but there is no reason why a committee should not be appointed to consider these factors and draw up a report indicating the best method of procedure in this connection.

L. C. Lichty.[13] There have been four noteworthy steps made in the development of an analysis of the internal-combustion-engine cycle:

1 The air-standard cycle
2 The use of variable specific heats
3 The use of the actual mixture with the above
4 The inclusion of chemical equilibrium in the combustion and also the expansion process.

The object of an analysis is to determine the maximum possible efficiency of the ideal cycle and to use this as a goal which one should strive to approach. The difference between the indicated thermal efficiency of an actual engine and the maximum thermal efficiency of an ideal engine under the same conditions is a measure of the possibility for improvement. The use of the air-standard cycle is, or should be, obsolete as a basis for comparison, for it represents much more than the maximum efficiency that might be obtained in the ideal cycle. An analysis which does not include the last three of the items mentioned above gives a result that can never be attained even in the ideal case.

A well-designed internal-combustion engine with a 5-to-1 compression ratio using gasoline as a fuel will have an indicated thermal efficiency of about 30 per cent. With the analysis under discussion, the maximum attainable with 100 per cent air is 37.5 per cent, while considering chemical equilibrium,[14] the maximum is 35.9. Instead of a possible improvement of 30 to 37.5 per cent, only 79 per cent of this improvement is possible, 21 per cent of the difference being explained by a consideration of equilibrium conditions. An item which is an inherent characteristic of the medium, which will explain one-fifth of the difference between actual and ideal efficiencies, is of considerable importance and should not be disregarded.

The air-standard cycle with constant specific heat has been superseded by the variable-specific-heat cycle; it in turn has been improved by a consideration of the actual medium being used. With the application of the present knowledge of chemical equilibrium the efficiency of the ideal internal-combustion-engine cycle has been determined more closely than ever before. The use of this item in the determination of the ideal efficiency is a distinct step in advance and gives one a true idea of the maximum possible efficiency attainable.

The work of Goodenough and Baker[14] takes into account all of the data available regarding the behavior of the medium used in an internal-combustion engine and furnishes us with a true guide with which to compare actual performance. Engine efficiencies determined by comparison with Goodenough and Baker's efficiencies represent true performance factors. Engine efficiencies determined from other than such analysis represent fictitious values which discredit the engine performance, in the light of present knowledge on this subject.

C. N. Cross.[15] The authors of this paper should be congratulated for having presented to the engineering profession a contribution which advances one more stage the detailed information concerning internal-combustion-engine performance. This paper presents a very ingenious method of attack of the problem and it represents a vast amount of laborious detail which speaks loudly of the authors' patience and perseverance.

However, it is the opinion of the writer that the authors err to some extent when they, after having expended so much effort to arrive at an exact series of results which they urge shall be adopted as a standard by the Society, omit an important variable. Nowhere in their extended development has any provision been made for the variations of the specific heat at constant pressure for changing pressure. The effect of this variation is by no means negligible and as yet its full extent at high temperatures and high pressures is only partially determined for air,[16] and so far as the writer is aware, is entirely unknown for the other gases involved.

If the authors wish to be utterly accurate and complete in their proposed standards for the efficiency of internal-combustion engines, it would seem to the writer that Equations [8] and [9] should include terms which allow for the changes due to pressure. Until such time as that is possible, the "Air-Standard Efficiency," proposed in 1905 by a committee of the Institution of Civil Engineers of Great Britain appointed to study the standards of efficiency of internal-combustion engines, should remain as the standard of performance. The Committee stated that—

> "......Apart from the special difficulty that knowledge of the values of $c_p$, $c_v$, and $k$ at high temperatures [the writer adds *and high pressures*] is defective, the calculation of their values for each special mixture of gases used in internal-combustion engines is cumbrous, and in ordinary trials almost impracticable. There is further difficulty that the values are not quite the same for compression and expansion strokes. In the opinion of the committee, it would introduce some uncertainty and difficulty, without adequate compensating advantage, to make the standard engine cycle depend on a knowledge of the physical constants of the mixture used. The discussion of the constants for various mixtures of gases already given shows that, apart from the unknown change at high temperatures, these constants do not differ by more than 2 per cent to 5 per cent from those of air in such mixtures as are used in gas engines. The advantages of simplicity and definiteness in the standard are so great that the committee recommends that the standard engine should be taken to work with a perfect gas of the same density as air. This in no way prevents any one from discussing the distribution of heat losses in any particular mixture of gases. But it does render more definite the statement of relative efficiency, without, in the opinion of the committee, introducing any error of practical importance."

It is the opinion of the writer that the above-quoted statement of the committee is still substantially valid. And further,

[16] See M. Jakob, "Specific Heats of Air for Ranges of Temperature from —80° C. to 250° C. and for Pressures from 0 to 200 × 10[4] Kg. per Sq. Metre," in *Science Abstracts*, A, Physics, vol. 27 (1924), p. 194. The original appeared in *Zeit. Tech. Physik.*, vol. 4 (1923), No. 12, pp. 460–468.

that it would be inadvisable, in the light of our present incomplete knowledge of the values of the various physical constants of gases under all the varying conditions existing in the cylinders of internal-combustion engines, to adopt, or even urge for general adoption, any new standard of ideal efficiency at the present time.

G. B. Upton.[17] It is said that the revolutionary advances in recent years in knowledge of the nature of matter are due primarily to an increase in the accuracy of measurement of fundamental constants. Engineering is working out today advances paralleling those of physics and chemistry. Such a change to more accurate fundamental standards is the calculation of the "real-mixture" standards for internal-combustion engines; without such "real-mixture" standards we cannot make intelligent headway in improvement of the utilization of heat in the engines.

Knowledge of the specific heats of gases at high temperatures is still undergoing change, but those changes promise henceforth to be of little importance. The time is ripe for definition of the "real-mixture" ideal cycles for internal-combustion engines and calculations of ideal efficiencies based upon the real properties of the actual working substances. In this definition no one, the writer thinks, will disagree with the paper as to conditions (*a*), (*b*), (*c*), and (*d*); but the case is otherwise with conditions (*e*) and (*f*).

In the first part of condition (*e*), which is a double-header, the authors decide that when an engine is operated on any mixture richer in fuel than the "theoretical mix," the theoretical cyclic efficiency charged against the engine shall be that calculated for the theoretical mix. This penalizes the "engine efficiency" for the use of a rich mix, which may be a good way to educate the operator of the engine. On the other hand, the operator may know something which is not in the thermodynamic analysis, that at full power of the engine a lean mix will give a very hot and oxidizing exhaust which will burn out the exhaust valves. If the engine efficiency is to be measured fairly for all mixes rich or lean, then the penalization for use of rich mixes should fall upon the cyclic efficiency. The discusser has done this roughly by multiplying the cyclic efficiency for the theoretical mix by the mix ratio of the rich mix and dividing by the mix ratio of the theoretical mix; but this is an over-correction, because the rich mixes from their content in their products of combustion of CO and $H_2$ get an effect like that from $N_2$ and $O_2$ in the lean mixes—the ratio of specific heats for either rich or lean mixes is higher than that for the theoretical mix. Also, for many of our liquid fuels the increase in "gas constant" by combustion (or number of molecules present) is greater for rich than for lean mixes. Decision as to how the rich mixtures are to be treated is obviously a matter of arbitrary choice, with plausible arguments on either side.

The second part of condition (*e*) concerns the weight of residual exhaust gases entrapped with the new charge at the beginning of the compression stroke. A few years ago we did not consider these exhaust gases at all; our "working substance" in the "perfect-gas" style of thermodynamic theory was magically cooled at constant volume from the temperature at the end of the expansion line to the temperature at the beginning of the compression line, so that the cycle could begin anew. Now that we recognize the expulsion of used charge and taking in of new charge as parts of the real cycle, we need to know how much residual exhaust gas carries over from each cycle to mix with the new charge of the next cycle. The authors say that this quantity cannot be calculated accurately, but use an arbitrary assumption which may be fairly accurate, that it would fill one-half the clearance volume when reduced to the pressure and temperature assumed at the beginning of compression. Since the exhaust and intake pressure losses of the ideal cycle have already been assumed as zero in condition (*b*), both residual exhaust gas and new charge have atmospheric absolute pressure; the temperature of the total charge at beginning of compression is assumed in condition (*c*) as 200 deg. fahr., or 660 deg. fahr. absolute. Hence the authors have really assumed that the clearance volume full of residual exhaust gas, at the end of the exhaust stroke, had a temperature of 2 × 660 deg. fahr. absolute = 1320 deg. fahr. absolute = 860 deg. fahr. under all conditions of mix and compression ratios. Goodenough and Baker, in their University of Illinois Bulletin No. 160, for this same calculation make two successive assumptions. First, between the end of expansion and beginning of the exhaust stroke, an *isothermal* process reduces the quantity of gases in the cylinder in the ratio of atmospheric pressure to absolute pressure at end of the expansion line. Second, the exhaust stroke (of a four-stroke cycle, obviously) pushes out gas at constant (atmospheric) pressure, making a further quantity reduction in the ratio of clearance/(displacement + clearance); with retained gases filling the clearance still at the temperature of the end of the expansion line — 3000 or more degrees fahrenheit absolute. No wonder that the authors and Goodenough and Baker disagree as to the weight of clearance gases retained.

If we are setting up a "real-mixture" standard, why not calculate according to what the engine does and must do with the exhaust? When the exhaust valve opens, hot gases of an absolute pressure more than twice atmospheric are offered a passage like a nozzle through which to escape. They expand adiabatically, passing the valve with a velocity approximating that of sound in the hot gases until the cylinder pressure goes under twice atmospheric. In this period from 50 to 70 per cent of the exhaust gas escapes from the cylinder. Then the pressure still falls in the cylinder, with continuing adiabatic conversion of heat energy into velocity energy of escaping exhaust, velocities decreasing as the pressure runs down, until the cylinder pressure reduces to atmospheric. The resulting temperature in the cylinder is directly calculable from the pressure change and the adiabatic nature of the expansion as the exhaust gases blow themselves out of the cylinder. Then follows the exhaust stroke of the engine, if it is a four-stroke-cycle engine, expelling further exhaust gas till the volume is reduced to clearance volume, the temperature of the retained gas remaining, in a non-heat-conducting cylinder, the same as at the beginning of the exhaust stroke. Figured according to this adiabatic-expansion scheme the temperature of the exhaust gas trapped in the engine clearance is roughly 70 per cent of the absolute temperature at the end of expansion. Correspondingly, the volume occupied by this residual gas, when cooled to 660 deg. fahr. absolute, will be 0.27 to 0.30 times the clearance volume. In a real engine with "radiation" losses of heat to the jacket water the temperature at the end of expansion is appreciably lower than in the ideal engine and the residual exhaust gas is denser, amounting on account of this temperature item alone to 35 per cent or more of clearance volume when reduced to 660 deg. fahr. absolute temperature.

When the other effects in the real engine, of exhaust back pressure and intake suction, and heating of new charge on its way into the cylinder are taken into account, the arbitrary assignment of 50 per cent of clearance volume, at 660 deg. fahr. absolute, becomes a very fair statement of the real case. Whether this 50 per cent of clearance, as measuring full-load dilution of new charge with exhaust gas, is properly taken over from the

[17] Professor of Experimental Engineering, Cornell University, Ithaca, N. Y. Mem. A.S.M.E.

real engine into the ideal cycle by the authors, may be a matter of argument; but the corresponding calculation of Goodenough and Baker cannot be justified on any grounds whatever. Actual dilution must vary with mix ratio more than with compression ratio, but cannot be constant even in the ideal engine. We must choose between two cases: either we compute the residual charge for the ideal engine to get the exhaust-gas dilution for the working substances of the ideal engine, making that working substance different from that of the real engine; or we assume for the ideal engine the same dilution as the real engine with all its imperfections, thus making the working substance of the ideal engine exactly identical with that of the real engine.

Condition (*f*) of the paper is that dissociation is not to be considered. Dissociation is variable with temperature, and persists even to the end of expansion if temperatures are high enough. Practically, the temperatures are too low for dissociation effects at the end of expansion in actual engines, but not always so in ideal cycles. Dissociation acts in the same way as the fact that combustion requires time and does not really occur at constant volume. Portions of charge that burn before or after the inner-dead-center position of the pistons have lesser expansion ratios than if all the burn happened at the dead center, and have correspondingly lessened efficiencies. Dissociation holds off a part of the combustion which should happen at dead-center position, and lets it occur later on during the expansion stroke, at reduced expansion ratio. On the other hand, dissociation increases the gas constant of the products mixture, which helps to increase expansion work. It is dubious whether it pays to go through with dissociation calculations, because in the real engine the temperatures throughout the burned charge are not uniform but far from it so that we have no satisfactory basis on which to make calculations. This non-uniformity of temperature in the burnt charge means, however, that dissociation is greater in the real engine, for a given average temperature of gases, than in the ideal engine. The real engine runs enough colder than the ideal one so that dissociation is not likely to be appreciable except perhaps at peak of combustion. The discusser feels that dissociation is still too uncertain a topic for us to try to put its effects quantitatively into our calculations of standards. Because Goodenough and Baker assumed too small a value for dilution with spent gas, their whole expansion line is pitched at too high a temperature. This not only makes their efficiencies everywhere a bit too low, but especially vitiates seriously their numerical estimates of the importance of dissociation. Their too small dilution makes their expansion-line temperatures come out 250 to 200 deg. fahr. too high. Such a temperature difference may easily change the completeness of combustion from 95 per cent back to 85 per cent, vastly overvaluing therefore the dissociation and its effect on efficiencies.

Concerning the use of "lower" and "higher" heating values of fuels, admittedly we must use "lower" values for computing temperature rises in the ideal cycle and must even recognize that the "lower" value is a function of the temperature at beginning of combustion. But in computing our thermal efficiencies we are comparing our heat engines with a device for perfect recovery of heat from combustion of the fuel, such as the counterflow gas calorimeters are. The perfect heat machine recovers the "higher" heating value. If we choose to operate a heat engine on a cycle which makes us throw away exhaust heat, it is entirely proper that the cyclic efficiency should be lower in consequence of that choice. The fact that the calculation of details (separate processes) of the cycle makes the computer use the lower and not the higher heat value of the fuel (because in the combustion process $H_2O$ is always vapor) should not warp his judgment as to how the cycle compares with a perfect heat utilization. It is physically possible to build a steam boiler in the form of a Junker gas calorimeter and get 100 per cent boiler efficiency with natural draft and yet with discharge gases reduced to atmospheric temperature; we do not build boilers that way because the interest on the plant cost would exceed the saving on fuel. Similar practical considerations lead us to use the Otto and Diesel cycles for internal-combustion engines, letting the exhaust go out too hot for $H_2O$ to be possibly condensed; the consequent heat loss as compared with a calorimeter is properly chargeable against the cycle of operation.

P. H. Schweitzer.[18] We have heard conflicting opinions on many factors with regard to establishing efficiency standards for internal-combustion engines. Higher and lower heating value, dissociation and no dissociation, admitting deficiency of air in the ideal cycle or excluding it, complete scavenging or residual gases. The writer has no desire to enter into any of these controversies, but instead of that would add one more. All recent efficiency calculations like those of Goodenough and Baker, of David, and of the authors are based separately on the Otto cycle and on the Diesel cycle. It might not be out of place to call attention to the proposal made by Professor Langer, who suggests abolishing the Diesel cycle altogether as an ideal reference cycle and basing the efficiency values on the Otto cycle solely, even if compression-ignition engines are being considered.

The writer will not attempt to reproduce Langer's argument which was presented at the 1927 meeting of the Society of German Engineers and is printed in the June 25 issue of the *Zeitschrift des Vereines deutscher Ingenieure*, but will mention a few good points in its favor. Constant-pressure combustion was formerly considered desirable because it gave lowest maximum pressures. Being desirable it was set up as an ideal standard. From the standpoint of efficiency the cycle with constant-pressure combustion is not ideal at all and is decidedly inferior to the cycle which admits all or most of the heat at dead center. The more our skill in machine construction improves the less we fear high pressures, and today very few builders of Diesel engines attempt to imitate the true Diesel cycle, which sacrifices efficiency to lower the pressure peaks. High-grade Diesel engines of today burn the greater portion of the fuel at or near dead center. That means a pressure rise during combustion, but it results in higher m.e.p.'s, lower exhaust temperatures, and better economy.

Taking the constant-pressure cycle as a reference, it is possible that some day we shall find that an actual Diesel engine has a thermal efficiency higher than ideal, simply because it burns the fuel quicker than corresponds to constant pressure. The engine efficiency would then be better than 100 per cent. This is absurd. If we do not want to add undesirable complications by introducing the dual cycles as ideal reference cycles, it is logical to accept the proposal of Professor Langer and compare all internal-combustion engines with the Otto cycle, which admits all of the heat at dead center and which really represents the limit which can be reached in efficiency with engines of the present general design.

Edgar J. Kates.[19] This paper presents calculations of great help to the busy engineer who wishes to measure the performance of an Otto or Diesel engine. The "air-standard" efficiency formerly in voge is now known to be so much in excess of the efficiency based on real gases and on real specific heats that it

[18] Associate Professor of Engineering Research, Pennsylvania State College, State College, Pa.

[19] Consulting Engineer, New York, N. Y., Chairman of Oil and Gas Power Division, and Mem. A.S.M.E.

is of little practical value. On the other hand, the calculation of the ideal efficiency, taking into account the actual constituents of the mixture and the variations in specific heat, is so laborious a task for most engineers that they have denied themselves the benefits of this method of checking the performance of the engines with which they were concerned. This difficulty the authors have gone far to eliminate through the exceedingly simple and practical form into which they have condensed the results of many intricate computations. With the help of the charts given in this paper, the process of finding the ideal efficiency is reduced simply to locating a single point on a curve.

Though the charts cover a wide range of conditions for the Otto and Diesel cycles, they unfortunately do not apply to one of the most modern types of oil engines that operating on the "dual cycle," which is a combination of both the Otto and the Diesel. In the dual cycle, part of the fuel is burned under constant-volume conditions at dead center, as in the Otto, and the rest is burned at constant pressure during the first part of the power stroke, as in the Diesel.

The dual cycle is particularly well adapted to engines with mechanical fuel injection, and results in an excellent combination of easy starting qualities, moderate pressures, high thermal and mechanical efficiencies, and large power output. The lowest fuel consumptions so far reported for oil engines, about 0.35 lb. per b.hp-hr., were made with engines operating on the dual cycle.

Engineers would gratefully welcome the publication of data and charts similar to those of this paper but applying to the dual cycle which is now being widely employed.

## Authors' Closures

F. O. Ellenwood. The authors are very grateful to those engineers who have contributed to the discussion, which is so essential for general progress in matters of this kind, but they also desire to express special thanks to Professors Goodenough and Upton who have taken considerable pains to work out the technical relationship involved in certain calculations and to express their opinions regarding many important points. All engineers who have given this subject careful thought are forced to realize that it is a very complex one.

Regardless of whether the work that has thus far been done by different investigators in Europe and in this country may be considered as a satisfactory base on which to establish a standard, it certainly must be true that the exchange of ideas and general study and discussion that comes from this work will in itself be of much value to the profession.

Considering the individual discussions, the authors believe that the arguments advanced by Professors Marks and Cross, that the time is not yet here when we should make these calculations, are well answered by Professor Allcut, who asks: "Where would we be today regarding the preparation of our steam tables, had we waited until we were sure of the proper values to use for both saturated and superheated steam?" In other words, engineers and scientists can never attain the ultimate in matters of this kind, but they can often take decided steps toward it. Professor Marks has undoubtedly presented an unduly pessimistic view of the situation regarding specific heats. In this connection, it seems to the authors very appropriate to quote from a paper by Sir Dugald Clerk, presented before the Institution of Civil Engineers, January 10, 1928, when he says in a discussion of this same subject: "The time has come for the application of accumulated knowledge to the substitution of real working fluids for the ideal properties which were necessary because of ignorance of the real."

The authors fail to appreciate, possibly as much as they should, the suggestion of Professor Marks that an air standard be substituted for the hot-air standard discussed in the paper. It is not altogether clear what particular advantage this would have because, as he says, "it would actually give correct values for the Diesel at the lower limit of power, that is, for the Diesel with no fuel injected." It is certainly true that most of us are much more concerned with a standard that applies to Diesels that are using at least some fuel.

Professor Cross raises the question of whether the specific heats of gases are seriously affected by the change in pressure involved in the internal-combustion motor. Taking his own reference (Jakob) on this subject, it is readily seen that for the temperatures and pressures involved in the internal-combustion motor, the effect of the variation in pressure on the specific heats is too small to be considered of any significance.

The result of the calculations of Herr Jakob show that for an increase of pressure of 500 lb. per sq. in. the increase in $c_p$ for air is about 7 per cent at a temperature of 32 deg. fahr. and about 1.2 per cent at a temperature of 482 deg. fahr., so it is fair to ask Professor Cross what he considers the increase might be at 1000 or 3000 deg. fahr. The variation in $c_v$ is roughly half as large as in $c_p$ at 482 deg. fahr. The same conclusion may be reached by consulting Glazebrook's "Dictionary of Applied Physics," vol. I, page 415, or by plotting the values given by Partington and Shilling in "The Specific Heat of Gases." In all of these references it will be found that for very *low temperatures* and for very *high pressures* the effect of pressure on the specific heat of gases is of great importance, but for the *pressures and temperatures involved in the internal-combustion motor*, the effect of pressure on the specific heat is quite negligible.

In the latter part of Professor Allcut's discussion, he questions the following statement occurring on page 7 of the original paper: "This available energy, as previously explained, can never be based logically on anything but the lower heating value for the internal-combustion motor." Professor Allcut apparently does not realize that it is one thing to talk about the heating value to be used in determining the net work or available energy of the ideal cycle involving a real mixture with variable specific heats, and an entirely different matter to talk about the heating value on which the efficiency of such a cycle may be based. All of the references that he gives regarding the most recent test codes in America and Europe have said nothing, so far as the authors can ascertain, about the use of the higher heating value for determining the rise of temperature of the mixture in an internal-combustion motor. The quoted statement of the authors certainly says nothing regarding the use of any heating value for the purpose of obtaining the thermal efficiency of any heat engine, ideal or real. When it comes to the question of computing the rise in temperature by the combustion of the fuel after compression in an internal-combustion motor, the case is entirely different from that involved in calculating efficiency.

The temperature at the end of compression is always so high that only a low heating value is available to produce a rise in temperature during combustion, but this in no way prevents the use of any other heating value agreed upon by engineers as the proper one on which to base the thermal efficiency of the engine, both ideal and actual. As Professor Goodenough says in his discussion: "In no phase of analysis of a cycle can the higher heat of combustion possibly enter into the calculation. It is only in the final step, the determination of the efficiency, that the high value functions." Professor Upton also makes the point clear that only the lower heating value can be used in the calculation of the rise of temperature of the ideal cycle, although he is a firm believer in the use of higher heating value for the thermal efficiency of the actual and ideal engine. The authors can appreciate Professor Allcut's viewpoint because they, as

well as many other engineers whom they know, have had to pass through the stage in which it is difficult for the mind to realize that a higher and lower heating value can both very logically be used in the same problem, one for determining the rise in temperature of the working substance, and the other for the determination of the thermal efficiency.

Mr. Baker refers to the use of steam with a quality of 95 per cent in an engine and states that we do not charge the engine with dry saturated steam in such case. This illustration is used in connection with his discussion of the ideal Otto engine that should be used as a standard with which to compare the real engine running with a deficiency of air. It seems to the authors that a little thought on this subject will indicate why the comparison is of no value, because the steam engine does not have any combustion of fuel taking place within the cylinder—and it is exactly this point, the combustion of fuel within the cylinder of the engine, that is involved. The authors believe that an ideal heat engine should be defined as one in which there is no loss of energy due to leakage, fluid or mechanical friction, heat transfer, or incomplete combustion of fuel. With this as a fundamental conception of what constitutes an ideal heat engine, whether the combustion takes place in the working cylinder or not, it is then apparent that the ideal cycle need never be calculated for any case in which there is insufficient air to support complete combustion. Since Mr. Baker has chosen to introduce an illustration involving steam, it is in order to call his attention to the fact that the ideal boiler with furnace is often used as a standard with which to compare the performance of the actual one. In such a case the ideal boiler furnace is supposed to be one in which there is just sufficient air supplied for the complete combustion of all the fuel used. The supply of sufficient air to support combustion would seem to be one of the most basic premises in any ideal combustion process. Just because an Otto engine may, on a rich mixture, possibly run cooler, start easier, stall less readily, or do a number of things that may be considered desirable in an automobile engine, need not alter our conception of what the ideal should be. It seems to the authors that running an Otto engine with a deficiency of air should show up in its decreased engine efficiency just as logically as running it with too much cooling water. If the ideal Otto is at times to have insufficient air for complete combustion of the fuel because it may be desirable to operate a real engine that way sometimes, why not also make our ideal engine one in which the loss to the water jacket is the same as in the actual case? Adiabatic processes and sufficient air for complete combustion are about equally basic in the ideal heat engine, as the authors see it. However, this question is of much interest in dealing with the Otto engine and undoubtedly is, as Professor Upton says in his discussion, "a matter of arbitrary choice with plausible arguments on either side."

Professor Schweitzer calls attention to a suggestion of Professor Langer's that the Diesel cycle be abolished altogether as a standard and that only the Otto be used, because many of the late Diesels have such an appreciable portion of the combustion taking place at constant volume. This suggestion probably merits careful consideration because of its technical value, but surely not because any present or prospective Diesel engine has given any evidence of causing embarrassment by having an indicated engine efficiency greater than 100 per cent.

Mr. Kates suggests that it might be desirable to make the calculations cover the dual-combustion cycle. Such calculations are even more complicated than those for the Diesel cycle, and it seems to the authors that it would be best to wait until certain questions regarding the Otto and Diesel can be considered further.

According to Professor Lichty, "the true performance factors" are now to be found in the Goodenough and Baker values. This statement will no doubt be received by the scientific world with the utmost interest, because it implies that no future work need ever be done on specific heats, dissociation, or any other of the many complex factors entering into the calculation of the ideal cycles of internal-combustion motors. It appears that Professor Marks and Professor Lichty represents the two extremes in this respect, because the latter apparently thinks that the last word has been said on the subject, while the former believes that such calculations should not be attempted now because our knowledge is too incomplete.

The authors believe that Professor Goodenough cannot justify his assumption that in the ideal case the residual gases may be considered as expanding at constant temperature. If instead of his isothermal expansion these residual gases be considered to expand adiabatically with an average value of $\gamma = 1.3$, the weight will be about 50 per cent greater than the value 0.604 lb. per lb. of fuel, as calculated by him for case 11.

The authors made their assumption regarding this very complicated question of how to estimate the weight of residual gases after considerable effort had been made to try to find a reasonable method of calculation. That their method is not without some merit, aside from its simplicity, is shown in the discussion of Professor Upton and also by the fact that Professor Goodenough concedes that this method gives results that "agree fairly well with the conditions in the actual engine," although he questions the logic of making the residual weight agree in the ideal and actual cases. Some engineers may believe that the weight of residual gases is not of sufficient importance to justify serious consideration, but the calculations given in Professor Goodenough's discussion point clearly to the necessity of care in making this estimate, especially when dissociation is considered. His figures show $T_3$, the absolute temperature at the end of combustion in the ideal Otto, to be 257 deg. higher with his value of the residual than with the authors', when neither considers dissociation. This region of temperature (5000 or more deg. fahr. absolute) is one where relatively small changes of temperature produce large changes in dissociation. Consequently, it seems to the authors that both the overly high temperature, from too little dilution, and overly high dissociation, result in lowering of the Goodenough and Baker cyclic efficiency unduly. In general the effect of assuming too small a dilution of the fresh charge with spent gas causes a multiple error in understatement of cyclic efficiency, if dissociation is considered.

Professor Upton has pointed out that the authors' assumption about residual gases is, essentially, that for all mixtures and compression ratios the clearance is filled with exhaust gas at 1320 deg. fahr. absolute. He has also outlined a logical ideal process by which the residual gas left in the clearance runs down in temperature and pressure from the condition at the end of the expansion line to the condition at the end of the exhaust stroke. That his statement of this ideal process is reasonable can be seen by studying the measured temperatures of the last exhaust gas escaping in actual cases, as given in Bulletin No. 150 of the University of Illinois, by Rosecrans and Felbeck, entitled "A Thermodynamic Analysis of Gas-Engine Tests." Their results show that the actual residual gas temperatures were found to be from 1260 to 1760 deg. fahr. absolute, with various mixture ratios, fuels, and compression ratios. These actual temperatures are of course somewhat lower than the ideal, because of the heat transfers during combustion and expansion in the real engine.

Professor Goodenough points out that the computations for the Diesel cycle are affected but slightly by the different weights of residual gases, but that for this cycle the chief difference is in the interpretation of the combustion process. The authors are not convinced of the superiority of his method, especially since

he assumes the fuel to be "completely vaporized before entering the cylinder." In this connection it should be remembered that the heating values of oil as determined by calorimeters sometimes vary more than 1 per cent for different samples from the same tank.

Even though in the past it may have been considered by some engineers a relatively simple matter to specify the processes and working substance involved in ideal cycles, it should now be recognized that for the internal-combustion motor both of these items afford some chance for differences of opinion, and possibly the arguments that can be advanced for two opposite viewpoints may be equally valid. In such a case further study and consideration of the subject by competent engineers will undoubtedly assist in making arbitrary, but satisfactory choices, where they need to be made, in order to effect standardization.

F. C. Evans. In regard to cases of engines operating with a deficiency of air, there is a very evident and not entirely unexpected difference of opinion. Rather than argue further in support of our point of view as expressed on the first page of the paper, namely, that such cases should be compared with a perfect-mixture standard, the present author prefers to indicate a more indirect but also more important conclusion. The value of this and similar work on standards of performance for internal-combustion engine is minimized unless within the next few years a very widespread adoption of engine efficiencies for internal-combustion engines results. Differences of opinions of the character just mentioned would necessarily have to be adjusted before these standards would be accepted for general use. The authors of this paper prefer to keep the goal in mind, namely, widespread use of engine efficiencies in connection with internal-combustion-engine tests, and would sacrifice ideas of the preceding character in the face of real opposition rather than defeat the ultimate purpose by excessive resistance on some debatable points. This disagreement shows the necessity of competent organized action to compromise on some points as the next step toward general use of these engine efficiencies.

Professor Goodenough demonstrates that the quantity of residual gases influences the results. And the present author believes every one is in agreement that this is a difficult matter to determine accurately. It is obvious that our assumption is only approximate. However, Professor Goodenough, in his specific problem, bases his residual-gas weight on a clearance gas temperature of 3521 deg. fahr. abs., which is much too high in the opinion of the authors.

In this connection Professor Upton presents another idea, namely, that this residual-gas quantity is greater with a two-cycle engine than with a four-cycle engine, justifying to some extent using a figure too high for the latter type of engine in order that the same standard may be applied to the two-cycle type without too great an error.

Dissociation is another factor that obviously must be subjected to some compromise action. The authors have stated their position in this matter fully in the paper and it would be futile to discuss the matter further here. An arbitrary ruling by a competent group would settle an issue that otherwise will be open to continual argument, provided all would abide by the decision of such a committee.

The authors are aware that the heating value of fuels depends on the temperature at the start of combustion, as Professor Goodenough points out. This factor was ignored because an average heating value was arbitrarily assumed for each fuel, which value being only an average will undoubtedly be too far from the actual heating values on some tests to justify too great refinement. As Professor Goodenough points out, there is a relatively unimportant difference.

# Oil-Spray Investigations of the N.A.C.A.

## Oil-Engine Performance—Combustion Losses—Value of Research—Oil-Spray Investigations of the National Advisory Committee for Aeronautics—Photographic Records of Fuel Sprays and Graphs for Use in Studying Spray Characteristics and Fuel Injection in High-Speed Engines

By W. F. JOACHIM,[1] LANGLEY FIELD, VA.

The development of the oil-burning engine since Dr. Diesel built his first oil engine in 1897 (1)[2] has gone forward in several directions. Today we find that, of the several types of internal-combustion engines burning fuel oil, the so-called oil engine has gained much favor and is being manufactured in increasingly greater numbers than is the Diesel or air-injection engine, the semi-Diesel or hot-bulb engine, or those engines carbureting or injecting their fuel oil into vaporizing manifolds and igniting it by electric spark as in the gasoline engine. This increase in popularity of the oil engine is well deserved, because its theoretical thermal efficiency is about four per cent higher and its accessory power requirements about seven per cent lower (2) than its air-injection competitor, and because its construction is more simple.

### Oil-Engine Performance

However, the practical success of the oil engine does not depend solely upon these factors. The detail design and arrangement of the combustion chamber, valves, and pistons, and the degree, direction, and timing of the turbulence they produce, have marked effects on the performance of an engine. The compression ratio, the timing and rate of injection, and the promptness and thoroughness with which the oil is atomized and mixed with the cylinder air, control to a large extent the lag and speed of both ignition and combustion. Oil-engine performance is therefore not proportional to the efficiency calculated from the compression ratio, as is nearly true for gasoline engines, but is dependent upon the success with which the engine design and all the details of injection are carried out.

If indicator cards from many oil engines are examined it will be found that they usually differ considerably. The compression pressure may be as low as 280 lb. per sq. in., or as high as 550 lb. per sq. in.; the maximum cylinder pressure may vary from 500 to 1000 or more lb. per sq. in., and the type of combustion will range from that at practically constant pressure to that at practically constant volume (3 to 9). This extreme variation in design and in the resulting combustion of the fuel is partly accounted for by the effects of increasing the engine speed in the effort to adapt the oil engine to railroad, automotive, and aircraft service (10 to 20). It is strong evidence, however, that the problems of burning fuel oil in engines are not only viewed differently by different designers but, at the present time, are not perfectly understood and lack solutions that permit full attainment of the desired performance.

### Combustion Losses

Simple calculations show that if there were no thermal losses sustained in transforming fuel oil into power we should obtain an indicated horsepower-hour for a consumption of about 0.14 lb. of oil. There are, however, three thermal losses that increase this ideal fuel consumption considerably. They are the heat lost, first, in the exhaust gases, second, in the cooling water and other radiation with complete combustion, and, third, the heat energy lost because of either "late" or incomplete combustion. If the thermal losses incident to the magnitude and timing of the cylinder pressures and temperatures in the construction of the theoretical indicator card amount to 40 per cent, then the efficiency of the cycle is 60 per cent and, without other losses, we should obtain an indicated horsepower-hour for a consumption of about 0.23 lb. of fuel oil. If the cycle efficiency is only 50 per cent, we should still obtain an indicated horsepower-hour for 0.28 lb. of oil.

While the author has recorded fuel-oil consumptions down to 0.26 lb. per i.hp-hr. in the experimental aircraft single-cylinder oil engines of the National Advisory Committee for Aeronautics, running at 1600 r.p.m., this figure was for one-quarter load (21, 22). At the same engine speed and at an approximate commercial full load, taken at an air-fuel ratio giving 112 lb. i.m.e.p. with 50 per cent excess air, the fuel consumption was 0.35 lb. When the load was further increased, as is necessary in aircraft engines, to an air-fuel ratio giving only 15 per cent excess air, the fuel consumption increased to around 0.44 lb. per i.hp-hr. Many large-size, slow-speed, commercial oil engines have fuel consumptions that are quite comparable to the values quoted for the same percentages of excess air. These increases in fuel consumption over the low theoretical value of about 0.26 lb. are largely the result of either late or incomplete combustion of the injected oil, and may be laid directly at the doors of improper design and our present imperfect knowledge of oil injection.

### Value of Research

It has been found that if good performance is to be obtained in an oil engine, the most careful study must be made of all the processes and requirements of oil injection, atomization, distribution, ignition, and combustion. For example, if the injection of the oil is at too high or too low a pressure, or its rate or timing is unsuited to the desired indicator card; or the atomization is too coarse to permit clean combustion in the time available, or is too fine and lacks penetration; or if the distribution of the oil particles in the spray is poor so that the spray contains very lean and very rich portions, and is not properly aided by turbulence; or if the ignition is late so that a large part of the fuel charge may burn at practically constant volume and cause excessive cylinder pressures, or if it is slow and results in after-burning; then the combustion will not be complete, controlled, nor properly timed, and the engine performance will be low. The value of research on oil sprays therefore lies in the discovery and practical investigation of all of their atomization, distribution, and combustion characteristics.

### Methods of Investigating Oil Sprays

There are six major methods of studying oil sprays. These are: (1) Injection into the atmosphere; (2) injection into

[1] Mechanical Engineer, Langley Field, Va.

[2] Numbers in parentheses indicate similarly numbered references in the bibliography published at the end of the paper.

Presented at the Oil-Power Conference held at Pennsylvania State College, State College, Pa., April 21–23, 1927, during Oil Power Week. Awarded the Rudolph Diesel Prize for the best paper presented during that week.

liquids; (3) injection on to targets; (4) injection into cold compressed gases; (5) injection into heated compressed air and (6) injection into engines, i.e., actual engine tests. Each method has both advantages and disadvantages and is of different ultimate value.

1 *Injection into Air.* All oil-engine engineers have undoubtedly studied fuel sprays by observing them in the atmosphere. While this method is often misleading as to the size and shape of a spray when it is injected into an engine (23), many of the variables are proportional for different nozzles and valuable preliminary information may be obtained. Kuehn, in Germany (24), sprayed a small quantity of oil on a sooted glass and calculated the average diameter of the fuel particles from their total weighed volume and their total counted number. By making many tests he determined the approximate effects of injection pressure and three nozzle designs upon atomization. Sauter (25, 26) has reported a method for calculating the average size of fuel particles from the photometric diminution of light passed transversely through a widely dispersed spray. A second method suggested by Sauter consists in calculating the particle size from the amount of electrical energy carried from a charged nozzle by a spray in unit time.

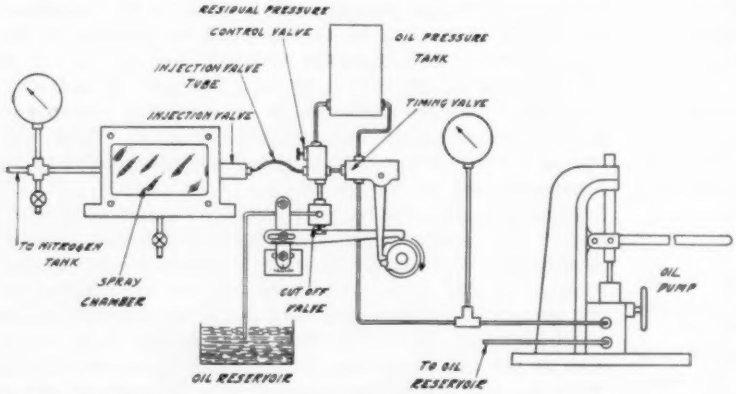

FIG. 1 DIAGRAMMATIC ARRANGEMENT OF APPARATUS FOR PRODUCTION AND CONTROL OF SPRAY

A considerable amount of preliminary work on injection into the atmosphere was done by the author before the Committee's present high-speed spray-photography equipment was completed. This consisted in the observation or measurement of the maximum penetration, relative atomization, shape, and combustion characteristics of Diesel-oil sprays. The effects of nozzle adjustment and injection pressure were pronounced. The maximum penetrations ranged up to about sixteen feet; the atomization ranged from large particles which fell rapidly to almost invisible particles that quickly disappeared by evaporation in the air; the spray shape varied from long, thin streams to full, bushy sprays; and the combustion from smoky, red flame to clean, intense white flame. Spray velocities and coefficients of discharge were calculated from the measured rate of fuel discharge. The plotted results gave smooth curves for all of the variables. The oscilloscope was also used, both on engines and on special injection-system test equipment, to permit slow motion study of the start, growth, and cut-off of oil sprays produced by various injection valves and pumps.

2 *Injection into Liquids.* The study of sprays by injection into liquids has been more limited, largely because of the obvious differences between gases and liquids, which render the results of uncertain value, and because of the difficulty of making practical observations and measurements. Some of these difficulties have, however, been largely overcome by special means. Hauser and Strobel (27) caught sprayed fuel particles in a film of glycerine on a glass and measured their diameters with a microscope. Woltjen (28) injected fuel sprays into compressed air in a steel bomb, catching the fuel particles in a solution consisting of 70 per cent of distilled water and 30 per cent of "Queol D," a tanning extract, in the bottom of the bomb. This solution held the oil particles in suspension and permitted photomicrographs and therefore size measurements to be made. By injecting with different fuel pressures, with and without injection air, and with different air pressures in the bomb, Woltjen obtained considerable data on the factors affecting atomization. Shepherd (29) and others injected oil sprays directly into water and observed their relative penetrations. If the effects on the density and viscosity of liquids on oil sprays were determined, as has been done for gases (30), this general method could be extended and would permit the practical determination of spray-particle size for many test conditions.

3 *Injection on to Targets.* The injection of oil sprays on to targets has probably been practiced to a greater extent than injection into liquids. The targets are mounted on the fly-wheel of the engine, or on special injection-system test equipment, and one or more sprays made to impinge against them. While this method is of little value in the determination of the atomization or penetration of an oil spray, it does give important records of the lag, rate, and duration of injection. By injecting at various loads and speeds, with various injection-valve adjustments or injection-tube lengths and diameters, and having means to measure the fuel pressures and discharge quantities, a fuel-injection system may be quite accurately and completely calibrated. Considerable experimentation by this method at the Committee's Langley Field laboratory (31 to 33) has yielded valuable information and disclosed injection phenomena that have materially aided in the design and practical application of various injection systems to aircraft-type oil engines.

4 *Injection into Unheated Compressed Gases.* Extended investigations on oil sprays have generally been carried out by injecting them into chambers containing unheated air or other gases under pressure. Some investigators have built heavy glass bombs or cylinders and observed the retarding effects of various gas pressures upon the injected sprays. Riehm (34) constructed a chamber with an impact plate and magnetically controlled balance with which to measure the kinetic energy of fuel sprays. By injecting his sprays under various pressures, and varying the chamber gas pressure and the distance between the nozzle and the impact plate, he obtained valuable data on the variation of spray energies, velocities, and penetrations with nozzle design and various operating conditions. This method of oil-spray research with modifications and additions was independently recommended to and adopted by the Pennsylvania State College in 1923 and 1924. The National Advisory Committee for Aeronautics perfected its present apparatus for the study of fuel sprays in the fall of 1924 (35). The photographic method is used. A spray chamber with windows, means for injection control of the spray and its intense, high-speed intermittent illumination and recording on photographic film, during its development, is employed. This equipment and the results of some fundamental investigations will be briefly discussed later.

5 *Injection into Heated Compressed Air.* The study of oil sprays by injection into heated compressed air has, in general, been limited to the determination of ignition temperatures and the time lag between injection and ignition. Many experi-

menters, realizing the importance of the auto-ignition temperature in the design and operation of oil engines, have conducted extended investigations on many fuels. Dixon, Holm, Moore, Wollers and Ehmcke (36 to 38), and others have made ignition-point determinations at atmospheric pressure by dropping the fuel oil on to hot plates, or by injecting it into heated air or oxygen. Alt (39) repeated and extended certain researches on the ignition point at atmospheric pressure on many oils, using two ignition-point testers, and made comparisons of his results with the approximate ignition temperatures required in engines. Hawkes (40) sprayed shale oil into a chamber containing heated compressed air and obtained what he termed "practical ignition temperatures" by measuring the time lag between injection and ignition for various test temperatures. The ignition lag for his sprays varied from 0.16 sec. at 630 deg. fahr. to 0.007 sec. at 930 deg. fahr. Tausz and Schulte (41) determined the ignition temperatures, chiefly in air, of several oil-engine fuels, and mixtures of these fuels, by two methods and for various pressures up to about 540 lb. per sq. in. The first method determined the ignition temperature of the fuels when dropped into heated air at constant pressure, and the second method the ignition temperature when the fuels were sprayed into heated air, the pressure of which was increasing as in an actual engine. Their data cover a wide range of conditions and check engine tests closely. The National Advisory Committee for Aeronautics has recently undertaken the design and construction of additional oil-spray ignition and combustion apparatus to be used with its present high-speed spray-photography equipment. This combined equipment will be employed to study the effect of air pressure, temperature and turbulence, combustion-chamber shape, exhaust-gas dilution, and all the variables of injection, atomization, and distribution upon the ignition temperature, lag of auto-ignition, and rate of combustion of oil sprays.

6 *Injection into Engines.* The investigation of oil sprays by injection into an engine usually consists in determining the engine performance. The information obtained in engine tests, though of vital importance in analyzing the complete machine, is not directly applicable to the study and analysis of oil sprays because of the influence of the combustion-chamber design and other engine variables. Junkers, however (6), has employed fused-quartz windows in an engine and recorded the timing and progress of combustion for different conditions. No definite data from this work have as yet been received. While this method of oil-spray study may be adapted to specific engines, the effects of any single variable may easily be hidden by a number of other difficult-to-control and interdependent variables in the engine, and the method is costly for fundamental research.

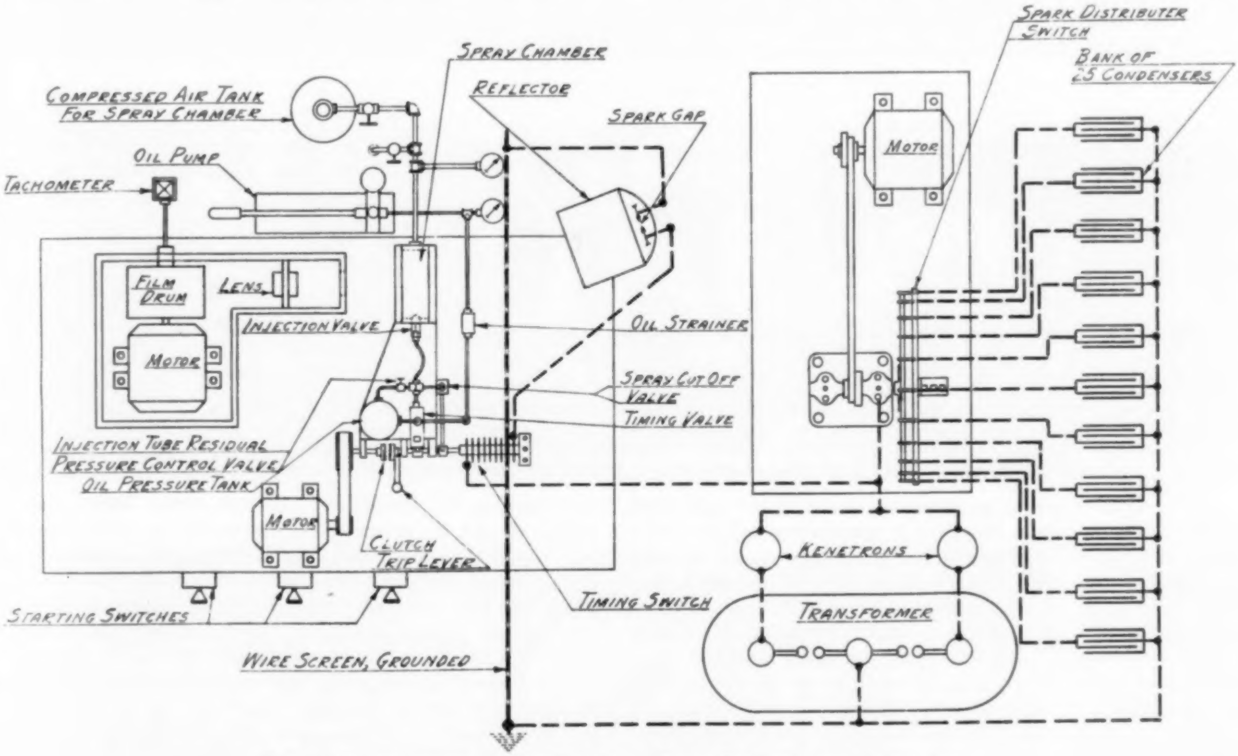

Fig. 2 Diagrammatic Arrangement of Spray-Photography Apparatus

## N.A.C.A. Oil-Spray Investigations

The present method used by the National Advisory Committee for Aeronautics to study the characteristics of oil sprays, as previously stated, is that of injection into unheated gases under pressure in a chamber, and photographing the rapidly moving spray at progressive stages from the instant of its appearance at the nozzle, through spray cut-off, to its practically complete development and distribution. The equipment which permits the taking of these ultra-high-speed moving pictures of oil sprays consists of three major parts: the spray-production apparatus, the spray-illumination apparatus, and the spray-recording apparatus.

The spray-production apparatus is shown in Fig. 1. It includes a high-pressure hydraulic hand pump with which the oil is pumped to the test pressure in an oil pressure tank; a timing valve which controls the oil discharge from the oil pressure tank to the injection valve, and a spray cut-off valve which controls the period of injection. A camshaft is provided to operate the timing and cut-off valves and to control

the speed of operation. The camshaft is driven at the required test speed for one revolution by a special clutch and disengaging mechanism, thus producing only one spray. An initial pressure-control valve permits the investigation of various initial pressures in the injection tube. Injection valves are used which permit the investigation of various stems, nozzles, and operating pressures. A spray chamber with large optical-glass windows is used which permits both the observation and photographing of the spray when injected into any selected gas. The gas may be under pressure up to 600 lb. per sq. in. The spray chamber is designed to permit the study of mechanically and hydraulically operated injection valves, and of sprays up to six inches in length. Usually only single sprays are injected into the spray chamber for study with this apparatus.

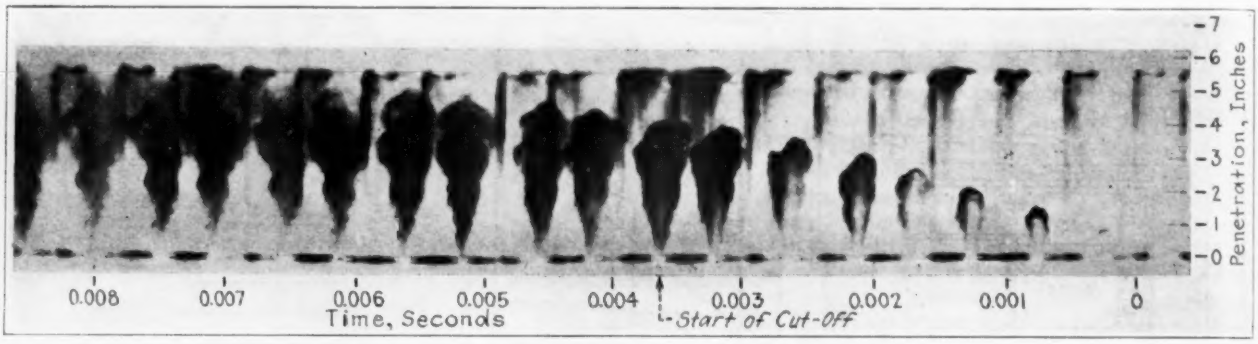

FIG. 3 MEDIUM CENTRIFUGAL SPRAY FROM INJECTION VALVE NO. 7
(Diesel oil of 0.85 sp. gr. injected at 8000 lb. per sq. in. into compressed air at 200 lb. per sq. in.)

The spray-illumination apparatus is shown in the right half of Fig. 2. It includes a 100,000-volt transformer and kenotrons with which to charge 25 large-capacity condensers, and a large-diameter, motor-driven, rotary distributer switch which permits the charging and discharging of the condensers in sequence up to a rate of about 4000 per second. A reflector is provided to focus the high-intensity sparks from the condensers upon the spray. A master condenser switch, which is operated by the spray-control camshaft, coordinates the occurrence of the sparks with the occurrence of the oil spray in the spray chamber. The duration of each electric spark is less than one millionth of a second, so that even though a spray may be traveling with a velocity of 500 ft. per sec., the resulting spray image on photographic film is sharp and well defined.

The spray-recording apparatus is shown in the left quarter of Fig. 2. It consists essentially of a large-aperture, high-grade photographic lens for focusing the spray image upon a photographic film, a film drum which rotates the film at high speed, and a light-tight camera box enclosing the lens and film drum. The speed of the film past the lens may range up to 300 or more feet per second, the speed being adjusted to obtain sufficient spacing between the spray pictures to prevent overlapping.

A reproduction of a photographic record of a medium centrifugal oil spray obtained with the N.A.C.A. spray-photography apparatus is shown in Fig. 3. The penetration in inches for various times after the start of injection may be measured from the ordinate and abscissa scales given. The start of cut-off is marked. The spray near the injection valve immediately following cut-off has little penetrating power and tends to mask the cessation of injection in this record. The cut-off, however, is controlled by mechanical adjustment and may be checked by inspection of records of sprays injected into air at atmospheric pressure such as are shown in Figs. 4 and 6.

A considerable amount of information may be obtain from these photographic spray records. They may be studied visually as to their peculiarities and general contour. The point of cut-off may be established as noted above. Phenomena occurring after cut-off, such as dribbling, secondary discharges, low penetration, and twisting of the spray, may be studied. The relative atomization for different sprays may be estimated. The shape, position, and possibly the causes of the small clouds of oil particles thrown out from the main spray, as shown particularly in Fig. 6, may be investigated. The importance of such irregularities in oil sprays should not be underestimated as they may readily become the foci of ignition.

The spray images on the film may be measured, and, since the photographic reduction and speed of the film are known, the penetration may be plotted against time. From such penetration-time curves the velocity and deceleration of the spray tip may readily be computed. The spray-cone angle may be measured, and, by summing the volumes of a number of disks into which the spray may be divided, the volumetric growth of the spray may be approximately determined. By making other tests in which many sprays are caught in a container and weighed, the quantity of oil in one spray may be computed. If the volume of a spray at cut-off be divided by the volume of the oil injected, the resulting figure gives the number of times the liquid-oil volume has been made to increase by injection and atomization under any particular set of conditions. Such data provide a direct measure of the distribution of oil sprays.

The N.A.C.A. spray-photography apparatus is equipped to study either mechanically or hydraulically operated injection valves. The effects of injection pressures up to 12,000 lb. per sq. in. and of spray-chamber gas pressures up to 600 lb. per sq. in. are investigated. Different fuels have been employed and several gases at various pressures in the spray chamber have been used in studying the effects of fuel characteristics and of gas density on sprays. Several designs of injection valves and various stems, nozzles, and injection tubes have been investigated in determining the effects of injection-valve and injection-system design.

Several investigations on the various characteristics of oil sprays have been completed to date. These can only be mentioned briefly. The first research determined the discharge characteristics of a mechanically operated injection valve with a 0.0155-in. round orifice. Diesel oil was discharged through this orifice at pressures up to 8000 lb. per sq. in. into air at atmospheric pressure and into nitrogen at pressures up to 300 lb. per sq. in. The results have been published in terms of spray penetration, velocity, and deceleration in N.A.C.A. Report No. 222 (42).

Fig. 4 shows a set of reproductions of photographs similar to those taken in the first research. These oil sprays were obtained by discharge through a 0.022-in. round orifice installed in an auto-

Chamber Pressure, Atmospheric

matic injection valve, and are much like those published in N.A.C.A. Report No. 222. The high rate of penetration for injection into air at atmospheric pressure and the appearance of this spray should be noted, as they illustrate the manner of its development and provide a means for visualizing one's oil sprays when observing them in the air. The pronounced decrease in penetration, the increase in spray cross-section, the small irregularities, and the appearance of greater atomization of the sprays injected into air at 200 or more pounds per square inch indicate some of the effects of a dense gas. The penetration-time curves for the 0.0155-in. orifice used in the first research, for injection pressures from 2000 to 8000 lb. per sq. in. and for spray-chamber gas pressures up to 300 lb. per sq. in., are reproduced in Fig. 5.

The second research determined the factors affecting the air. Had these sprays been observed only for the case of injection into air, it might have been assumed that their shape would remain the same when injected into an engine cylinder. This assumption would probably result in a misfit between the spray and combustion chamber, and consequently in inferior engine performance.

The variation of penetration and spray-cone angle for different amounts of centrifugal force applied to the oil in the jet are shown in Fig. 7. The better maintenance of penetration for the sprays produced by high centrifugal force, even when injected into air at 400 lb. per sq. in. pressure, is shown by the two penetration curves.

Fig. 8 shows the effect of centrifugal force on spray distribution. A non-centrifugal spray was found to have about

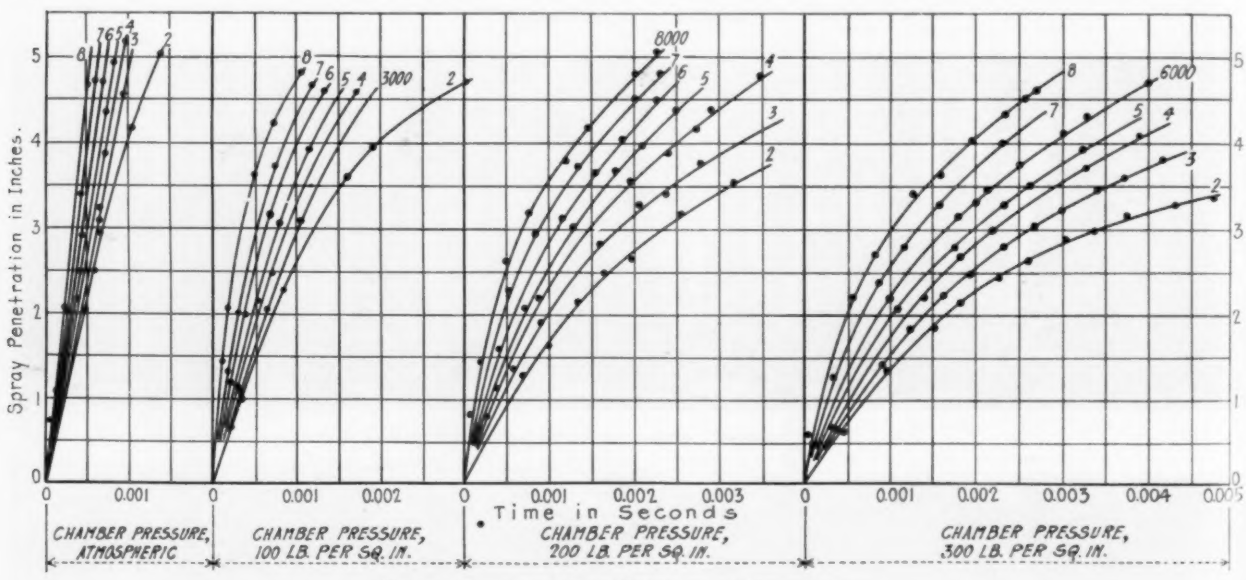

Fig. 5 Effect of Fuel Pressure on Penetration
(Injection pressures, 2000 to 8000 lb. per sq. in.; orifice diameter, 0.0155 in.)

exact reproducibility of oil sprays and the phenomena of secondary discharges after cut-off. The results have an important bearing on the smooth and reliable operation of oil engines, and have been published in N.A.C.A. Report No. 258 (43).

The third research determined the effects of the several factors that control the efficiency of discharge, atomization, and distribution of centrifugal-type injection valves. The results are given in terms of spray penetration, velocity, volume, and distribution as controlled by the diameter and length of the orifice, the position of the seat, and the area and pitch of the centrifugal grooves.

Fig. 6 shows a series of reproductions of photographs taken of a high-centrifugal-force spray. The sprays were produced by passing the oil through 23-deg. helical grooves, turned on the end of the valve stem, just before its discharge through a 0.040-in. orifice. The relatively low penetration and large spray-cone angle for the case of injection into air at atmospheric pressure are noteworthy for comparison with the non-centrifugal sprays of Fig. 4. It may be observed that this spray appears to be hollow and very well atomized. Cut-off has taken place between the fifth and sixth pictures. The advance of the end of the spray is slow, thus giving evidence of the low penetrating power of atomized oil when not driven forward by the continuance of the jet.

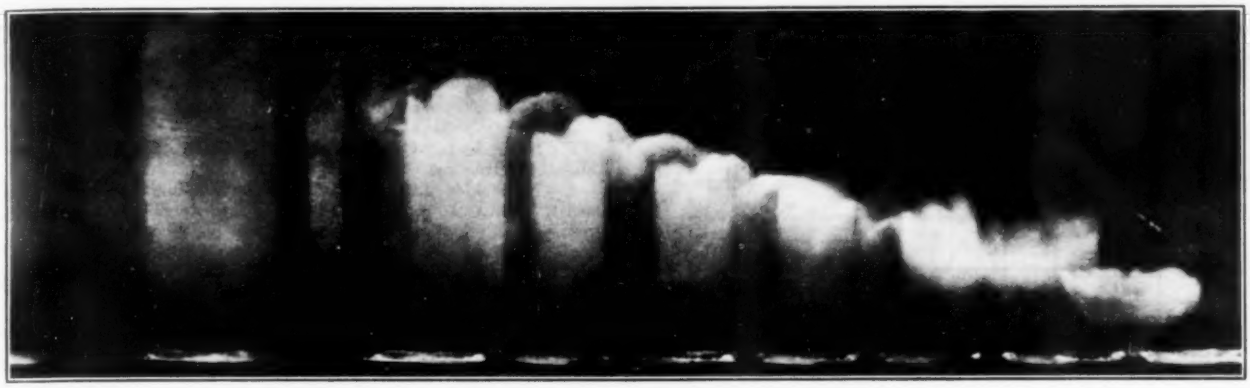
The great value of photographic spray records is evident on inspection of the sprays for the case of injection into dense

500 times the volume of the liquid oil in the spray 0.004 sec. after its appearance at the nozzle. When centrifugal force was applied to the jet under similar test conditions the spray could be distributed throughout a volume about 1000 times that of the liquid oil. This increase in distribution is obtained at the expense of some penetration, but the better mixture obtained with the air, and the finer atomization, aid combustion at the higher engine speeds. The results of the complete investigation are published in N.A.C.A. Report No. 268 (23).

The fourth research determined the effects of the viscosity and specific gravity of the fuel used on spray characteristics, and of the injection of Diesel-engine fuel oil into nitrogen, carbon dioxide, and helium at various pressures.

The effects of fuel characteristics on sprays were studied by injecting gasoline, kerosene, Diesel-engine fuel oil and a furnace fuel oil through the same injection valve into nitrogen in the spray chamber under the same test conditions. The specific gravity of these fuels ranged from 0.70 to 0.90. It was found that the penetration increased with specific gravity, but there was a corresponding decrease in the spray-cone angle and in the distribution. These results and the pronounced effects of high centrifugal force on the penetration, spray angle and distribution of sprays produced with these four fuels are shown in Fig. 9.

Although unconfirmed by engine tests, the advantages of increasing the distribution of heavy-oil sprays by means of



Chamber Pressure, Atmospheric

Chamber Pressure, 200 Lb. per Sq. In.

centrifugal force are clearly indicated by comparisons of the data for non- and high-centrifugal injection. While the penetration for the 0.90 specific gravity fuel decreased from 7.4 in. after 0.004 sec. to 5.45 in. with the application of centrifugal force, a decrease of 26.3 per cent, the distribution increased from 460 to 980, an increase of 113.0 per cent. Under the same conditions the penetration of gasoline decreased 33

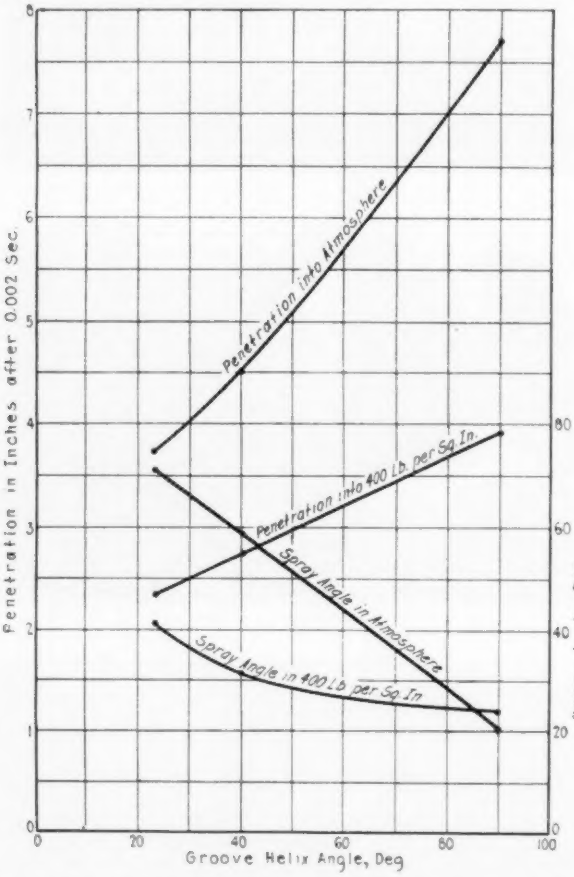

FIG. 7 EFFECT OF GROOVE HELIX ANGLE ON CENTRIFUGAL SPRAYS
(Injection valve No. 7; orifice diameter, 0.022 in.; injection pressure, 8000 lb. per sq. in.)

per cent with the application of centrifugal force and the distribution increased only 83 per cent.

The penetration of Diesel-engine fuel-oil sprays injected into nitrogen, carbon dioxide, and helium are shown in Fig. 10. This graph gives cross plotted data from several tests such as are presented in the insert. Since the experimental data lie on smooth curves when plotted against absolute gas density, oil-spray characteristics are dependent upon this factor rather than upon the gas pressure only. The data show that the effects of gas viscosity are negligible. A report is being prepared on the complete investigation.

A fifth research is nearly completed on the factors controlling the occurrence and velocity of pressure waves in injection systems for a large range of conditions, and the program for a sixth research on the factors controlling the exact action, injection lag, operating pressures, and fuel-delivery rates of injection valves is being formulated. Reports on these investigations will be published in the future.

By means of such photographic records of fuel sprays produced by various injection-valve designs, different fuels, and different pressure conditions as are presented in this paper, and by means of the graphs developed from them the characteristics of sprays for oil engines may be studied from many viewpoints, and the injection of fuel into the cylinders of high-speed engines perfected.

# Manufacture of Diesel Fuel Injectors

By C. R. ALDEN,[1] DETROIT, MICH.

*The paper deals with details of design and manufacture of parts of fuel-injection pumps, such as plungers and their bushings, and check valves, which must be made with greatest precision in order to permit the injection of an accurately metered amount of oil and to be tight against high pressures. Results of tests to determine the length of bushing necessary to prevent leakage around a plunger are reported and show that this need be much less than is usually specified. The characteristics of materials from which such parts can be manufactured are also given. It is suggested that the parts considered may be easily standardized with benefit to the oil-engine manufacturer.*

THE difficulty in meeting the fuel-injection requirements of the modern high-speed oil engine is ever before the Diesel-engine designer. The need for extreme accuracy in certain parts of the fuel-injection system is keenly realized when it is considered that a four-cylinder four-cycle oil engine rated at 50 hp. at 1200 r.p.m. and consuming 0.5 lb. of fuel per horsepower-hour under full load will require the injection of but 0.00017 lb. of fuel per impulse. This corresponds to approximately 0.0055 cu. in. or 0.0327 cc. The time allowed for completing the injection of this amount of fuel is frequently not more than $^1/_{240}$ of one second. An error in metering of 0.000017 lb. per impulse will cause one cylinder to carry 10 per cent over or under its proper share of the load.

When flexibility of engine performance is considered it is realized that with the engine idling, the indicated brake horsepower would probably not exceed 5 for which the normal fuel charge per impulse would be about 0.000017 lb. and from which a variation of 0.0000017 would represent an error of 10 per cent.

It is readily appreciated that when such exactitude is maintained throughout the entire range of engine performance the problems of the Diesel-engine designer are at least paralleled by those of the artisan who must produce the fuel-injection system.

## Cooperation Between Designers and Builders

In a number of respects it is the author's opinion that designer and builder have been slow to cooperate to their maximum advantage. For example, the author remembers seeing a fuel pump of European design in which four plungers were to be fitted and lapped into four holes in the fuel-pump block as were also the suction and discharge check valves and bypass valves. An accident to one of these fitted holes would therefore mean either scrapping of the entire block or the fitting of an oversize plunger or valve. To make such a block of hardened material would be an economic if not a mechanical impossibility, as would also the making of such a block of stainless or corrosion-resisting material. All three requirements, interchangeable precision parts, sufficient hardness, and resistance to corrosion, are vital to the successful manufacture and marketing of oil engines under conditions now existing in the United States.

In another instance an American manufacturer requested a quotation on lapped valve stems of $^3/_8$ in. diameter, and, in order to make a tight fit against the pressure employed, specified a lapped bushing $6^1/_2$ in. in length. Such an instance would not be cited except that it is typical of Diesel designers to specify a length of lapped fit which is longer and more expensive than is required to secure perfect tightness. This makes the parts more expensive to manufacture than is necessary. Frequently the excessive length of the fitted parts defeats its very purpose through inability to make both hole and plunger perfectly straight and necessitating a poor fit in order to obtain a free motion of the parts.

## Research on Plunger Bushings

The results about to be reported are not presented as an exhaustive research but simply to show

1 That straightness and roundness and a very small difference in diameter allows free mechanical motion;

2 That the length of carefully fitted parts has little to do with their tightness against air pressure or light oils (i.e., kerosene);

3 That it now seems that the length specified for fitted parts to prevent leakage at high pressures need not be greater than that required for mechanical purposes.

To demonstrate these facts the following pieces were prepared (See Fig. 1):

*A* A bushing of hardened steel;
*B* A plug gage;
*C* A plunger;
*D* A second plunger.

The important dimensions of the above are shown in Fig. 1. Checking up the clearances it is found that the difference between the minimum hole (0.87604 in.) and maximum gage (0.87607 in.) shows the gage to have a negative clearance or press fit of 0.00003 in., yet the gage can be wrung through the bushing by hand. The minimum clearance between the bushing and plunger *C* therefore becomes the minimum bushing diameter 0.87604 in. minus the maximum plunger diameter of 0.87608 in., or a clearance of 0.000032 in., while the minimum clearance between the bushing and plunger *D* is 0.000036 in.

It can be seen that either plungers *C* or *D* fit very freely in *A* so long as relative motion is maintained but when the air film which exists between plunger and bushing is destroyed by side pressure, these wring together as would the plane surfaces of two gage blocks.

The inspection test of the author's company for production fuel-pump plungers and bushings designed for delivering lightest oils against highest pressures is that when clean and dry they must be mechanically free to relative movement and when assembled an air pressure of 85 lb. per sq. in. applied at one end while the opposite end is submerged in water at atmospheric pressure, will not produce more than four well-defined bubbles of leakage air per minute.

Plunger *C* with bushing *A* makes an acceptable combination, while plunger *D* with bushing *A* would be rejected. The difference between the maximum diameters of *C* and *D* is only 0.000004 in.

## Effect of Length of Fitted Portions on Leakage

To determine the effect of the length of the fitted portions upon the amount of air leakage, the air-pressure test was performed upon bushing *A* and plunger *C* assembled together but with *C* partially withdrawn from *A*. The point of rejection (four bubbles of leakage air per minute) was not reached until only $1^1/_2$ in. of *C* remained surrounded by *A*.

With reference to the leakage between bushing *A* and plunger *C* when only $1^1/_2$ in. of *C* remains surrounded by *A*, it seems significant that the increase in diameter of *A* coincident with the

[1] Chief Engineer, Ex-Cell-O Tool & Mfg. Co. Mem. A.S.M.E.

Presented at the First National Meeting of the A.S.M.E. Oil and Gas Power Division, The Pennsylvania State College cooperating, State College, Pa., June 14 to 16, 1928.

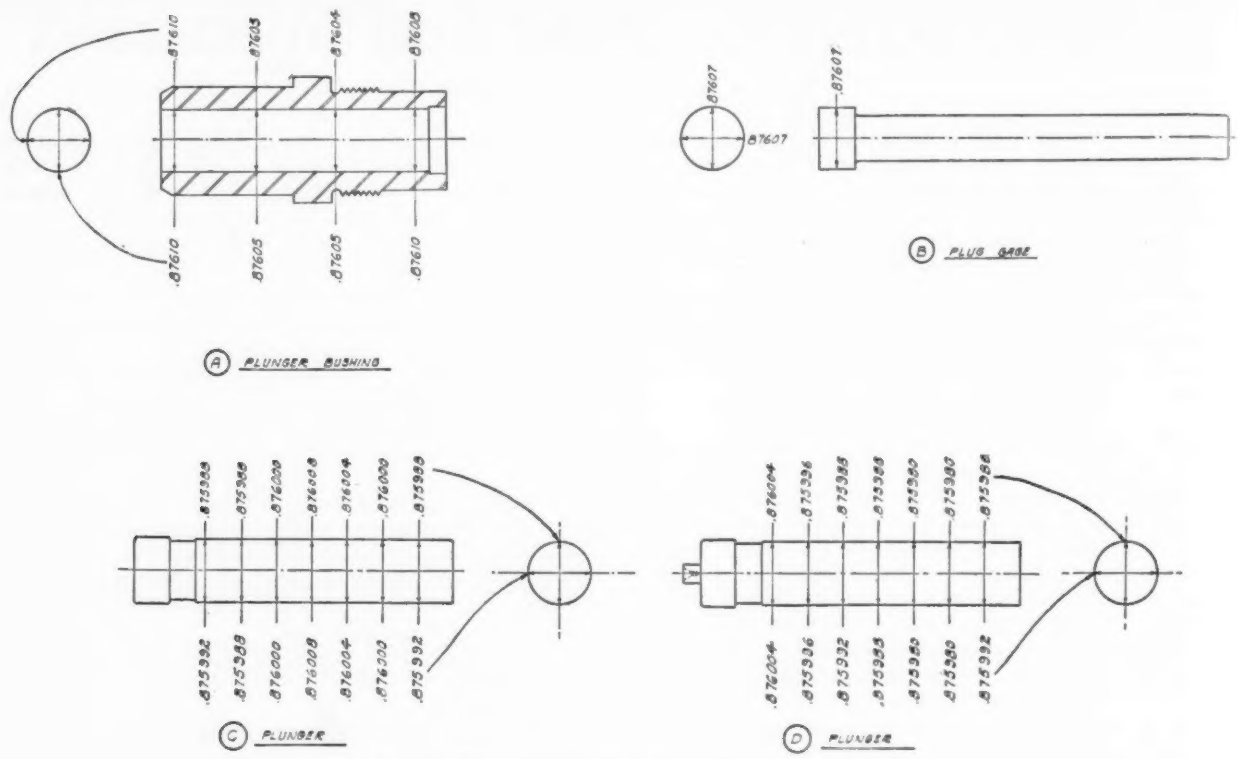

FIG. 1 DIMENSIONS OF TEST PLUNGERS AND BUSHING

decrease in diameter of plunger *C* in its partly withdrawn position increases the minimum clearance to 0.000036 in., under which condition plunger *D* with bushing *A* shows substantially the same leakage. The author is inclined to attribute the increased leakage (of compressed air) to the increased clearance rather than to the decreased length of the telescoped diameters.

It is realized that viscous oils under the circumstances described will perform very differently from compressed air, though not sufficiently differently to warrant attempting to substitute "length of plunger and bushing" for "precision of fitting" as a measure to prevent leakage past fuel-pump plungers.

To determine the relation between rejectable air leakage and the leakage of light oil, *A* and *C* were dried and again assembled in the vertical position with only $1^1/_2$ in. of their lengths coinciding. The volume of *A* not occupied by *C* was filled with kerosene. At the end of thirty minutes standing at atmospheric pressure no leakage whatever was apparent. Air pressure at 85 lb. per sq. in. was then applied on top of the kerosene. At the end of three minutes sufficient kerosene had leaked to form a barely noticeable fillet where *C* entered *A*, but this fillet had not become sufficiently heavy to cause a drop to run down the plunger *C* until 32 min. had elapsed (one hour and two minutes after placing the kerosene and 32 min. after applying a pressure of 85 lb. per sq. in.).

To determine the effect of relative motion (reciprocation) between *A* and *C* with $1^1/_2$ in. of length coinciding and with kerosene at a pressure of 85 lb. per sq. in., plunger *C* was reciprocated in *A* with $^1/_4$-in. strokes at the rate of about 300 per minute. At the end of 1000 strokes the amount of leakage was not noticeably greater than it was when the parts were stationary. The test was discontinued. Observation of similar parts in service indicates that the leakage of fuel oil under operating conditions is not greater than under the continuous pressure mentioned above.

It should here be mentioned that minimum leakage past pump plungers plus perfect mechanical freedom of the parts when cleaned and dried is not the only criterion for successful fuel-pump plungers and bushings as parts exhibiting these satis-

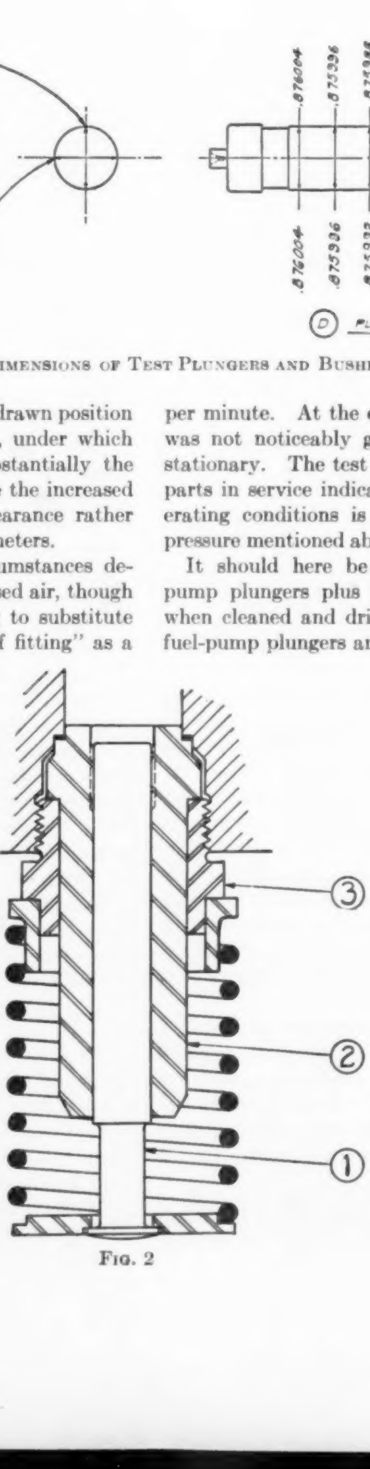

FIG. 2

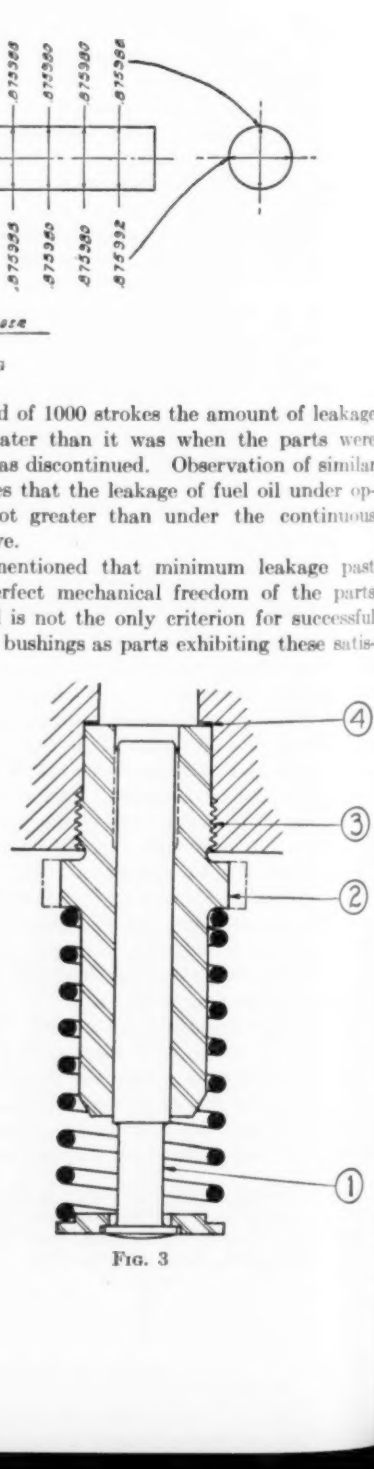

FIG. 3

factory characteristics are not necessarily proof against galling and sticking in service. Sufficient leakage must be allowed to keep the parts bathed with a film of fuel, even though fuel oil has little lubricating value. The clearance must therefore be increased—

1 As the working pressure of the pump is decreased
2 As the stroke of the pump is increased
3 As the speed of the pump is increased
4 As the gravity of the fuel is increased
5 Slightly as the diameter of the plunger is increased.

At some future time sufficient reliable data will have been compiled to permit an equation of the general form

$$C = KH^aG^bD^cP^{-d}$$

to be evolved, in which

$C$ = clearance required between plunger and bushing
$K$ = a constant
$H$ = the product of the length of the stroke by the number of strokes per minute
$G$ = gravity of the fuel oil
$D$ = diameter of the plunger
$P$ = pressure delivered.

### Effect of Design on Cost of Parts and Engine Maintenance

In order that all parts requiring precision workmanship or replacement in service shall be adapted to American manufacturing and servicing methods, it is desirable that the parts, or at least the individual assemblies, shall be interchangeable. The following circumstances make this practice almost imperative:

1 Precision parts such as plunger bushings, valve guides, check valves, injection nozzles, etc. can almost invariably be put on production basis;

2 Frequently by careful standardization the same parts can be made applicable to engines of widely varying sizes;

3 Such parts can be hardened where otherwise impracticable;

4 Such parts can be made of corrosion-resisting material which might not otherwise be feasible;

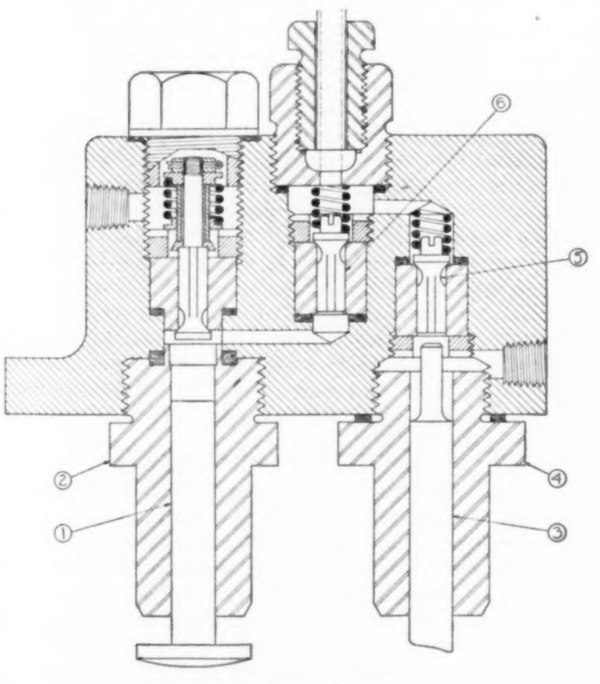

Fig. 4 Check Valves

5 Parts (especially check valves), can be quickly replaced when necessary and overhauled at the operator's convenience;

6 Parts can be tested before installation, minimizing engine shutdown time.

That the design of fuel-injection details has decided effect on difficulties at assembly and in service is shown by the following:

Fig. 2 shows a fuel-pump plunger (1) and fuel-pump-plunger bushing (2) of the design commonly called a collar-mounted plunger bushing, as the bushing is held on its gasket by the pressure of nut (3) on an enlarged diameter or collar which is a part of the plunger bushing.

The advantage of this construction is that proper seating of the plunger bushing on its gasket is less sensitive to inaccuracies in boring the gasket seat and tapping the thread square with the axis of the hole. However, it is important that the plunger bushing should be counterbored or relieved throughout that part of its inside diameter which lies below the lower edge of the collar, shown dotted in Fig. 2, as the setting up of any compressive stress in the plunger bushing after it has once been accurately fitted to the plunger will result in a distortion of the inside diameter of the bushing sufficient to cause the plunger to stick.

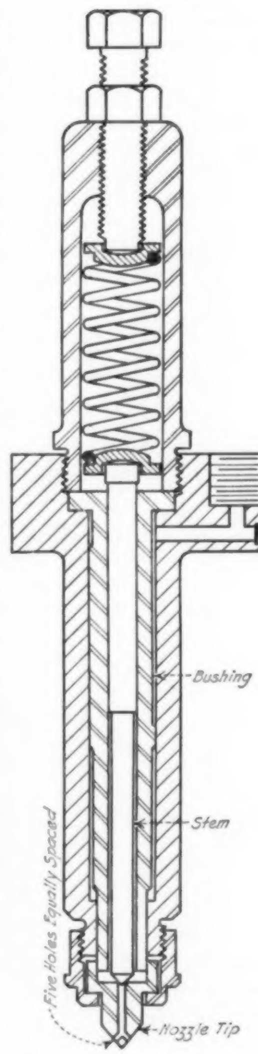

Fig. 5 Spring-Loaded Valve

Fig. 3 shows a portion of a cross-section of another fuel pump of which plunger (1) moves in bushing (2). This is of the threaded type. The advantage of this type is the elimination of the necessity for the nut (3) of Fig. 2. However, care must be exercised in making the axis of the tapped hole in the main pump body (3), Fig. 3, coincide with the axis of the plunger, and in making the pitch diameter of the thread on the plunger bushing (2) substantially under that of the thread in pump body (3), and the gasket seat (4) square with both.

If possible it is also desirable to counterbore or relieve the inside diameter (shown dotted) to avoid placing any of the fitted portion of bushing (2) under compressive or torsional stress. When this cannot be done on account of other conditions, it is necessary to lap plunger (1) and bushing (2) together, while bushing (2) is screwed into a block under conditions similar to those under which it will operate when finally assembled in pump body (4). Even when this is done difficulty may still be experienced unless all threads have been held reasonably square with the gasket seats.

Fig. 4 shows check valves in various combinations as suction valves, discharge valves, back-flow valves, or bypass valves. By making these of hardened steel the seat may be worked at high unit pressures without wear or distortion through hammering. Frequently valves of one given design may serve several pur-

poses in the same pump, thus simplifying the list of replacement parts to be carried in stock.

One commonly used type of bypass or cut-off valve is illustrated in Fig. 4, of which (1) and (2) represent the fuel-pump plunger and its bushings, (5) and (6) represent the suction check valve, while (3) and (4) enable the raising of detail (5) from its seat, thus bypassing any remaining displacement due to the uncompleted stroke of (1), and allowing this discharge to be returned into either the suction channel or a separate bypass channel.

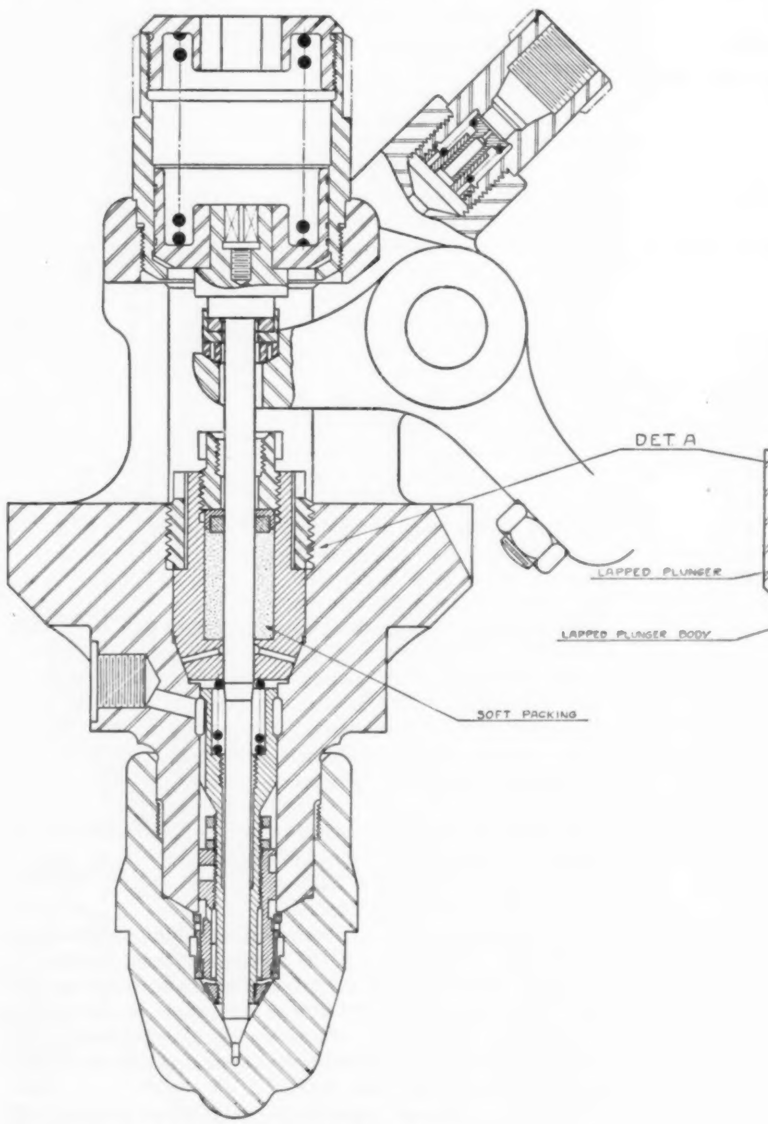

Fig. 6 Air-Injection Fuel Nozzle

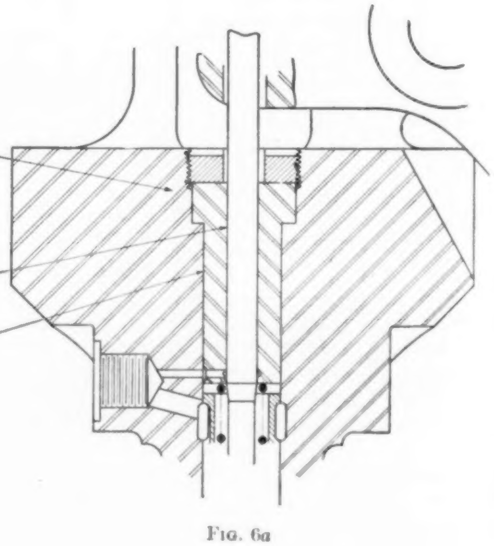

Fig. 6a

Fig. 5 shows a spring-loaded fuel-injection valve, the stem of which is lifted by the hydraulic pressure of the fluid. This valve also involves a lapped stem and bushing with the additional requirements of accurate concentricity and precision fits in order that the nozzle tips may be made interchangeable without the necessity for regrinding the valve seats at each exchange. The drilling of the small holes which often are as small as No. 76 (0.020 in.) is also an operation which calls for special equipment and a considerable degree of skill. Fig. 6 shows an air-injection fuel nozzle for which a suggested redesign has been shown in Fig. 6a. The fuel nozzle in Fig. 6 uses a soft packing, while in Fig. 6a it is redesigned to employ a lapped bushing and plunger. A somewhat similar though not identical application of a lapped valve stem and bushing applied to air-injection fuel nozzles has been in operation for approximately eight months without complaint of any kind and while the manufacturer is not ready to commit himself as to whether such a design should be adopted as standard, the design does have simplicity and freedom from parts that would require frequent replacement or adjustment. As shown at the bottom of Fig. 6a, the fit is lubricated and sealed with the fuel oil, and inasmuch as the pressures encountered are much less than they are in ordinary fuel-pump applications, especially for solid-injection engines, it would seem that this construction might be given consideration by builders of air-injection engines.

## Materials of Construction

It is required that details of fuel pumps be made of materials

that can be worked to the required degree of precision, usually by grinding or lapping processes. The materials after finishing must offer great resistance to wear and preferably exhibit considerable resistance to corrosion.

### Unhardened Tool Steel

Unhardened tool steel takes a beautiful finish, but has come under the suspicion that it is subject to galling. However, in defense of the material, it should be mentioned that at the early date at which this difficulty was encountered, plungers were being fitted more tightly than has later been found necessary to prevent leakage. This material is also subject to the objection that it is actively corrosive in the presence of impurities which are found in many fuel oils.

### Hardened Tool Steel

Hardened tool steel has characteristics similar to those of unhardened steel except that in the hardened state few difficulties with galling have been experienced and these seem traceable to the presence of foreign material such as emery, carborundum, or other abrasives needlessly admitted at assembly.

### Stainless Steels

Many of the stainless steels contain such a high nickel content that it is impossible to harden them. Steels of this character have not been tried for fear that difficulty with galling might be encountered.

Not many brands of corrosion-resisting steel capable of being homogeneously hardened are available. The price seems exorbitant, and the material is machinable only with considerable difficulty. In a standard 20 per cent salt-spray test in which cast iron, tool steel, nitride hardening steel, and hardening stainless steel were present, all samples showed very noticeable corrosion at the end of one hour. However, the sample of stainless hardening steel was less affected than the others, and upon wiping off the corrosion with a 10 per cent muriatic acid solution it was found that the polish on the parts had been barely perceptibly etched, which could not be said of the other samples. Although many thousands of pump parts made from hardened stainless steel have been in service for approximately two years, no reports of any difficulty with corrosion have been received, and the galling by which some parts have failed is believed to have been caused by preventable abrasive dirt.

### Nitride Hardening Steels

A steel known as nitride hardening steel which takes an extremely hard surface when treated at the relatively low temperature of approximately 900 deg. fahr. in the presence of ammonia is understood to have been developed originally by the Krupp interests in Germany. This steel, it is claimed, offers unusually high resistance to corrosion and may, when more universally available and more uniform in quality, become a contender as a material for fuel-pump parts. When properly hardened, it seems to be sufficiently non-corrosive.

### Plunger Bushings

Plunger bushings of ordinary close-grained cast iron have worked satisfactorily, except that special precautions must be taken against allowing them to become charged with the abrasive while lapping. Cast iron also offers no protection against corrosion; and considerable labor may be expended on a part before learning that it is unsuitable on account of porosity. These difficulties argue against the choice of this material. Experimentation is in process with cast iron hardened by various methods and with certain cast-iron alloys in which the density can be increased and some protection from corrosion obtained. These experiments are prompted, however, more by the motive of reducing the cost of the material required than that of obtaining a material having greater freedom from operating difficulties than the hardening corrosion-resistant steel previously mentioned. It is also probable that neither cast iron nor cast-iron alloy will be found suitable for such parts as bypass or check valves on account of the difficulty in obtaining a narrow seat sufficiently free from pores to be certain of freedom from leakage. From the foregoing it is seen that many problems encountered in the field of design, choice of materials, and methods for economically manufacturing interchangeable parts are yet to be solved.

Neglecting entirely the hydraulic phenomena which are a problem of the Diesel designers and confining ourselves strictly to the problems of the Diesel-engine manufacturer, let us give brief attention to the three phases of the problem that has just been outlined.

### Design of Operating Parts Which Must Prevent Leakage Under Hydraulic Pressure

Little is known of the length of lapped or fitted telescoped concentric cylinders required to prevent hydraulic leakage while allowing axial mechanical motion and the variation of this length with the diameter of the plunger or stem; nor of the variation of this length with the pressure under which the parts are to be operated and the variation of length with the grade of fuel to be handled; nor of the effect of the length of stroke upon the clearance between the plunger and the bushing.

Investigation should be made of the precision of fit required under the varying conditions outlined above.

Investigations should be made of methods of mounting or assembling the parts which would permit of the minimum total cost when considering

1 Original cost of manufacture of parts
2 Length of life of the parts
3 Convenience of making service replacement of parts.

Investigation should also be made of the choice of materials which have the necessary resistance to corrosion, resistance to mechanical wear, and freedom from distortion through relieving of internal stresses after the manufacturing operations have been performed. After these requirements have been met it will be necessary to choose materials of minimum cost, having the most favorable machining and processing properties.

### Standardization

The analysis of any number of fuel-injection pumps will show that they consist essentially of certain plungers and bushings, bypass valves, check valves, and other precision parts on which the proper functioning of the pump depends. It is true that the mechanism for operating these parts, the form of the principal parts in which the precision details are mounted, the location and method of driving the pump, etc. will probably always differ widely, as long as oil-engine designers retain their individualities. However there is hardly an oil engine built today which, by the making of certain very simple changes, would not permit the application of standard precision details of the kind which have been under consideration in this paper.

Were these details so standardized, the combined volume of the precision details required as the number of oil engines manufactured continues to increase would uncover a sufficient volume of business to be of interest to manufacturers who are suitably equipped for economically manufacturing these specialities. The resulting competition should insure the Diesel-engine manufacturers of a higher grade of fuel-pump parts at a much lower cost.

## Discussion

R. L. Boyer.[2] Aside from the fuel system, a Diesel engine is essentially a reciprocating machine designed for high pressure. However, the fuel system presents a unique problem. A well-designed injection system can often make a good engine of a poor one, and a poor injection system frequently is the cause of troubles not thought of as being connected with it. The fuel system is really the heart of the engine, whether air- or solid-injection.

With the increased use of sulphur fuels, it has become almost necessary to provide each valve with a removable seat, for frequent grinding to the pump body is necessary, and eventually the body itself must be replaced.

Although the time may never come when all Diesel builders will agree on one design of fuel system there is no reason why individual fuel-pump parts cannot be standardized. Few oil-engine builders are equipped to handle such small and extremely accurate work, and the comparatively small number of these parts to be made does not justify the necessary equipment. The cost of such parts, when standardized, is reduced 50 per cent or more, due to increased volume.

Spare parts, as well as parts for a new pump, can be ordered from the specialist by his drawing number and from his stock room. The specialist can effect research on materials and in other ways in which the engine builder cannot spend so much time. All manufacturers doing business with the specialist would receive the benefits of these investigations, and this is a step toward cooperative research.

W. F. Joachim.[3] The economic aspect involved when each Diesel-engine builder makes all of the specialized engine parts is important as it means an outlay of costly precision-tool equipment and expensive labor without the opportunity for actual quality production. In the automotive industry many of the accessories are constructed by accessory manufacturers, who specialize on and produce such parts as spark plugs, magnetos, carburetors, generators, and starting motors more economically than the car builder. If Mr. Alden will explain how he makes his pump plungers, how the accuracy of the holes in the bushings is insured, state the minimum diameters to which he can operate the internal grinding process, and give the effect of using various steels and heat treatments, I believe it would be of considerable interest. No one has attempted to measure the actual clearance between pump plungers and bushings before, so that a description of how this is done is of interest. The cost of making long tool-steel parts goes up very rapidly with increase in length, and anything that can be done to decrease the actual length of fuel-pump plungers and bushings without increasing the leakage will be economically important. An investigation of the effects of the length and clearance of pump plungers and bushings and of the extent to which they may be varied with the viscosity and pressure of the oil, the amount of movement of the plunger, and the rate of movement should be encouraged, as much valuable data would be obtained.

Some of the methods used by the National Advisory Committee in its experimental pumps may be of interest. The parts are usually made of a high-grade tool steel, the bushing being with a male jig and the plunger with a female jig. The fit is determined by lubricating the plunger and bushing with a high-grade vaseline, attaching a spring scale, pushing the plunger in and pulling it back by means of the spring scale, the amount of force that is registered on the spring scale on the return movement determining the fit. A close-lapped fit requires a 5- to 10-lb. pull with slow relative motion.

We have also used the packed bronze bushing and steel plunger without leakage. Where high pressures have been developed, ranging from 4000 to as high as 15,000 and 16,000 lb. per sq. in., we find that as the injection pressure is increased above 8000 lb. the rate of leakage from this type of plunger increases. The rate of leakage depends upon the thickness of the shell and upon the actual design. If the fuel gets in between the plunger and its bushing at high pressure, it will tend to travel down the clearance space, and if pressure exists between plunger and bushing, it is going to expand the bushing and compress the plunger. If the bushing is thin, it will expand it a great deal. If it is thick, it will expand it; but the large amount of metal around it will prevent measurable external increase in diameter of the bushing and will only permit compressibility of the metal itself. To get around that condition in some of our high-pressure work we have designed a bushing which extends into the high-pressure chamber, the high-pressure joint being made at the outer end of the bushing so that the hydraulic pressure is permitted to flow around the outside of the bushing. We have not varied the shell diameter in such a case, and we have not varied the length of lapped fit, but we have obtained continuous leakproof operation.

In regard to other pump parts, such as the check valves, the Committee has used several of the types shown. The design of the fluted check valve is used by a good many oil-engine companies. We have found that in order to make these valves operate successfully without leakage it is only necessary to construct the width of the seat such that under the hydraulic loads, or the spring loads existing, the pressure between the metal at the seats is from 4 to 10 times the hydraulic pressure.

If there is any fuel between the seats of a pump valve so constructed, the high seat pressures, greatly exceeding the hydraulic pressure, will force the fuel from between the seats rapidly in both directions. The same comment applies to the seats of injection valves in general. In connection with the poppet valve of the type that Mr. Alden showed, and which a good many companies are using, I might state that one of this type has been repeatedly stressed to pressures around 40,000 lb. per sq. in. in an experimental pump and has given successful service without regrinding, relapping, or attention of any kind for the past five years. I feel that standardization of such parts and their manufacture by a company fitted to do that kind of work will be an economic gain to the oil-engine industry.

H. D. Hill.[4] The plea for standardization of fuel-injector parts holds a solution of a vexatious problem. The average engine factory does not include the precision machinery and trained personnel essential to the production of injector parts of the necessary accuracy in sufficient volume to reduce the cost to reasonable limits. Therefore, if standard designs for plungers, bushings, and valves in three or four sizes or enough to cover the field could be adopted, it seems that specialists would find it profitable to supply the demand with greater accuracy and lower cost.

Fig. 2 in Mr. Alden's paper illustrates the type of bushing we advocate, but we favor dropping it into the housing from above and holding it down on a shoulder by means of a threaded plug, which may also secure the discharge valve in a manner similar to that illustrated in Fig. 4. This would avoid ground or gasket joints under pressure between the bushing and housing, simplify the machine operations on the part, and reduce the area of the gasket, which would then rest on top of the bushing. We have made extensive service tests to determine the necessary length of fitted portions of $^7/_{16}$-in.-diameter plungers and bushings and have

[2] Diesel Engineer, The C. & G. Cooper Co., Mount Vernon, Ohio. Mem. A.S.M.E.

[3] Mechanical Engineer, National Advisory Committee for Aeronautics, Langley Field, Va.

[4] General Manager, Hill Diesel Engine Co., Lansing, Mich.

obtained a satisfactory seal of 1500 lb. pressure with 24 deg. B. caloil and an effective length of seal of only $^5/_{64}$ in. at the point of maximum pressure. The length of the stroke used was $^3/_{16}$ in. and the speed 600 strokes per min. Both plunger and bushing were of hardened steel. Our conclusions are that the fitted length is determined by the requirements of safe guiding of the plunger rather than leakage.

D. O. Barrett.[5] I am inclined to disagree with Mr. Alden as to cooperation between the designers of oil-engines and the builders of certain equipment. Mr. Alden seems to feel that oil-engine designers are inclined to design many of the parts so that these cannot be manufactured at a reasonable cost. Many of our spray-nozzle and pump parts have been changed directly, on recommendation of the builders of this type of equipment, much to the engine maker's sorrow. At times it seems that the makers of the smaller equipment are not fully conversant with the problems in oil-engine operation, and are prone to look at them merely from a mechanical standpoint.

Several of our pumps were changed from the design in Fig. 2 to that in Fig. 3, and upon attempting to use the purchased parts we found that these all tightened up at the inner end, making it impossible to move the pump plunger. These were then relieved, as shown, at the upper end with slightly better results, when it was again discovered that it was necessary to screw these bushings very tightly into a dummy corresponding to the fuel pump, thus compressing the metal at the upper end of the bushing, and then lapping in the plunger. This method has given fairly good results, but there is still a question whether the relief at the upper end of the pump plunger should not be eliminated. Any dirt or grit which may come into the pump is prone to settle in this relief, and consequently is drawn down alongside the plunger, scoring it. Were this same material to settle on the top of the plunger bushing without the relief, it would simply be pushed off and would not come directly in contact with the pump plunger.

As to the construction of fuel-pump and spray-nozzle bushings, we have tried out both the hardened and unhardened tool-steel bushings, and in both cases these have galled, and we have now standardized on cast-iron bushings. It is true that cast iron is apt to retain the abrasive material in the pores, but the solution is to secure a metal which shows little porosity. We have had good success in making these up in our own foundry, and bushings which we have cast were of almost as close a grain as unhardened steel bushings. Another point in the fit of the plungers and bushings is the type of fuel to be handled. With one fuel under our observation, unless the plungers are made abnormally loose, when the engine is started in the morning one or more of the plungers which happen to be left in the inner position at night will not return until forcibly pried loose.

The author's company is to be commended upon the experimental work done, but I believe that more consideration should be given the work accomplished by practical oil-engine operators, since upon this depends the success of the parts rather than the purely mechanical construction.

A. W. Morton.[6] There are several pertinent subjects that confront the representatives of the specialty manufacturer at every turn, and I should like to ask the consideration of the engine manufacturers on these three subjects: confidence, cost, replacement.

As to confidence, the agent of the specialty manufacturer can do a great deal for the engine designer or manufacturer if he can gain his confidence. The agent of the specialty maufacturer has an opportunity of travel all over this country and talk to engineers and manufacturers of many different makes of engines, and naturally he will absorb a great deal of information from these various visits. This information may sometimes prove very much worthwhile to the engine designer, and if he would only take the specialty manufacturer into his confidence and tell him his troubles, no doubt he would find that some one else had had similar troubles and how they were overcome. The representative of the specialty manufacturer does not have to tell tales and names at the same time. More frequently than not he has a store of information which would be of the greatest benefit to the engine designer or manufacturer, but he is loath to give this information when it does not seem to be wanted.

If the engine manufacturer is dubious about taking a specialty manufacturer into his confidence, it would then seem advisable for the engine manufacturer to turn to another specialty manufacturer with whom he believes he can safely trust his secrets. It would not be good business for the specialty manufacturer to betray the confidence entrusted to him by an engine manufacturer.

Frequently in my visits around the country I have to call on engineers four and five times before I can even begin to obtain the slightest recognition of friendship. The time taken to break down this barrier of reserve and indifference is time and money lost. Why cannot the engine manufacturer consider the specialty manufacturer more in the light of a friend who is trying to help rather than a competitor who is trying to get some of his business away from him? If the engine manufacturer would make contact with the specialty manufacturer and give him his confidence, it would undoubtedly work to the greatest possible advantage to both.

Cost is a question that needs scarcely to be discussed, for invariably when investigated thoroughly it can be found that the specialty manufacturer can manufacture the same parts very much more cheaply then the engine manufacturer. However, in many cases when the representative of the specialty manufacturer calls upon an engine manufacturer, the general manager or purchasing agent will send for one of his good mechanics, show him the part and say, "What can you make that part for?" The mechanic naturally wants to make a good impression with his boss, and he generally says that he can use such and such an automatic machine and turn out about ten per day. Little consideration does he give to the time taken to set up the machine for this purpose, and also to the fact that the first few lots going through will have to be put through as test pieces and undoubtedly ruined. Finally, when the machine is set up and ready to run, the first lot will invariably be oversize or undersize and will have to be scrapped, and no doubt the second lot will have to be rejected on account of material; and finally the superintendent of the shop will decide to put a more expensive man on the job, and by the time the parts are finally finished they will have cost many times the selling price of the specialty manufacturer's article.

Furthermore, the question of overhead is rarely considered in such cases. If all of these items are taken into consideration, it will be found that the article will not be as satisfactory as could be obtained from the specialty manufacturer, and the cost will be greater.

Replacement is a question that is very frequently overlooked, and is very often feared, but without any just reason. The engine manufacturer is prone to try to keep all of his business in his own shop so that he can control replacements to his own engines. He often feels that he can give better service than can the specialty manufacturer, but in this case he is undoubtedly wrong. The specialty manufacturer has a decided advantage over the engine manufacturer when it comes to replacements, because the specialty manufacturer can invariably adopt standards for the

[5] Chief Engineer, Superior Gas Engine Co., Springfield, Ohio. Mem. A.S.M.E.

[6] Vice-President and Chief Engineer, American Hammered Piston Ring Co., Baltimore, Md.

various parts he has to manufacture, so that many of these parts are interchangeable in various engines. Consequently, by means of this standardization the part can be manufactured more cheaply and a certain stock can be kept by the specialty manufacturer that the engine manufacturer cannot afford to keep, and therefore the question of service is a point decidedly in favor of the specialty manufacturer. Should he not have the exact part in stock, he can invariably set up his machines and make delivery on these parts far more quickly than can the engine manufacturer. In fact, the service performed by the specialty manufacturer can undoubtedly beat the engine manufacturer in every conceivable way.

The engine manufacturer often considers that the specialty manufacturer will take a lot of replacement business away from him which should by right come to the manufacturer of the engine. In this connection, do you think that the specialty manufacturer is willing to jeopardize the business of the engine manufactures in order to get some of the replacement business on any particular engine? I personally think the fear that the engine manufacturer has of the specialty manufacturer's getting his replacement business is unfounded. The specialty manufacturer naturally wants to get this replacement business, but preferably through the engine manufacturer, so that he cannot only hold the entire business of the engine manufacturer, but also help him to get more replacement business by giving better service.

A decided step in advance will have been made if the specialty manufacturer and the engine manufacturer will get together and talk over these problems and decide between them how they can help each other keep the replacement business where it belongs, namely, to the engine manufacturer; and then in turn the engine manufacturer will give it to the replacement manufacturer.

It is only by this cooperation between the engine manufacturer and the specialty manufacturer that this barrier of distrust can be broken down, and then both the engine and the specialty manufacturer will profit to the greatest advantage.

C. E. Beck.[7] I am interested in this subject because my time is engaged in the sale of Diesel engines, and if we can adopt some standardization of parts which will reduce manufacturing costs and thus overcome the argument that costs are too high, we naturally can sell more engines and thus increase production with a still further reduction of manufacturing costs. In some of the air-injection engines first installed in the West, corrosion, erosion, and wear of the fuel needles became manifest, and more especially on crude-oil pipe-line installations. Our former discussion on standardization of fuel oil applies to the country in general, but in pipe-line work Diesel engines consume a good deal of raw crude, taking it directly from the pipe line. Many of the crude oils contain acid, which manifests itself in the engine by corroding and pitting the fuel needles and the fuel-pump plungers and valves. Water in the fuel oil and in the injection air has an eroding effect upon fuel needles, sometimes tearing them off much the same as wet steam tears away the buckets or blading in a steam turbine. Water in the injection air has been largely eliminated by the use of intercoolers and aftercoolers of efficient design, although a careless operator may be negligent and not blow them out with sufficient regularity to prevent a few occasional globules of water from going through to the fuel valve. I visit many Diesel-engine plants each year and see the parts that become broken, worn, corroded, etc. Therefore, to manufacture fuel-pump and fuel-valve parts for air-injection engines, a material that will resist wear, corrosion, and erosion must be employed. We had rather good luck with cast iron originally, but later secured best results from cast-iron alloys.

# European Diesel-Engine Developments

## An Illustrated and Historical Account of Progress in Diesel-Engine Design and Application in Europe

By OLIVER F. ALLEN,[1] SCHENECTADY, N. Y.

WHEN I agreed to present this summary of the oil-engine situation outside of the United States, I did not realize the magnitude of the mass of data which would be available and I now find myself confronted with the embarrassing task of keeping this paper within reasonable limits and at the same time giving typical illustrations and figures presenting a reasonably clear picture of what is going on abroad without unduly emphasizing any particular type of engine or the products of any one shop or country.

Out of several hundred excellent pictures I have made a selection[2] which should be indicative of what our foreign friends are doing and I shall give a few data for the same purpose.

The growth of oil-engine manufacture has been so vast in Great Britain and on the Continent that I cannot possibly include reference to many important and interesting developments. I have time to mention only a few manufacturers and their products. I have tried to select those which are typical. I am sure that others, faced with this same task, would have made a different selection. If some familiar type or make has been omitted or only touched upon, please remember that I am only trying to sketch a general view of the industry abroad and have naturally used the materials which happen to have been available.

And here let me express publicly our great obligation to the officials and engineers of the oil-engine builders in Switzerland, Germany, Italy, France, Belgium, Holland, Sweden, Denmark, England, and other places for their courteous and generous response in sending data of what they are doing. I only regret that there is not time to give more details, for they are all instructive and interesting.

This paper will review briefly the history of the Diesel motor. It will then refer to the growth of the industry and touch upon what has been accomplished with solid injection, including automotive work, and with supercharging. The development of the double-acting engine will be described, and finally the latest tendencies in power station and marine applications will be referred to.

### Historical Sketch

Dr. Rudolf Diesel secured his first patent in February, 1892, in Germany, followed by another in 1893. The exploitation was initiated by the Maschinenfabrik Augsburg, now commonly called the M.A.N. Licenses were granted in 1893 to M.A.N. and Krupp in Germany, and to Sulzer Bros. in Switzerland.

The next contract was with Carels Frères of Ghent, Belgium, early in 1894. Under this license Carels completed a single-cylinder engine in August, 1894. Fig. 1 shows this engine, and is from a photograph, bearing the endorsements and stamps, which was registered for Belgian patent purposes.

Sulzer's first engine was produced in 1896.

The year 1894 is within the memory of most us. The thirty-four years that have passed are only the normal span of a generation and yet this great oil-engine industry has developed in this short period.

In 1898 the Diesel engine syndicate was formed, called the Allgemeine Gesellschaft für Diesel Motoren, followed soon by the Diesel Engine Company of England. The export of German, Swiss, and Belgian engines began about this time. Mr. Adolphus Busch purchased the United States and Canadian rights in October, 1897, and the first American Diesel, a 60-b.hp., 2-cylinder engine, was completed in September, 1898, by what is now the Busch-Sulzer Bros.-Diesel Engine Co.

Fig. 1 First Diesel Engine Built by Carels Frères, Ghent, Belgium, in 1894

Burmeister & Wain, of Copenhagen, Denmark, with long shipbuilding and marine-steam-engine experience, took a Diesel license in 1898 and produced their first engine in 1902.

Atlas of Stockholm started their Diesel engine works in 1898 and produced two-cycle, direct reversing marine engines in 1907.

[1] Manager, Automotive Sales, International General Electric Co., Inc. Mem. A.S.M.E.

[2] Colonel Allen showed many more pictures in the presentation of his paper than it has been found practicable to reproduce.—Editor.

Presented at the National Oil and Gas Power Meeting, State College, Pa., June 14 to 16, 1928, under the auspices of the A.S.M.E. Oil and Gas Power Division, The Pennsylvania State College coöperating.

Werkspoor of Amsterdam, Holland, took a license from M.A.N. in 1902 and built their first seagoing engine in 1908.

The development of commercial engines suitable for industrial plants required about nine years, and in 1902 what might be considered reliable standard engines were built in Europe and in the United States. At least one produced that year is still in running order and was in regular service until the fall of 1914.

In 1905 there was an exhibition at Liége, Belgium, at which a Carels 3-cylinder, 500-b.hp. engine was shown as the largest Diesel engine which had been built up to that time. Its generator was direct-connected.

By 1909 Schneider, the great French ordnance firm at Le Creusot, had taken a Carels license and as they wished to build larger engines than then existed, the Ghent works made in 1910 a 1000-b.hp. single-cylinder, 2-cycle, single-acting engine 820 × 1000 mm. ($32^1/_4$ × $39^1/_2$ in.), at 150 r.p.m. This engine developed full output on the test block at Le Creusot but smoked some. So far as I know, this was the first 1000-hp. cylinder built anywhere.

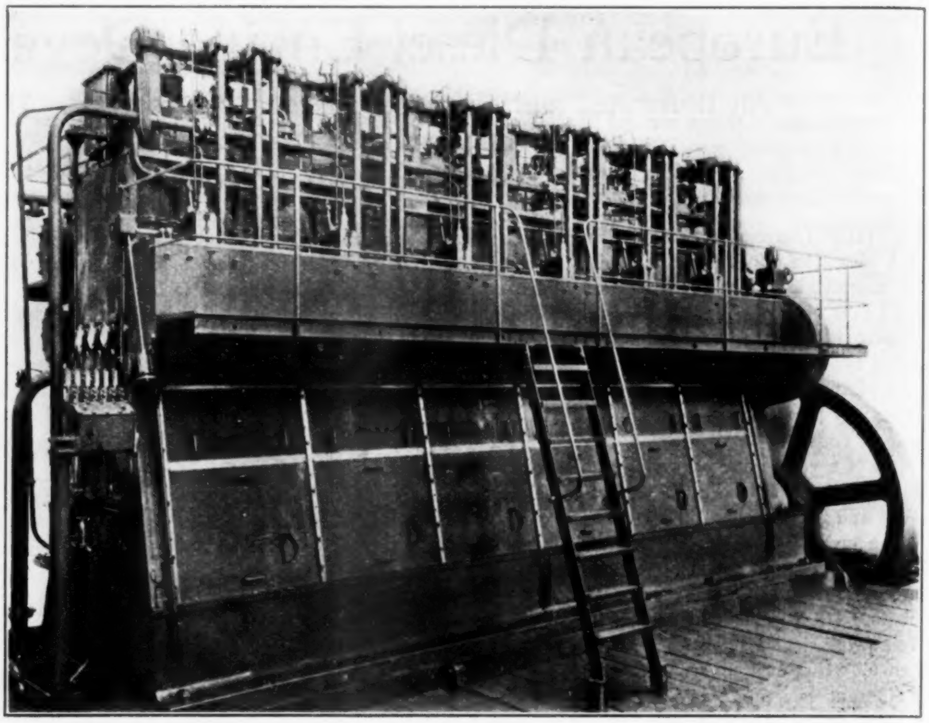

Fig. 2 M.A.N. Airless-Injection Diesel Engine, 6-Cylinder, 4-Stroke Cycle, 1575 B.Hp. at 187 R.P.M.

Vickers took a Carels license in 1910 and these two, Schneider in France and Vickers in England, started the development of Diesels for naval service which has since become so important.

Between 1900 and 1914 many licenses were granted by Sulzer, M.A.N., Carels, and others of the original builders.

The Phelps-Dodge Corporation bought two 1150-b.hp. Carels engines in 1913 for their Douglas, Arizona, plant. These are believed to have been the largest oil engines in the United States, when they were started in 1914. The Nordberg license followed and the large Diesel plants of the Phelps-Dodge properties resulted.

Before the World War interchange of engineering data and grouping of manufacturing interests in order to give to the public the best possible product, to the workman steady employment at fair wages, and to every market, all over the world, the product at the lowest prices consistent with these requirements, was unusual. It is now common practice and is being profitably applied in oil-engine manufacture by several important international groups. Not only is this growth of engineering cooperation among the nationals of the leading powers accelerating improvements and reducing costs to the ultimate user, but the personal contacts involved are a mighty powerful influence toward World Peace.

It is a great pleasure to be able to emphasize how really international this movement is, and to know that the United States, Japan, England, and the Continental countries are all among those contributing.

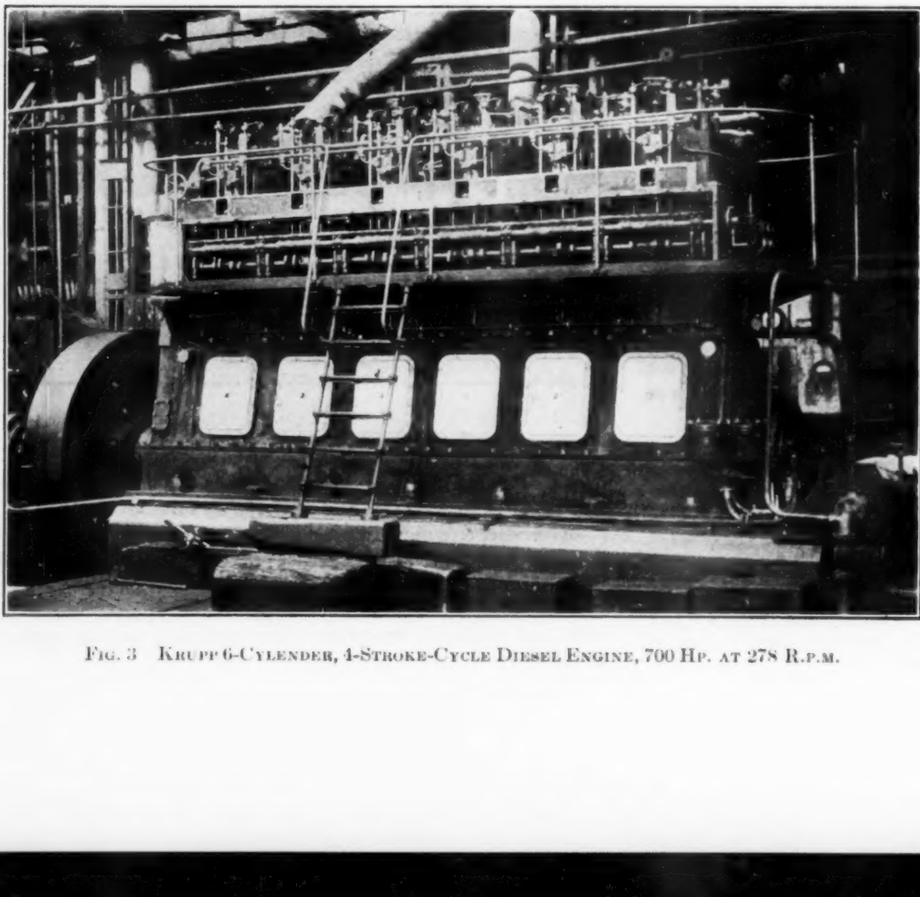

Fig. 3 Krupp 6-Cylinder, 4-Stroke-Cycle Diesel Engine, 700 Hp. at 278 R.P.M.

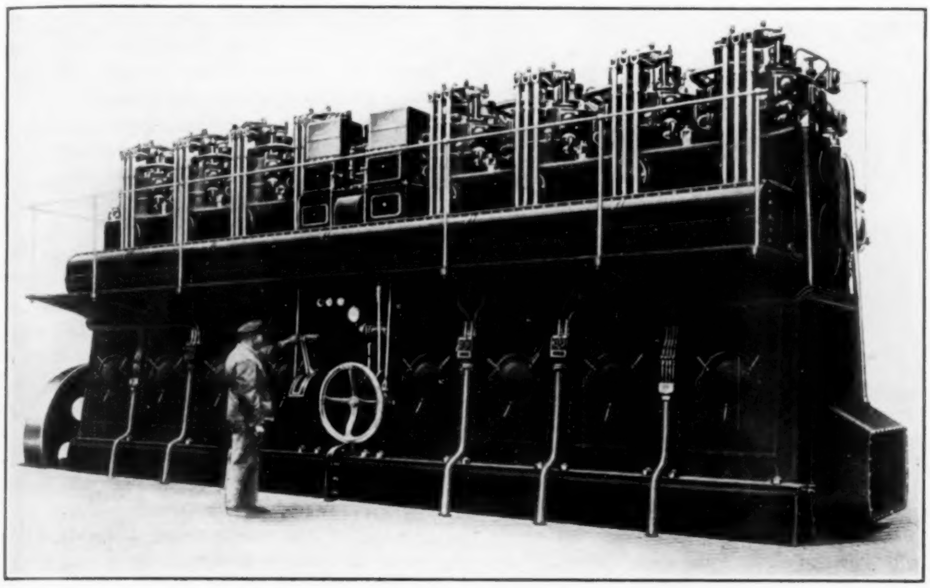

FIG. 4 DEUTZ 1200-HP. SOLID-INJECTION DIESEL ENGINE

Another shop which is producing large oil engines on an extensive scale is that of the A.E.G. at Berlin.

Space limits the mention of many other important plants such as Mitsubishi in Japan, Tosi in Italy, and the State Engineering Works in Moscow.

The greatest expansion of the industry has been in marine propulsion with such concerns as Harland & Wolff and Doxford in England, as well as several of those already mentioned, taking a leading position. According to the English *Motor Ship* of May, 1928, on April 1 of this year there was 1,333,875 i.hp. of marine Diesel engines building. This is about 100,000 i.hp. more than at the end of 1927. For over a year now both gross tonnage and horsepower of motorships under construction have continuously exceeded the total of reciprocating and turbine steamships combined.

It has been my good fortune to be intimately associated with this engineering and manufacturing international liaison work during the last ten years and I assure you it is sincere, earnest, and constructive. The generous responses of our foreign friends with data for this address is a concrete evidence of it.

Dr. Diesel was an outstanding example of the practicability of international cooperation. He consulted freely and frankly with the engineers of the many licensees in Germany, England, Belgium, and elsewhere and saw all their improvements without abusing their confidence or divulging their secrets, always helping all of them to advance the art.

## GROWTH OF THE INDUSTRY

In the quarter of a century since the Diesel engine became commerical a great industry has sprung up. One of the largest oil-engine works is Burmeister & Wain's at Copenhagen, employing 8000 men. Their developments have been chiefly in the marine field. There are one million horsepower of their engines afloat and over half a million building. They have engined nearly 300 ships of over 2000 gross tons, all with 4-cycle engines.

The M.A.N. works at Augsburg also employ a large number of men and have produced engines of 15,000 b.hp. on a single shaft.

The Sulzer Works, at Winterthur, Switzerland, with their licensees have built more than two and a half million horsepower of Diesel engines for stationary plants, for more than 300 ships, and for locomotives and railcars. Sulzer Bros. employ 4100 men and during 1927 they received orders for about 230,000 i.hp. to which should be added about 160,000 i.hp. ordered from licensees, making a total of 390,000 i.hp. of Sulzer engines sold last year. Their erecting shop is a busy place.

A typical smaller plant is the Carels Works at Ghent, Belgium, where slightly more than 1200 men are employed on Diesel-engine production. Mass production methods are employed on large parts.

## AIRLESS FUEL INJECTION

This brings us to the consideration of types and special features. We shall first consider the solid-injection or, as it is called

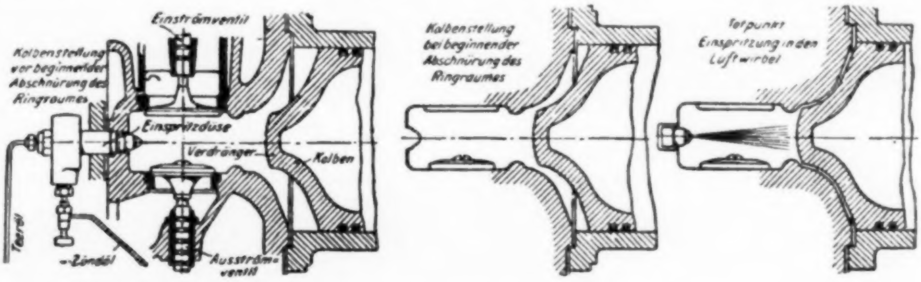

FIG. 5 PRECOMBUSTION CHAMBER OF DEUTZ DIESEL ENGINE

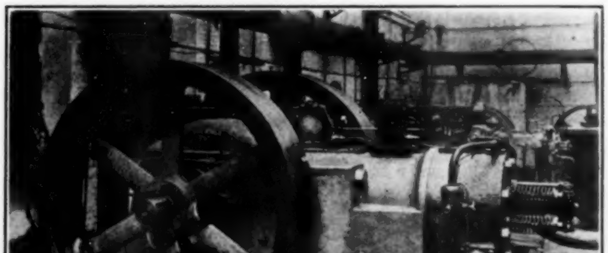

FIG. 6 DIESEL ENGINE OF INGERSOLL-RAND DESIGN BUILT BY CARELS

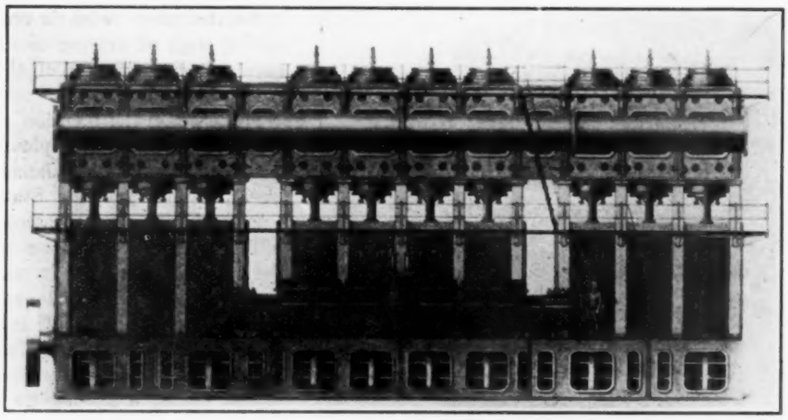

FIG. 7 A.E.G.-HESSELMAN DOUBLE-ACTING TWO-STROKE-CYCLE ENGINE, 1500 B.HP. AT 120 R.P.M.

abroad, airless-injection, and in England, cold-starting type.

The airless-injection type is an outcome of the desire to improve the performance of the hot-bulb type and at the same time avoid the complications of the air-injection type. It is practically a development of the last five years and seems to have been initiated in England, although so many engineers were working on the problem in several countries directly after the War that it is perhaps unfair to give any one group especial credit. It was well established in engines up to about 750 b.hp. some four years ago and is now employed in engines up to 11,700 b.hp. and proposed for some up to 15,000 b.hp.

M.A.N. have built airless-injection engines in a wide range of sizes. Fig. 2 shows one of their 6-cylinder, 4-stroke-cycle engines developing 1575 b.hp. at 187 r.p.m.

Another German manufacturer, Krupp at Essen, has built solid-injection engines. Fig. 3 shows a 6-cylinder, 700-hp., 4-stroke-cycle, 275-r.p.m. engine of their manufacture.

Fig. 4 shows a typical solid-injection 1200-hp. engine built by Deutz of Cologne, Germany. Deutz were one of the first to employ solid injection and in their early horizontal engines introduced a precombustion chamber as shown in Fig. 5.

The cylinder space is practically closed when the conical piston head reaches the annular neck in the cylinder cover, leaving the small precombustion chamber between the inlet and exhaust valves as the space into which the fuel is injected. It is interesting to note from the left end of the diagram that this type of engine is applicable to the use of tar oil (teeröl), with light oil (zündöl) for starting and partial-load service. A similar injection-pump arrangement for mixing heavy and light oils at the point of injection is employed by Carels, Sulzer, and others to permit using the cheap, bad, heavy oils, such as Panuco crude, and Bunker "C," in large engines.

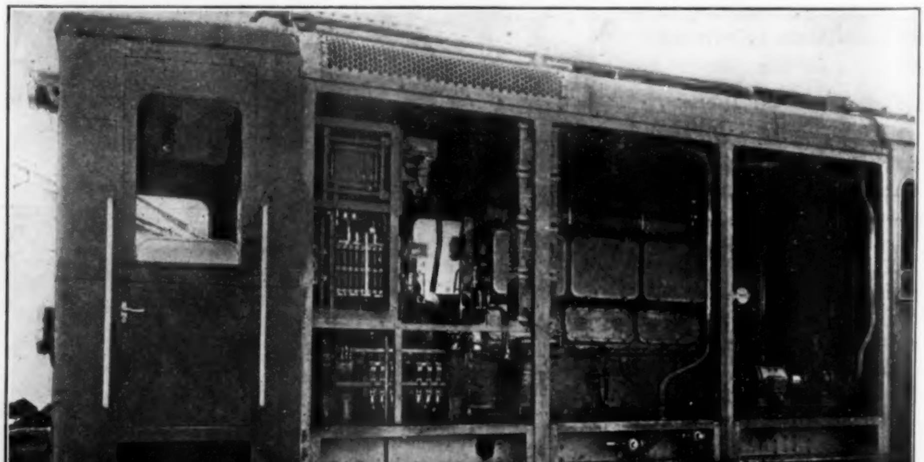

FIG. 9 ENGINE ROOM OF RAILCAR FITTED WITH A FIAT DIESEL ENGINE

Deutz subsequently developed the semi-spherical hollowed-out piston head and abandoned the precombustion chamber for their larger vertical solid-injection engines, of which they have built approximately 50,000 hp. in sizes up to 1350 hp. in 8 cylinders at 190 r.p.m. For their automotive type of engine, which will be referred to later, they have reverted to the precombustion chamber design.

As an example of international cooperation, Fig. 6 shows a single-cylinder horizontal engine being produced on a large scale in Belgium. It is a Chinese copy of the Ingersoll-Rand Company's Price engines designed and built in the United States.

In Europe and in many neutral markets the cost of gasoline is so much more than that of Diesel oil or gas oil, as it is frequently called, that small contractors' engines are solid-injection oil engines, although they may be very small.

Extensive use is made of the medium-size airless-injection engines for auxiliaries on ships and in power plants.

Fig. 7, which is a design for a 15,000 b.hp. double-acting, two-stroke-cycle, A.E.G.-Hesselman airless-injection engine, shows

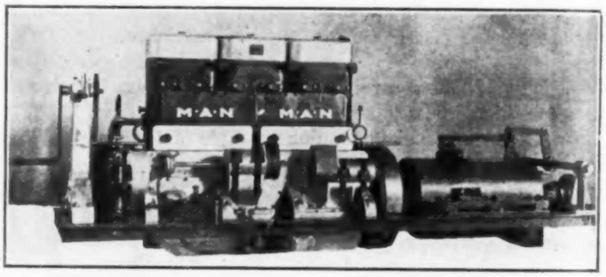

FIG. 8 M.A.N. AUTOMOTIVE ENGINE, 60 B.HP. AT 900 R.P.M.

to what sizes the solid-injection system is being applied. The M.A.N. are now building some 11,700-b.hp. engines of the solid-injection type.

The large Still engines of England, to which I shall refer later, also employ this type of fuel injection.

FIG. 10 RAILCAR OF THE SWISS FEDERAL RAILWAYS, WITH SULZER 300-B.HP., 4-CYCLE DIESEL ENGINE

## AUTOMOTIVE APPLICATIONS

While airless injection has been extended to these very large sizes, the automotive type of engine has been developed. The M.A.N. development, now utilized by Buda in this country, is fairly familiar. Fig. 8 shows one of the German-built 60-b.hp., 900-r.p.m. egines. In England and on the Continent, Diesel engines are already used for automotive work, including trucks, tractors, railcars, and locomotives.

Fig. 9 shows the power plant of a railcar recently tested on the Italian State Railways. The engine is built by Fiat in Italy

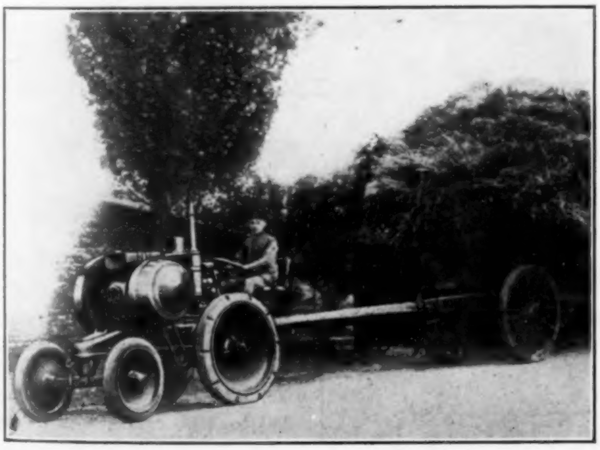

FIG. 11 DEUTZ ROAD TRACTOR

and is rated at 200 b.hp. Electric drive with direct-connected generator and ordinary traction motors is employed. Fiat also makes an engine with a normal rating of 150 b.hp., 170 b.hp. maximum, at 1200 r.p.m., which weighs with flywheel but without bedplate for supporting engine and generator only about 26 lb. per b.hp. normal rating.

Fig. 10 shows a railcar on the Swiss Federal Railways with a Sulzer airless-injection engine, rated at 300 b.hp. at 550 r.p.m. The power plant is in the center of the car and electric drive is used. The engine, with bedplate and accessories, such as fuel tank and cooling fan, weighs about 44 lb. per b.hp. Electric starting is also employed for this engine. This car has two bogie trucks, each with one motor axle and one driving axle. The length over buffers is 66 ft. 7 in. and between center pins, 44 ft. The drawbar pull at starting is 10,120 lb. and the maximum speed $37^{1}/_{2}$ m.p.h. The shop tests of the engine with fuel oil of 18,000 b.t.u. per lb. showed full-load consumption of 0.418 lb. per b.hp-hr. The trials were in February, 1928, over a 92-mile run with a trailer weighing 18 tons. The total train weight was 75 metric tons and the fuel consumption 0.0235 lb. per ton-mile.

Sulzer are now building Diesel locomotive power plants with this type of electric transmission up to 2500 hp.

Deutz, at Cologne, have brought out several models of automotive machines, all with solid-injection oil engines, such as tractors and locomotives, all with mechanical drive. Fig. 11 shows the road tractor in service and replacing horses.

Figs. 12 and 13 show the Deutz automobile Diesel engine which is said to use any fuel offered on the market. The small cylinders of this engine have precombustion chambers to aid in the burning of heavy oils as previously described. The cylinders are

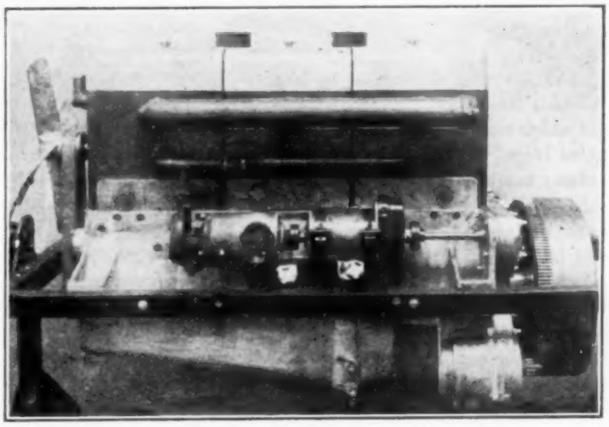

FIG. 12 DEUTZ AUTOMOBILE DIESEL ENGINE

cast in blocks of two. The 4-cylinder automobile model develops 40 hp. and weighs 39.6 lb. per hp. The 6-cylinder engine develops 60 hp. and weighs 34.5 lb. per hp. Both run at 1000 r.p.m.

Another railroad application was described in *Oil Engine Power* for April, 1928. This is a locomotive with a 250-b.hp. engine built by the Cie de Construction Mécanique Procédés

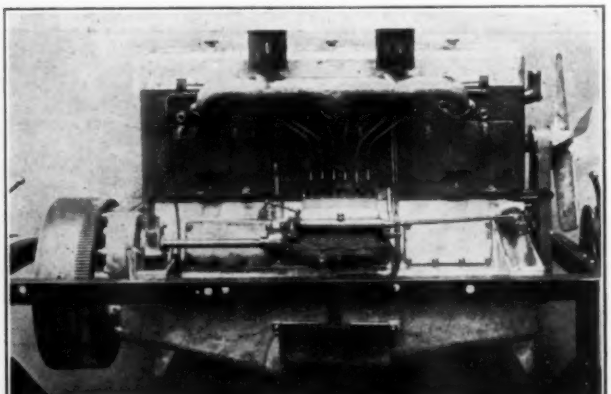

FIG. 13 DEUTZ AUTOMOBILE DIESEL ENGINE

Sulzer, Paris, with electric drive. This locomotive with about 80 tons trailing showed a gas-oil fuel consumption of from 0.024 to 0.043 lb. per ton-mile of total train weight according to grades,

loads, speed, and road conditions on the various divisions of the Tunisian Railways on which the train has been used.

The same issue of *Oil Engine Power* describes a new Junker's two-cylinder opposed-piston 45/65-b.hp., 1000/1500-r.p.m. automotive engine. This engine without flywheel weighs only 610 lb. or 13.6 lb. per b.hp. at the 45-hp. rating and only 9.5 lb. at the 65-hp. rating.

An interesting English development is the 500-b.hp. oil-electric train for the London, Midland and Scottish Railway of England, developed by William Beardmore & Co., Ltd., and the English Electric Co., Ltd.

The train, consisting of motor coach and three trail cars, accommodates 32 first-class and 255 third-class passengers. Empty, the train weighs 144 long tons. This means about 165 tons including passengers and baggage. The engine has eight $8^1/_2 \times 12$-in. cylinders and develops 500 b.hp. at 900 r.p.m. It weighs $14^1/_2$ lb. per b.hp. There is double-end control so that the driver can regulate the engine speed as well as manipulate the electrical controls from either end of the train. This train made its trial runs recently between Blackpool and Manchester and has been put into service on a short run out of Blackpool.

Diesel-electric railcars have been in regular service on the Swedish Railways since September, 1913. Half a dozen are in use which were started before the end of 1917. The Aktiebolaget Atlas Diesel of Stockholm have supplied about 50 oil engines for railway traction service, the majority with electric drive made by the A.S.E.A. (Swedish General Electric Co.). These engines range in size from 4-cylinder, 60 b.hp. at 600 r.p.m. to 12-cylinder, 300 b.hp. at 550 r.p.m. and are all of the 4-stroke-cycle air-injection type. Fig. 14 shows the 300-b.hp. engine and Fig. 15 the 150-b.hp. 6-cylinder engine installed in a Diesel-electric car.

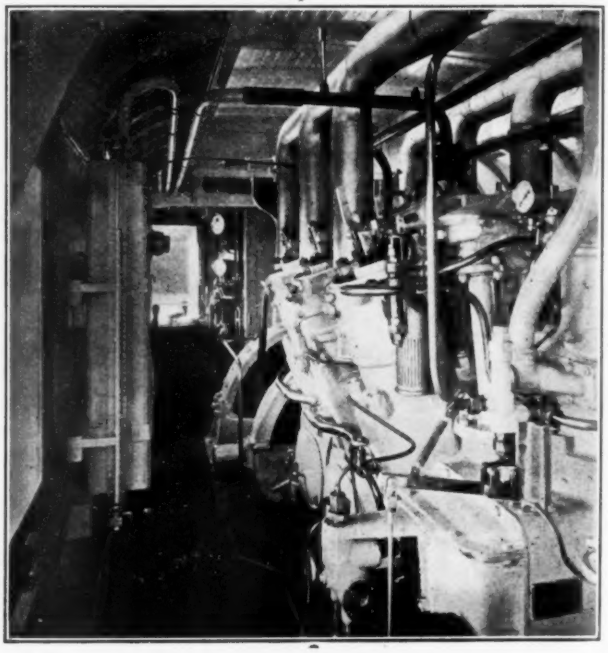

Fig. 15 150-Hp. 6-Cylinder Diesel Engine Installed in Railcars

While the engines just shown are all of the air-injection type, the Swedish Atlas have recently developed and sold several solid-injection engines for rail service. The new type is also 4-stroke cycle and so far is being made in four ratings, 4-, 6-, and 8-cylinder, 80, 120, and 160 b.hp. at 875 r.p.m. and 6-cylinder 250 b.hp. at 550 r.p.m. Krupp at Essen have developed a 100-hp. 1000-r.p.m. automotive engine weighing 1500 lb. as shown in Fig. 16, weighing 15 lb. per hp.

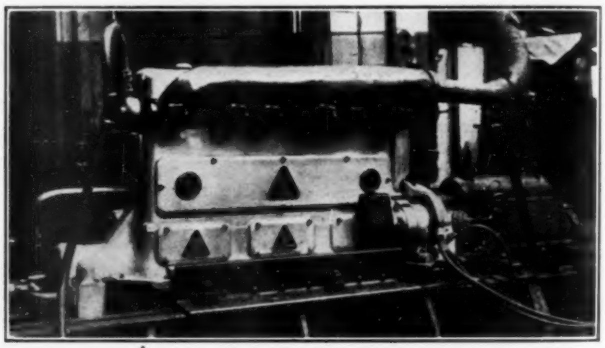

Fig. 16 Krupp 100-Hp. 1000-R.p.m. Automotive Engine Weighing 1500 Lb.

The illustrations of automotive engines, which have been mentioned were built by leading manufactures in five countries with a range of weight of from 9.5 lb. per b.hp. net for the engine alone to 44 lb. per b.hp. including some auxiliaries, with from 15 to 30 lb. for engine with normal equipment, predominating. The range of sizes is from 40 to 500 b.hp. and of speeds from 550 to 1500 r.p.m. with about 1000 r.p.m. predominating. There are several other makes, say at least a dozen outside the United States. It is therefore reasonable to say that the automotive, airless-injection Diesel engine in sizes up to 500 b.hp. weighing not over 30 lb. per b.hp. with a speed of about 1000 r.p.m. has arrived and that we can anticipate that reliable engines of half that weight at 1200 to 1500 r.p.m. will very soon be available from several manufacturers in five or six countries besides the United States.

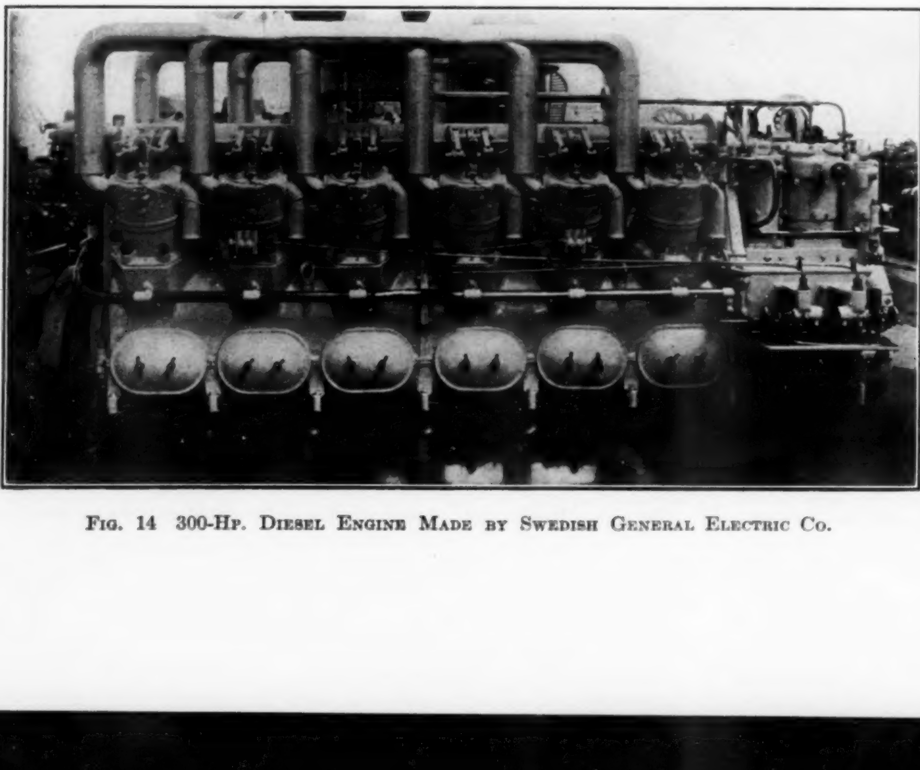

Fig. 14 300-Hp. Diesel Engine Made by Swedish General Electric Co.

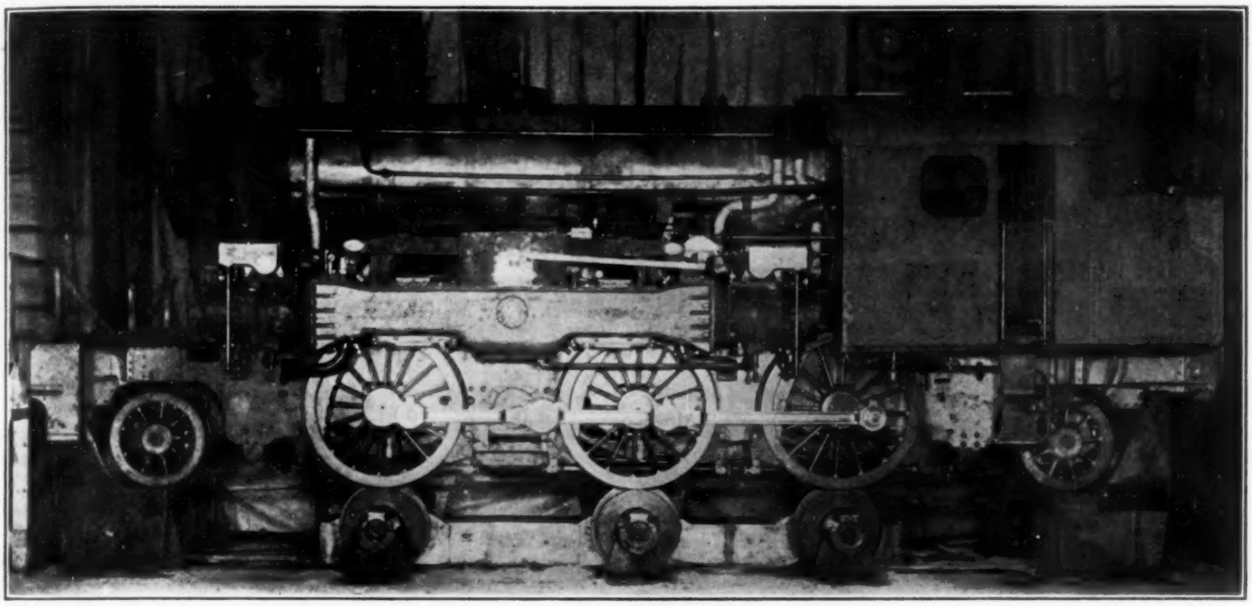

Fig. 17 Kitson-Still Oil-Steam Locomotive

With engines weighing 15 lb. per b.hp. at a speed of 1200 to 1500 r.p.m. the electric-drive Diesel locomotive and railcar have a very large field all over the world as the relation of weight of power plant to its supporting structure and to the weight of trailing load will permit the horsepower per ton required for efficient railway service.

An interesting development has been the Still engine in England. Fig. 17 shows the new Kitson-Still oil-steam locomotive, direct-coupled, with gear side-rod combination drive built by Kitson & Co., Ltd., Leeds. This locomotive weighs 85 long tons with $19^1/_2$ tons on each of three driving axles. The engine has 8 cylinders $13^1/_2 \times 15^1/_2$ in. and operates on the 4-stroke cycle at 450 r.p.m. At 45 m.p.h. the drawbar pull is 7000 lb. During the last four months it has made several trial runs with as much as 118 tons trailing over a 31-mile triangular loop.

All of the automotive engines referred to, including the Still and the new Atlas design, employ airless injection. While the methods and pressures employed in injecting, atomizing, and controlling the charge when air injection is employed are pretty well standardized, the pressures, method of control, and arrangement of pumps vary widely in the solid-injection engines. Injection pressures vary from 1000 to 5000 lb. per sq. in. Some manufacturers, as, for instance, Deutz and M.A.N., use individual pumps for each cylinder but with different pressures. Ruston of England has recently changed to a single pump and a distributor, athough of a different type from that employed by the Carels-Ingersoll-Rand group. A.E.G.-Heselman use individual pumps with suction-valve control. Others use a single pump with a high-pressure manifold and control by timing the opening of the injection valves. It is too early in this development to tell which combinations will survive but more accurate timing and quick, positive cut-off of the injection oil stream combined with improved spraying action during injection of the fuel oil seem to indicate the direction in which research is tending.

The trend of foreign rail transportation development, especially for narrow gage, for lines with infrequent service, and for industrial works, certainly seems to be toward the Diesel

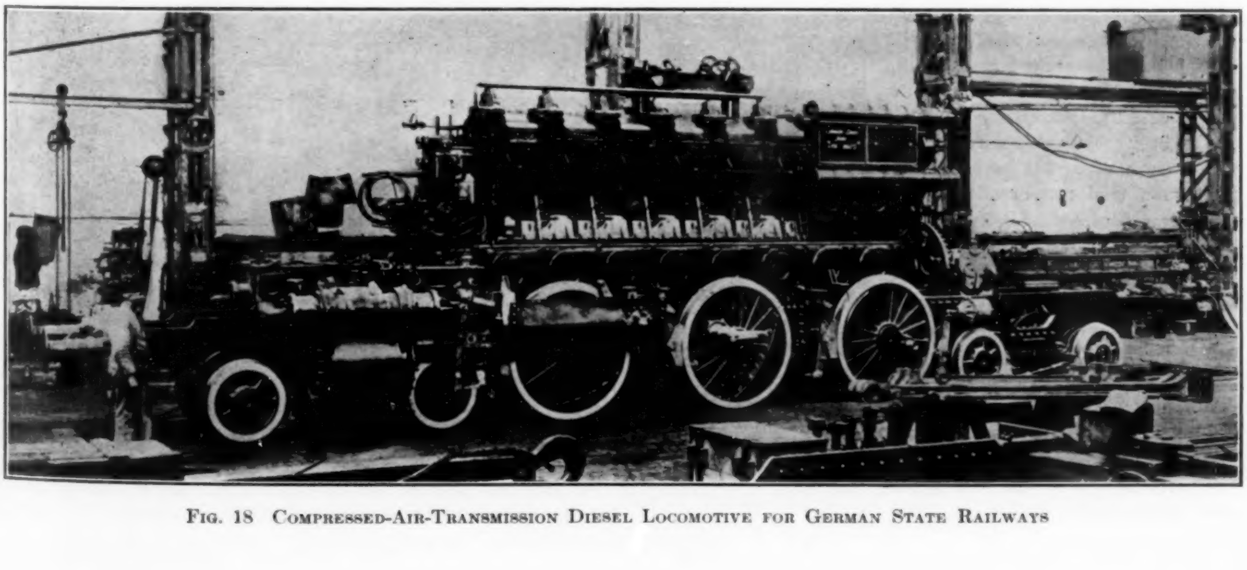

Fig. 18 Compressed-Air-Transmission Diesel Locomotive for German State Railways

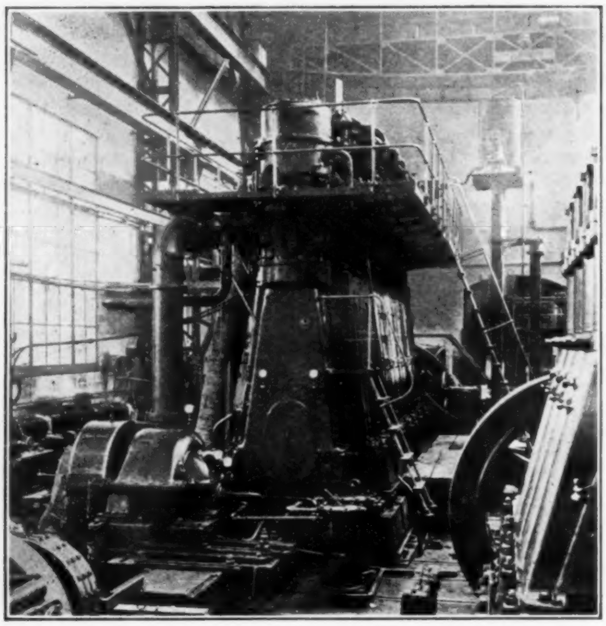

FIG. 19 DIESEL ENGINE WITH BÜCHI SUPERCHARGER DRIVEN BY EXHAUST-GAS TURBINE

motor used in railcars and locomotives with electric drive (except for very small machines).

I have not mentioned aircraft engines, for, while I understand that much research and experimentation is going on both in England and on the Continent, there is no new development about which I am at liberty to make any announcement. Nor have I referred to road transportation except by tractors. Much experimentation is going on with oil engines for trucks of various sizes and types and M.A.N. have supplied over 120 engines of the 4-cylinder type, developing 45 hp. at 1000 r.p.m. for German auto trucks. No doubt the use of heavy oil engines will be extended to road transport but many of our foreign friends, who are best informed regarding such service, especially passenger buses in cities, feel that the cleanliness of gasoline compared with gas oil or other Diesel fuel will keep oil engines out of passenger vehicles for some time to come.

It has been assumed that most readers are familiar with a few large experimental Diesel locomotives which have been built abroad and I will, therefore, only refer to two incidents of that development. Data have recently been released regarding the performance of two Diesel locomotives on a trial run of about 3200 miles from Moscow to Baku and return. Both locomotives were equiped with 6-cylinder oil engines having a maximum rating of 1100 hp. at 400 r.p.m. and a continuous rating of 800 hp. at 300 r.p.m. In one machine the engine was reversible and mechanical drive with a 3-speed gear box and magnetic clutches was employed. The other machine used electric drive. The performances of the two types were substantially the same. The speeds, which averaged about 18 m.p.h., were almost identical. The trailing load did not vary more than 5 per cent. The fuel consumption of the geared locomotive was about 5 per cent less than that of the electric-drive machine on the trip to Baku and about 10 per cent less on the return trip. It varied from about 0.013 lb. to about 0.015 lb. per ton-mile.

The German State Railways are now building a compressed-air-transmission Diesel locomotive at the Esslingen Machine Works. Fig. 18 shows the 1200-b.hp. 6-cylinder, 4-stroke-cycle, 450-r.p.m. M.A.N. engine direct connected to the compressor which furnishes air to the engine cylinders. As the locomotive is not yet completed definite data regarding its performance are not available.

## SUPERCHARGING

Like the evolution from air injection to solid injection, that from inhaling the fresh charge to forcing it in at above atmospheric pressure has resulted from the efforts of many engineers and much research in both Europe and America. As soon as the two-cycle engine with a scavenging pump appeared, and air in excess of the cylinder volume was forced through the cylinder and into the exhaust, the essential features of supercharging were created.

I will not attempt to trace the history of supercharging research and development beyond stating that Dr. Büchi and others have been working at it for about twenty-five years and that it attracted attention in connection with high-altitude flying over ten years ago and began to be generally studied about five years ago. An important European accomplishment is that of Dr. Alfred Büchi, of Winterthur, Switzerland. After several years of research, the Büchi syndicate has been formed and that system is now being used by Deutz in Germany, Werkspoor in Holland, Tosi in Italy, and the Swiss Locomotive & Machine Works in Switzerland, under long-term license agreements and by M.A.N., Harland and Wolff, and others for specific jobs. Up to January 1 of this year 37 engines had been built or were building employing this system. With the exception of five engines ranging from 450 to 750 hp. these are all of from 1200 to 4000 hp. and are for direct-drive ship propulsion and stationary-power-plant service.

Prof. A. Stodola, of the Swiss University of Engineering Science, at Zurich, has recently prepared a report on exhaustive

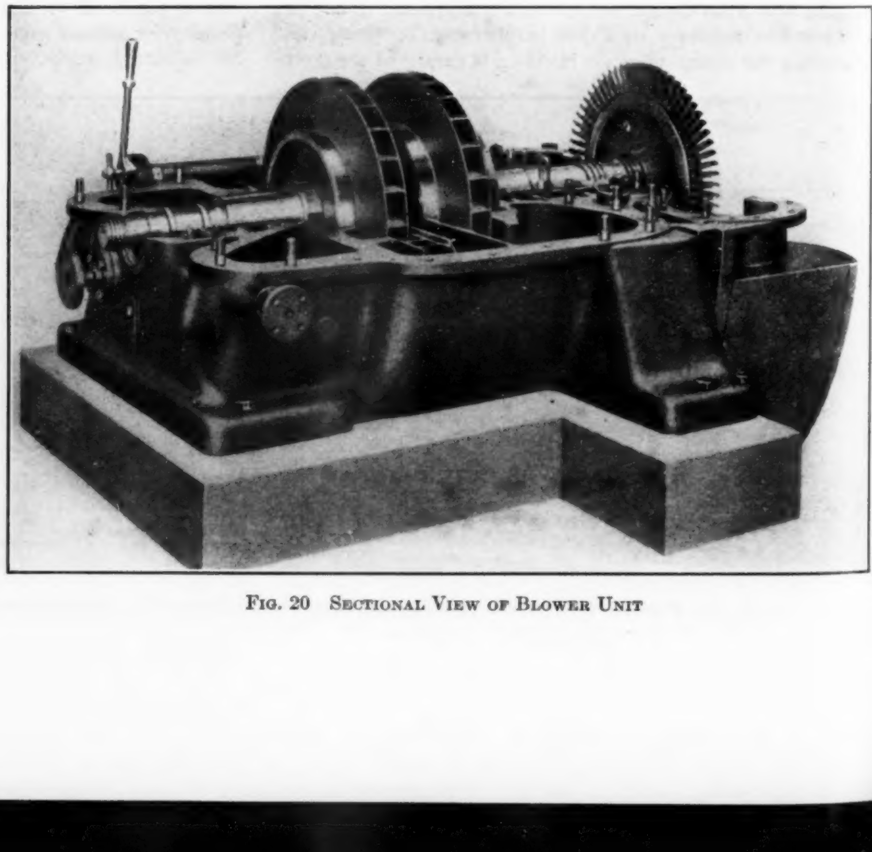

FIG. 20 SECTIONAL VIEW OF BLOWER UNIT

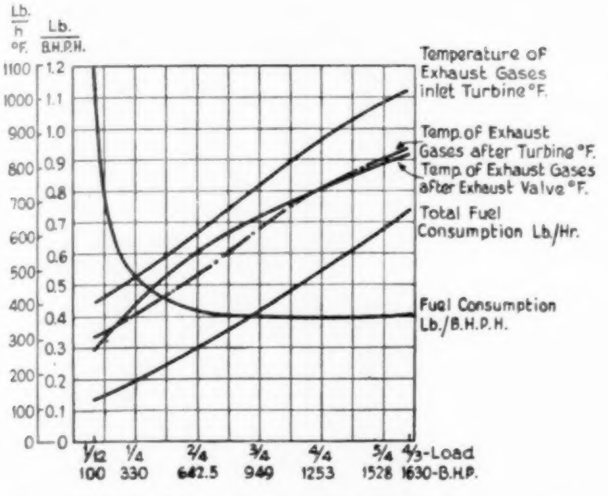

FIG. 21 FUEL CONSUMPTION AND EXHAUST TEMPERATURES, SUPERCHARGED ENGINE

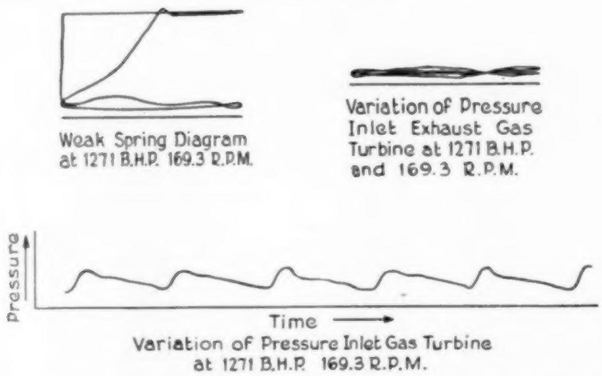

FIG. 22 EXHAUST PRESSURES, SUPERCHARGED ENGINE WITH EXHAUST-GAS TURBINE BLOWER

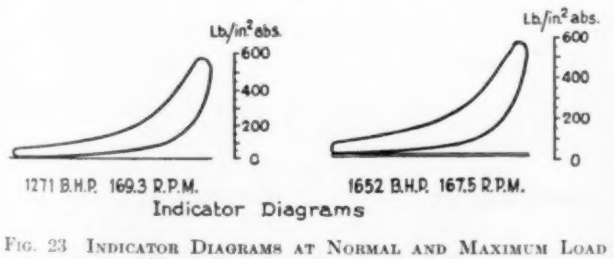

FIG. 23 INDICATOR DIAGRAMS AT NORMAL AND MAXIMUM LOAD WHEN OPERATING SUPERCHARGED

tests of a 6-cylinder, 4-stroke-cycle, 850-b.hp. engine built by the Swiss Locomotive & Machine Works and equipped with an exhaust-gas turbo-blower built by Brown-Boveri & Company of Baden, by means of which the engine has a rating of 1275 b.hp. supercharged and was tested up to 1652-b.hp. maximum load. This report has only very recently reached this country and while it has been translated into English, I will not attempt to give a résumé of it, but will call attention to a few outstanding features of the Büchi supercharging system.

Fig. 19 shows the engine at the Winterthur Works. The exhaust-gas turbo-blower can be seen at the left of the picture by the end of the engine.

Fig. 20 is a sectional view of the blower unit. At the right is the impeller of the turbine and at the left the two blower wheels. The diffusion vanes of the second impeller are adjustable. In order to prevent the exhaust of one cylinder from interfering with the scavenging of another, independent exhaust pipes are provided for this 6-cylinder engine. These lead directly to turbine nozzles so that the exhaust gases mix only after they have passed through the turbine.

Fig. 21 shows the fuel consumption and exhaust temperatures when the engine is operating supercharged. Fig. 22 gives some indication of the exhaust pressures, and Fig. 23 shows indicator diagrams at normal and maximum load when operating supercharged.

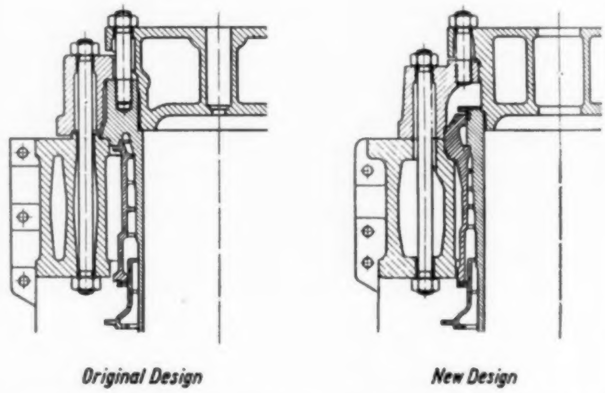

Fig. 30 Cylinder Cover, Liner, and Cooling-Water Jacket, A.E.G.-Hesselman Diesel Engine

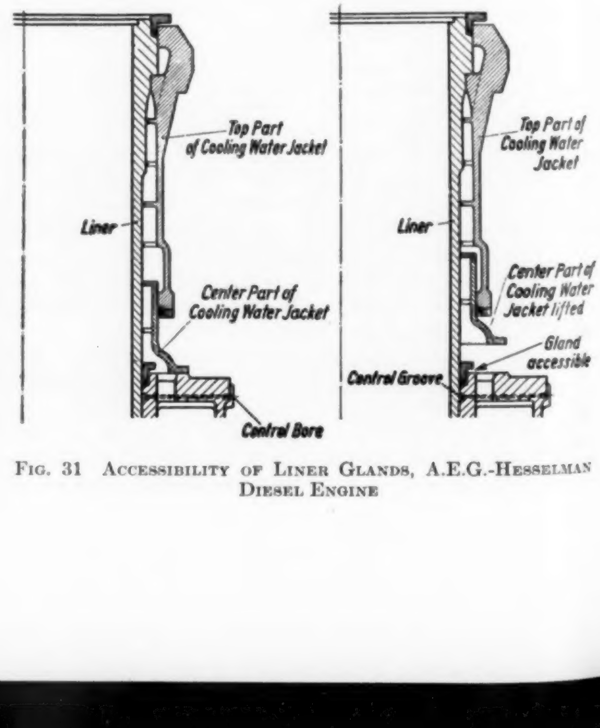

Fig. 31 Accessibility of Liner Glands, A.E.G.-Hesselman Diesel Engine

In summing up the results of his tests, Prof. Stodola said:

1 The Büchi turbo charging system increases the normal output of an ordinary 4-cycle engine by 50 per cent, the maximum output by 100 per cent.

2 The temperatures of the combustion and of the exhaust gases are the same or even lower than with ordinary Diesel engines.

3 The fuel consumption per brake horsepower-hour is lower and less heat is carried away in the cooling water; the absolute amount of the latter is 42,500 B.t.u. per hr. and sq. ft. of the piston areas, a very small amount for this size of engine.

Sulzer Bros. have long employed a system of supercharging their standard 2-cycle engines and, in fact, it was while he was their chief engineer that Dr. Büchi did much of his supercharger experimentation. Sulzer Bros. recommend the use of supercharging only at above three-quarter load.

The curves of Fig. 24 show the performance of an engine rated at 1500 b.hp. without supercharging and 1800 b.hp. with supercharging. According to these data, supercharging increases the continuous full load by about 20 per cent and peak load by another 20 per cent so that the maximum output of the engine supercharged is about 1.44 times the normal continuous load without supercharging.

Supercharging is also being applied by other manufacturers to marine, stationary, and automotive engines.

### Double-Acting Engines

While the opposed-piston type of Diesel, as exploited by Junkers, Doxford, Fullagar, etc.,

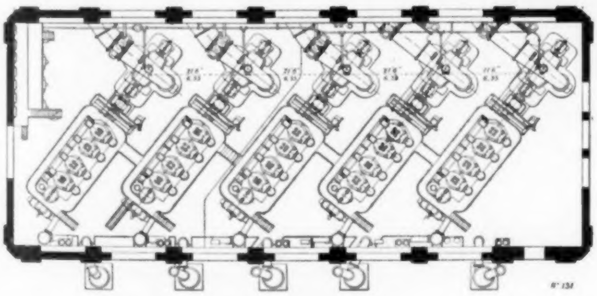

Fig. 32 Arrangement of Five 1000-B.Hp. Carels Engines Direct-Connected to Worthington Pumps at Gladstone Dock, Liverpool

originated about 1900 and was commercial before 1914, I do not know of any double-acting commercial engine until during the last few years. A design involving two pistons and no cylinder covers was easier to accomplish than one piston and two cylinder covers.

One of the first large double-acting engines was the product of the combination of Werskpoor of Holland and the North Eastern Marine Engineering Co., of Wallsend on Tyne. It was a four-stroke-cycle machine, with a single cylinder 800 × 1400 mm. ($31^1/_2$ × 55 in.) and developed 750 hp. at 95 r.p.m. It was tested early in 1924.

Burmeister & Wain are perhaps the outstanding exponents of four-stroke-cycle, double-acting Diesel engines. Their engines of this type are so large, so numerous, and so well known that I will not describe them. Both of these designs are being built by many manufacturers.

The first successful European two-cycle double-acting engine I saw was the single-cylinder M.A.N. machine at Augsburg in November, 1924. As a result of its success, the largest Diesel in the world was built from M.A.N. designs by Blohm & Voss at Hamburg. This engine[3] is in the Electricity Works at Hamburg, and is rated at 15,000 b.hp.

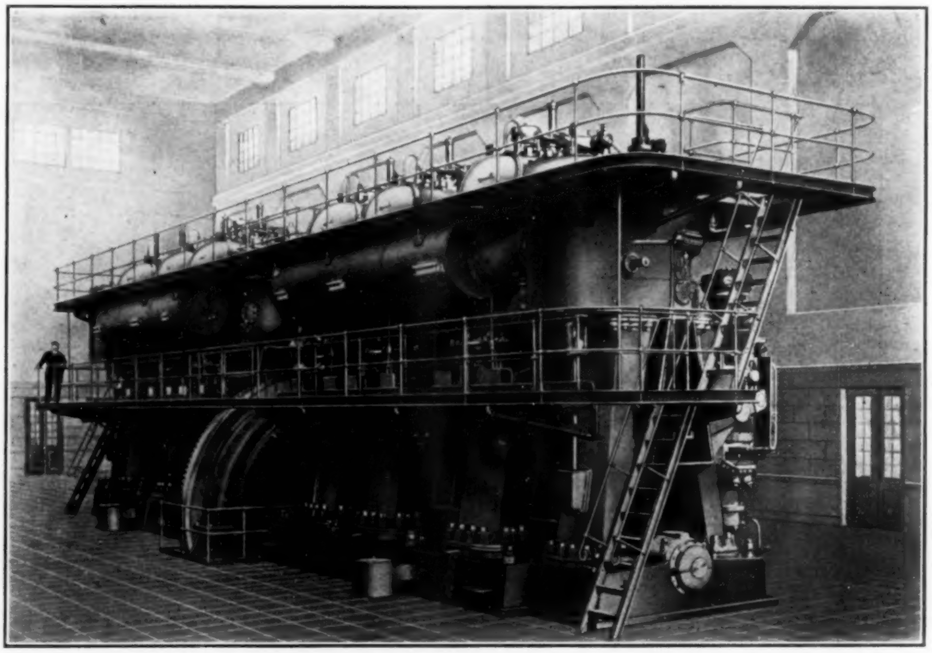

Fig. 33 3000-B.Hp. Carels Engine Now Being Installed at Guayaquil, Ecuador

Dr. Bannwart, director of the Hamburg Electric Power System, recently said of this unit:

Since the set was put in service early in September, 1926, we have not experienced the least trouble, as the motor runs very well and has proved its value as a stand-by in emergencies for a couple of times already. The set is operated for about six to eight hours daily, according to the season. During the months of December and January, the set is operated for two to three hours in the morning and four to six hours in the evening. During these periods the motor carries its full load, i.e., 10,500 kw., and the load is decreased in steps of about 15 min. until the steam plant carries the whole load again and the motor is shut down.

During the normal operating cycle when the engineers are ready for the signal for starting the motor, it takes about four minutes until the generator is connected to the line. The starting of the motor itself takes about three minutes. It has happened a couple of times already that the motor had to be started because of an emergency call from the steam station Tiefstack. Such emergency cases were due to boiler trouble or to sudden fogs which increased the lighting load. In these emergency cases when the engineers are not prepared for the starting, it takes not more than six minutes until the generator is connected to the line.

About three years ago, Krupp built a single-cylinder, double-acting trial engine which developed 1300-b.hp. at 84 r.p.m. It is shown in Fig. 25.

In 1926–27, Sulzer, at Winterthur, built a single-cylinder,

[3] A picture of this engine may be found in the paper by Edward B. Pollister, "The Economic Field for Large Diesel Engines," Fig. 3. See Trans. A.S.M.E., vol. 50, paper No. OGP–50–11.

double-acting experimental engine[4] with a 900-mm. bore and 1400-mm. stroke which developed 2400-b.hp. at 110 r.p.m. Its mechnical efficiency was 70 per cent. This engine has been running over a year most satisfactorily. It has, I believe, the largest capacity per cylinder of any Diesel so far produced. It has a direct-connected two-cylinder scavenging pump and a three-stage injection air compressor.

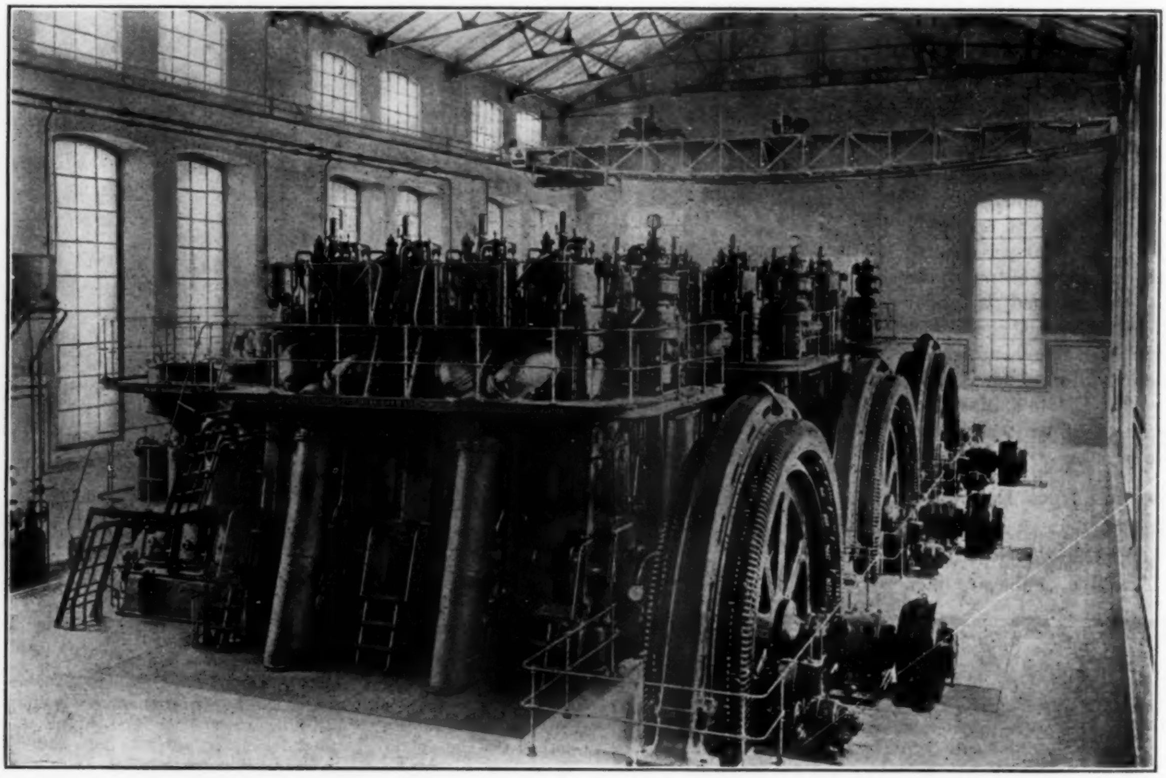
A.E.G. in Berlin were working on this problem at the same time and in 1926 produced a 1000-b.hp. single-cylinder A.E.G.-Hesselman engine. Its dimensions are 680 mm. by 1200 mm. and it runs at 120 r.p.m. In developing this engine, spray penetration and other airless-injection problems were studied, full credit being given to Miller, Beardsley, and others who have been working in this country. As this was the first very large solid-injection engine, a few details will be shown.

and will employ airless injection. At the same time they are building a 7-cylinder engine of the same bore and stroke and 5600 b.hp. at 164 r.p.m. for the Anglo-Chilean Consolidated Nitrate Corp., which will use air injection.

This makes one wonder how long the injection air compressor will survive even on the largest engines.

The large double-acting engines are being built with both direct-connected reciprocating scavenging air pumps and with electric-motor-driven turbo-blowers. It is too early in this development to predict the field in which each type will survive.

It is also too soon to make definite statements regarding the net fuel consumption. Very few data have been released as to the net fuel consumption of these large two-cycle, double-acting engines. That which is available indicates, however, that, after deducting the power required for the scavenging pumps, the fuel consumed at from three-quarter to full load is of the order of 0.39 to 0.4 lb. per b.hp-hr. under the best operating conditions.



[Fig. 34 Diesel-Engine Power Station, Metropolitan Underground Railway, Madrid, Spain

Fig. 26 is a view of the top combustion chamber and the top of the piston, and Fig. 27 the arrangement of the oil spray both top and bottom. Other details are shown in Figs. 28 to 31.

In 1927, Carels in Belgium started to build a 4000-hp. double-acting engine of the type supplied the U. S. Shipping Board by Worthington in this country.

Both Burmeister & Wain and Werkspoor use air injection in their 4-cycle engines. Of the five 2-cycle makes mentioned all but A.E.G. started with air injection. Recently Sulzer have secured favorable results with solid injection in their experimental engine and M.A.N. now have on the test floor at Augsburg two double-acting, 2-cycle engines sold to the Henningsdorf electric power plant, Berlin. Each of these develops 11,700 b.hp. in 10 cylinders, 600 mm. by 900 mm., at 215 r.p.m.

### Power Stations

Diesel engines have been used in power stations since the start of the industry and they have been direct connected to generators for about a quarter of a century. Generally speaking, up to 1918 Diesel engines were not used in power plants requiring maximum reliability and were generally not recognized as equal to steam engines for service where continuity of operation was an important factor. One exception to this was the installation at the Gladstone Dock, at Liverpool, where five Carels 1000-b.hp., 4-cylinder, 2-cycle, single-acting engines direct connected to Worthington pumps were installed in 1913. This is believed to have been the largest Diesel plant in England at that time. Fig. 32 shows the arrangement of the station.

These engines have been in continuous service and were not

[4] A picture of this engine may be found in Fig. 4 of the paper by Edward B. Pollister on "The Economic Field for Large Diesel Engines." See Trans. A.S.M.E., vol. 50, paper No. OGP-50-11.

re-conditioned until last year when an addition was made to the Dock. They are now available for another fifteen years' duty.

Another outstanding installation of long service is the Shanghai, China, power station, which, I believe, is the largest Diesel stationary power plant in existence. This has five engines totaling 20,000 b.hp. built by Sulzer Bros. of Winterthur, which at their guaranteed 20 per cent overload represent 24,000 b.hp. output.

A 5250-b.hp. Sulzer, 2-cycle, single-acting engine has been dispatched as an additional unit in the Shanghai plant.[5] The larger engines in this plant, including the new one, are of the 2-cycle type especially arranged for burning heavy fuel at all loads and this engine showed during the trials the full-load fuel consumption of 0.414 lb. per b.hp-hr. with 18,000-B.t.u. oil. Reference has already been made to the large power plant at Hamburg and Berlin.

Another important installation is that of three M.A.N. 4-cylinder, double-acting two-cycle engines developing 2250 b.hp. at 150 r.p.m. for the Metallurgical Works, Roter Oktober, at Stalingrad, Russia.

Fig. 33 shows one of a pair of 3000-b.hp., 6-cylinder, 2-cycle single-acting Carels engines now being installed in a central station at Guayaquil, Ecuador.

The first direct-connected generating units like the Liége machine had separate flywheel and generator which is the design that has been generally followed in the United States and England. The Continental development, however, has been in the direction of combining the generator rotor and the flywheel to save space and weight. The station of the Metropolitan Underground, at Madrid, with three 1500/1800-b.hp. Sulzer engines in it, illustrates the flywheel type. See Fig. 34.

The generator of the 15,000-hp. engine at Hamburg is of the normal type because of the uniform torque effort of nine double-acting, 2-cycle cylinders, and there is a strong feeling that as the number of cylinders and rotating speed increase, as typified by the two 11,700-hp. Henningsdorf engines of 10 cylinders, 215 r.p.m., the flywheel problem will become as simple as it was with high-speed reciprocating steam engines.

The power plants of the character which I am describing have represented a quality of installation equal to that of the very finest steam and hydraulic plants and the quality of the

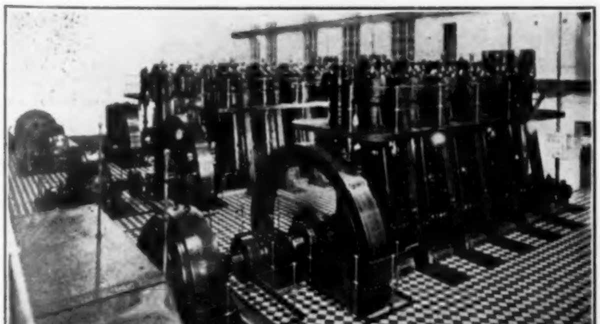


Fig. 35 Concordia Power Plant, Engine Room From Switch-Board Gallery. Three 780-Hp. Carels-G.E. Sets

Continental engines combined with this high-grade station design and intelligent supervision have combined to produce power plants which are fully equal to any other type as to reliability and continuity of service.

Fig. 35 is a view from the switchboard gallery of the concordia power plant, Argentina, and shows three 780-b.hp. 4-

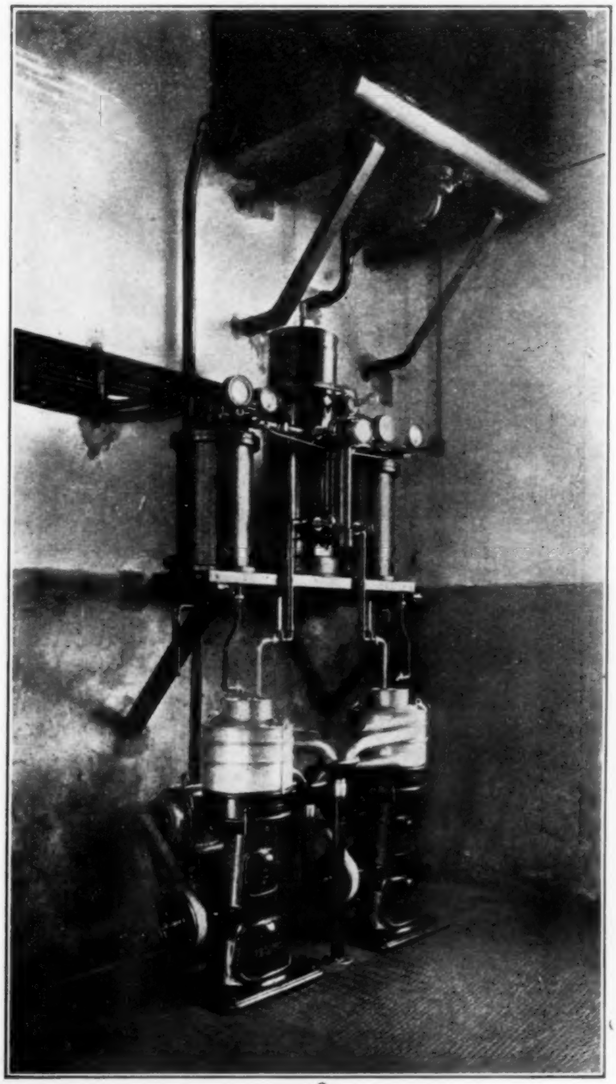

Fig. 36 Centrifugal Pumpers for Fuel Oil, Concordia Power Plant
(Note two electrical and one water heater.)

cycle Carels engines. The arrangement of the oil centrifuges is shown in Fig. 36.

### Marine Engines

The first direct reversing marine Diesel engines were, I believe, of the 2-stroke-cycle, single-acting type and were first built about 1907 by two or more manufacturers. At that early date marine engines of 1000 hp. were manufactured. In the intervening ten years, the marine Diesel has taken the leading position in ship propulsion indicated above, and according to Lloyds, Register of July 5, 1927, there were over 500 full-powered Diesel-motor steel ships of over 2000 gross tons in actual service. These include ocean-going liners as large as any except a few of the great trans-Atlantic high-speed passenger ships.

Both the 4-stroke-cycle and 2-stroke-cycle types have been developed up to the largest sizes in several countries and airless injection is now being applied by at least two Continental manufacturers and one in England to very large marine engines.

Reference has been made to the Kitson-Still locomotive engine. The original Still idea of combining an oil engine and steam engine

[5] A picture of this unit may be found in Fig. 10 of the paper by Edward B. Pollister, Trans. A.S.M.E., vol. 50, paper No. OGP-50-11.

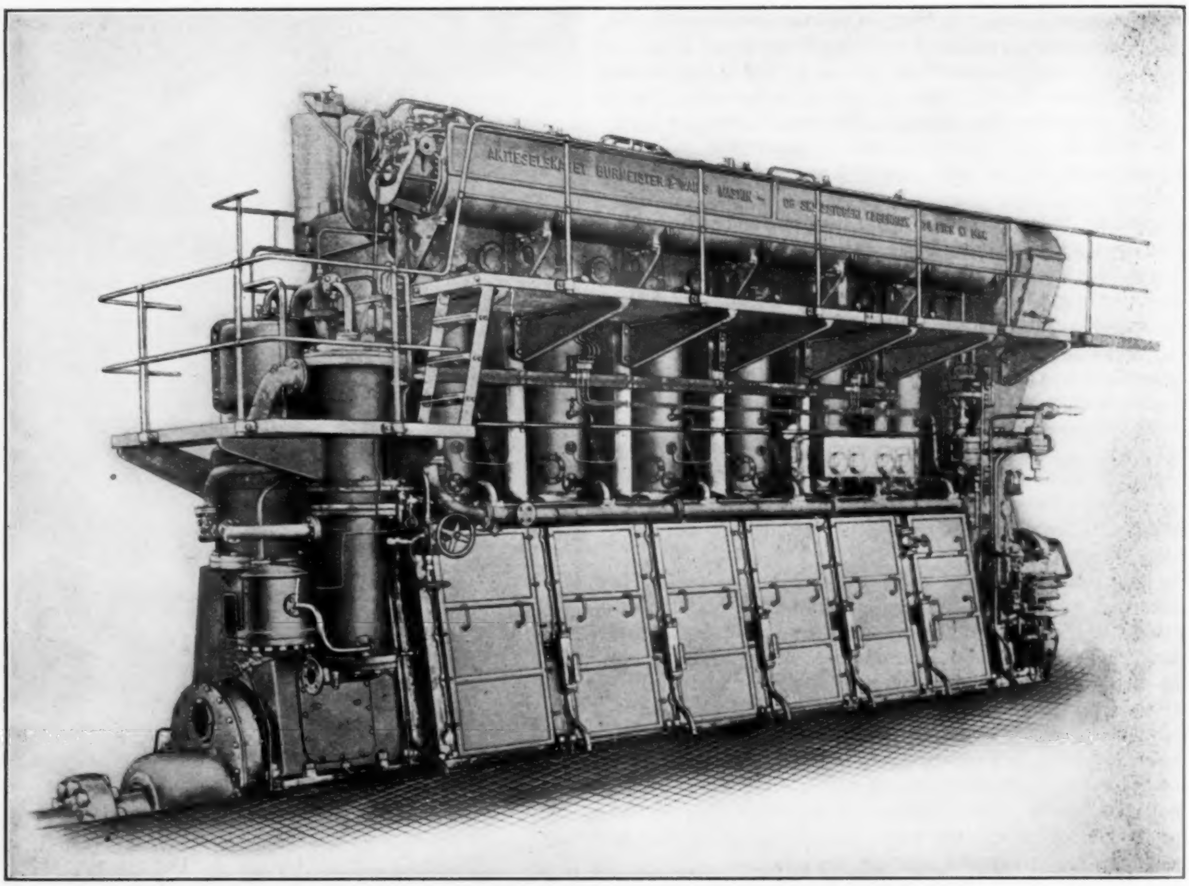

FIG. 37 ONE OF THE MAIN DIESEL ENGINES INSTALLED IN *MS. Britta*

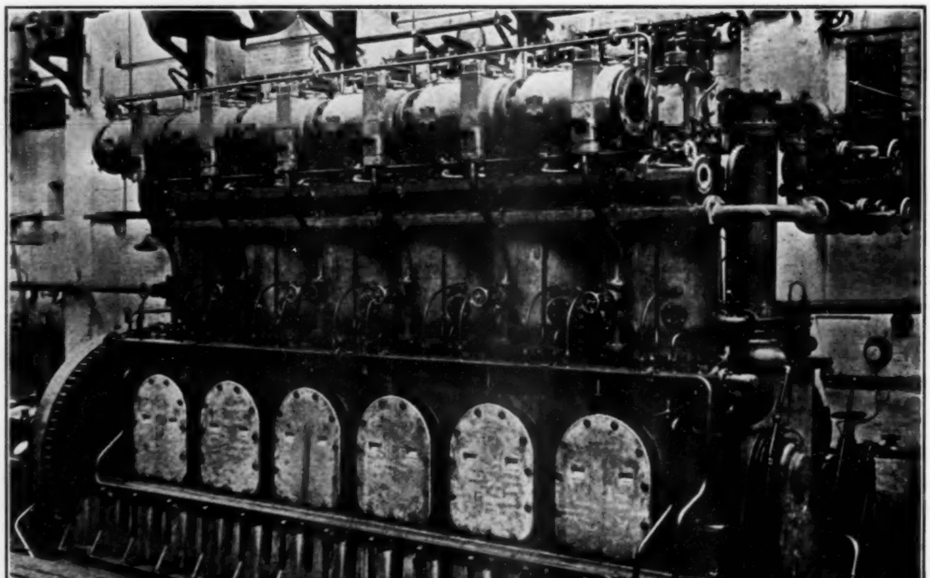

FIG. 38 DIESEL ENGINE FOR *MS. Brunswick*

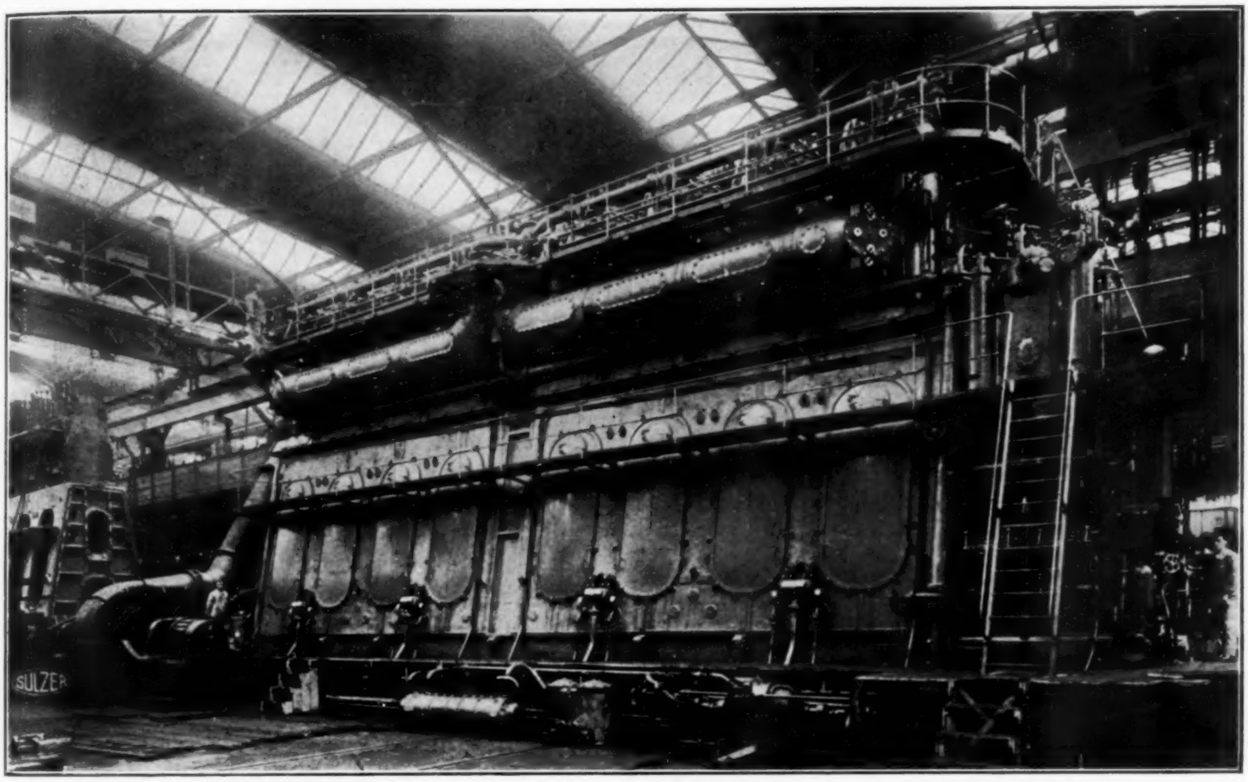

Fig. 39 8-Cylinder Sulzer Marine Engine

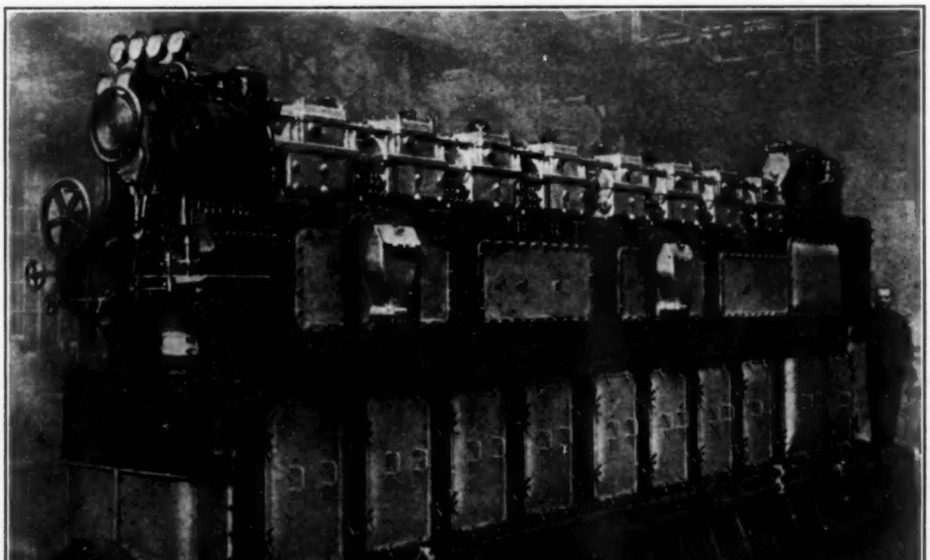

Fig. 40 Fiat Marine Diesel Engine for Submarines

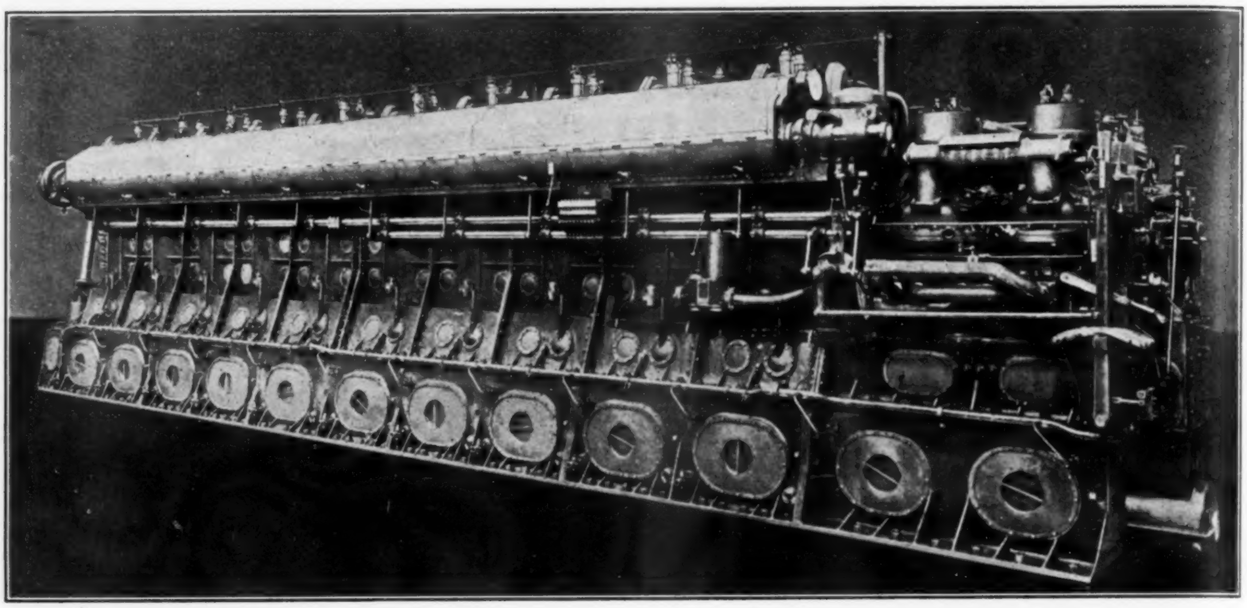

FIG. 41 M.A.N. MARINE DIESEL ENGINE FOR SUBMARINE

in the same cylinder with a single piston has been adhered to in the locomotive. It is interesting to note that in building two 2500-s.hp. Scott-Still engines for the motor vessel *Eurybates*, the Scott Shipbuilding & Engineering Co., Ltd., of Greenock, while retaining the solid-injection fuel system have separated the oil and steam cylinders. A diagram appearing in the *Engineer* of London, of March 30, 1928, shows these new engines. The oil-engine cylinders are of the normal 2-cycle, single-acting type with a few of the special Still features and a scavenging air chamber below the piston which takes the air from the turbo-blower before it enters the cylinder. The steam-engine part of the unit is designed according to standard marine steam practice.

This shows reversion to a simpler type on the part of the Still people in England and points in the same direction as the abandonment of the injection compressor for large marine engines by the A.E.G. and others, and is an added indication of development in the direction of simplification and reduction in weight which should still further enlarge the field of Diesel application.

The installation of beautiful, big Diesel engines in ships is going on so fast that it would be easy to show hitherto unpublished illustrations of the boats, the engines, and their auxiliaries, but only one or two more indications of present-day tendencies will be cited.

Fig. 37 shows Burmeister & Wain's 6-cylinder, 4-cycle, single-acting, trunk-piston Diesel engine developing 3000 i.hp. at 145 r.p.m., of which two have recently been installed in the twin-screw motor tanker *Britta* built at Helsingfors and may be taken as typical of direct-drive motor-tanker engines.

The United States has taken the lead in the introduction of electric drive for ship propulsion. With Diesel engines this has been applied to tug boats, ferry boats, yachts, and tankers, but has not been introduced in Europe as extensively as here.

Another instance of the effect of American developments on European practice is the equipment of the motor tanker *Brunswick* being built by Scotts for the Atlantic Refining Company. The propelling machinery which is now being installed will consist of four six-cylinder, 750-b.hp. Carels-Ingersoll-Rand engines as shown on test in Fig. 38, each direct connected to a continuous-current generator. The vessel will have a single-screw, electric-motor driven. This is the largest Diesel-electric equipment so far produced abroad and is also another example of international cooperation, as the hull is built in Scotland, the electrical machinery by the British Thomson-Houston Company, affiliated with the General Electric Company of the United States, and the oil engines by the Carels Works in Belgium from designs supplied by the Ingersoll-Rand Company.

Fig. 39 shows a Sulzer 8-cylinder, 820 × 1440 mm., 2-cycle, single-acting engine developing 7000/8000, b.hp. at 100 r.p.m. with separate motor-driven scavenging blower illustrative of

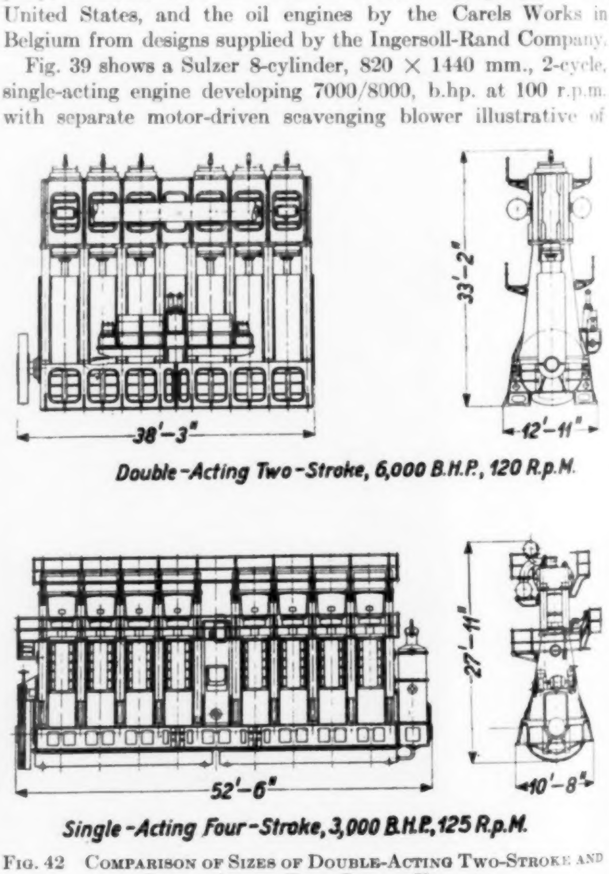

FIG. 42 COMPARISON OF SIZES OF DOUBLE-ACTING TWO-STROKE AND SINGLE-ACTING FOUR-STROKE ENGINES

the largest 2-cycle air-injection marine engines now being built.

The development of the Diesel submarine type of engine is still going on in Europe. Fig. 40 shows a 2200-b.hp., 380-r.p.m. Fiat engine and Fig. 41 a 3000-b.hp., 390 r.p.m. M.A.N. engine.

I have referred to the importance of reduction in weight in reference to automotive engines. Incidental to reduction in weight, there is a reduction in space. This reduction in dimensions is essential for the increase in capacity of automotive engines because of the limitations of clearance diagrams. In the case of stationary engines, reduction in weight and size means a saving in transport and power-house structure costs. When we come to marine engines, in addition to the first cost of the space in the hull taken by the propelling machinery, there is the question of the earning capacity of space saved when propelling machinery of smaller dimensions can be used. For some classes of vessels this is a very important factor, and the introduction of the double-acting engine has had a marked effect on this.

Fig. 42 shows the comparative space occupied by one 6000-b.hp. double-acting, 2-stroke-cycle engine as compared with one single-acting, four-stroke engine of half the output.

Very little reference has been made to fuel economy, chiefly because the improvements in fuel consumption are not of great magnitude and are of minor importance compared with the design problems, the solution of which produces Diesel engines giving reliability and continuity of service equal to the best steam and hydraulic plants and those which will effect reductions in weight and increases in rotative speed essential to the expansion of all kinds of applications and especially those concerned with transportation. One example of what a motorship is doing will be given.

No doubt there are many other equally good examples, but I have selected this one because Mr. James Smith, superintending engineer of the Union Steamship Co., of New Zealand, when passing through this country on his way to England a few weeks ago allowed me to copy some data from his personal log book and has authorized me to publish them. This is, therefore, first-hand, accurate information secured from the owners. These data refer to the *Aorangi* which was built by Fairfield in Glasgow. It has four two-cycle, six-cylinder, 3000/3600-b.hp. Sulzer Bros. engines. The *Aorangi* has made over 300,000 miles in the Pacific Service. Up to the end of 1927, when the engines were first overhauled, its performance had been as follows (figures refer to English long tons and imperial gallons):

Total distance, voyages, 201,043 nautical miles
Average speed, 16.44 knots
Total fuel, propelling, 23,359 tons
Fuel for other purposes, 4891 tons
Fuel in port, 2605 tons
Engine hours, 12,224
Average i.hp. propelling, 14,710
Average fuel per day propelling, 45.8 tons
Average fuel per day for other purposes, 9 tons
Average fuel per i.hp., 0.29 lb.
Total lubricating and cylinder oil, first year, 41,749 gal.
Total lubricating and cylinder oil, second year, 28,542 gal.
Lubricating and cylinder oil used in port, first year, 2652 gal.
Lubricating and cylinder oil used in port, second year, 1550 gal.
Lubricating and cylinder oil used per day, first voyage, 294 gal.
Lubricating and cylinder oil used, average last four voyages, 110 gal.
Average speed three best voyages, 17.1 knots
16.96 knots
16.88 knots
Highest daily speed, 18.1 knots

Now after going about 300,000 miles, the fuel per indicated horsepower on the voyage of December, 1927, was 0.311 lb. and for January, 1928, 0.315 lb.

Mr. Smith showed me the log of fuel consumption for a large number of voyages and it is amazing how little variation there is in the amount of fuel per voyage. The systematic and regular way in which this ship behaves in the matter of reliability, low maintenance, and uniform economy of fuel and lubricating oil is certainly a strong argument in favor of Diesel propulsion.

# Cooperative Diesel-Engine Research

By HARTE COOKE,[1] AUBURN, N. Y.

In order to get the best idea of the problems requiring cooperative research on the Diesel engine today, a sketch of the origin, uses, and past research on this subject should be given. The type of internal-combustion engine which operates on what is called the "Diesel cycle" was originated by Dr. Diesel in his efforts to improve the efficiency of the ordinary gas engine, his idea being to see if lower power costs could be obtained for operating refrigerating machines. His investigation showed him that an increase in the efficiency of the gas engine could be obtained by an increase in the compression ratio of the engine, this in the ordinary gas engine being limited to the compression at which fuel would ignite. He concluded that if he could compress the air only, and put the fuel in when the compression had been accomplished, he could get the compression ratio which would give the highest efficiency without limitations of preignition present in the ordinary gas engine.

His theoretical investigation of this cycle of operation was complete, and he wrote and published a book on this before any actual engine had been built, and the writer believes this is the first time anything of this kind was done. The usual process is to develop a machine, later on investigate its various principles and limitations, and then papers and books are usually written after the thing has been accomplished.

As this investigation showed promise of lower power costs, commercial firms in Europe were finally induced to develop the actual engine, and it is interesting to note that the original development of the Diesel engine was a cooperative process. A number of industrial firms in Europe joined to develop an engine with this cycle of operation suitable for commercial service.

The original idea was to use powdered coal as fuel, but on account of the complications and difficulties in accomplishing the desired results along these lines in connection with the high pressures and high temperatures which were much beyond the temperatures and pressures at which much experience had been obtained up to that time, the simpler and more satisfactory method of using hydrocarbon oil as fuel was adopted, the oil being atomized and introduced into the cylinder at high pressure by compressed air at a sufficiently higher pressure than the compression, not only to put the oil in the cylinder but also to atomize it, so that it would burn quickly and completely. With the initial problem solved by cooperative effort, the various firms that had joined in this work started the production of Diesel engines commercially.

The original idea was an engine which would reduce the fuel cost, as the cost of fuel in Europe at that time was a very large factor in the cost of power, and the very high efficiency of the Diesel cycle of operation would make a material reduction in the fuel costs for producing power. When these engines were put to work in actual service, it was found that there were other savings in the cost of operation, such as the lower labor cost per unit of output and lower maintenance than with a steam station, also that it had other advantages such as complete absence of standby losses while the engine was shut down, and the ability of the engine to take full load at short notice.

### First Diesels Were Single-Acting

The original engine was developed as a four-cycle engine with air injection, and in order to reduce the first cost a start was made to develop the Diesel engine working on the two-cycle principle so as to get more output from a given engine. These early engines were all single-acting.

These engines gradually came into service, first for central stations for driving generators and in industrial power plants, both as belted units and as engines coupled to a generator so that power could be transmitted through the works to various electric motors. On account of the low operating cos's, these engines began to be used for driving pumps, because in a pumping plant the load factor is usually very high, and the lower operating costs would justify the high first cost of the engines at that time. On account of the absence of standby losses and the ability to take on a load at short notice, these engines came into use as auxiliaries in water-power plants.

It was early seen that this type of engine had a great many advantages for marine use, and installations were made on various vessels, some of the first being with Diesel electric drive, the idea being to use moderate-sized engines at fairly high speed and a slow-turning motor on the propeller. However, owing to the lack of development of marine electrical equipment at this time more or less trouble was had, so that the direct drive which had been tried out in several cases proved to be more satisfactory, and the engines were made in larger and larger sizes for direct drive for various vessels.

These marine engines for direct drive had to be made reversible, which proved to be a problem easily solved, and a great many of the early vessels were made with the twin-screw arrangement, for the reason that the engines available were only of moderate power and to get the amount of power required for a given vessel the twin-screw arrangement seemed to be the best way.

Among the problems of the Diesel-engine builders as this development went on were first the limitations as to what output could be secured from a given engine; and the reliable Diesel-engine ratings today are based on actual experience with the operation of Diesel engines at certain ratings rather than on any theoretical determination or test demonstration of what the maximum possible output might be. There were also problems of materials, as in the early development of this industry materials were not available that are available today, neither was the information on the characteristics of the different materials as complete as it now is.

They also had problems in regard to fuels, as then they did not understand the effect of the different fuel characteristics nor were the quantities and qualities of fuel available that are available now. There were also problems of lubrication, as it was not understood at first just how the cylinder lubrication could be taken care of under the conditions of the extreme pressures and temperatures which this cycle of working developed.

In regard to the research which was conducted during this period, a good deal of research was conducted by the individual manufacturers to perfect the various arrangements for the preparation of fuel for combustion in the cylinder and the shape and arrangement of the combustion space. In regard to research on the output limitations, this was regulated more by actual experience and practice than by any special research that could be carried out. Oil engines could develop considerable power under test conditions, but it was found in actual practice that it was advisable to carry a lower load than test results showed it was possible for the engine to develop.

When the metallurgists found what characteristics in a ma-

[1] Engineer, McIntosh & Seymour Corp. Mem. A.S.M.E.

Presented at the First National Meeting of the A.S.M.E. Oil and Gas Power Division, the Pennsylvania State College cooperating, State College, Pa., June 14 to 16, 1928.

terial were desired, the metallurgical research developed materials that were more advantageous for the various uses than had been previously available. In regard to fuels, as time went on experience developed difficulties with certain fuels, and the use of these fuels in actual service usually developed the cause of the difficulty, so that the remedy could be applied and the particular fuel in question made usable.

In regard to troubles with lubrication, as experience developed with these engines it was found that some of the early fears in regard to lubrication problems were groundless, and the oil men when they found just what characteristics were desirable for use in a Diesel engine were able to produce oils which would render the satisfactory service desired.

### Larger Fuel Supply Made Available

During this development, the period of the war came on, and the necessities of war caused a very rapid development of the types of Diesel marine engines which had proved so suitable for use on submarines and developed materials and processes which eventually proved to be of advantage to the Diesel-engine manufacturer; but another change, which was the rapid introduction and use of the automobile, gave a very rapid development by the metallurgists of materials and also information on the use of heat treatment of materials which was a great help to the Diesel-engine industry. Also with the tremendous increase in the use of the automobile, petroleum supplies were developed to a tremendous extent, and the great demand for gasoline improved processes of refining crude petroleum, so as to give enormous supplies of suitable fuels for Diesel engines, and also the experience gained with the lubrication of engines for automobiles proved to be of great benefit to the lubricating engineer in taking care of the lubricating problems on the Diesel engine.

Now that the Diesel-engine industry has the tremendous benefit of development in other lines, all these things have facilitated the commercial development of the Diesel engine itself. At the present time the use of the Diesel engine is more diversified than ever before. Stationary engines are used in a great many central stations, and when we hear of central stations we always think of magazine descriptions of plants with a capacity in the hundreds of thousands of kilowatts, but as a matter of fact, the size of station that is usually installed is the one that can best serve the particular neighborhood where it is used, so that in general the average Diesel engine used today is somewhere between 300 and 800 hp.

Such engines are in use in central stations, cement plants, oil pipe-line pumping stations, flourmills, and various industrial plants, brick-making plants, plaster mills, city waterworks, for irrigation, for drainage pumps, for marine service, and they are coming into use as the main drive on the very largest and fastest ships and are now built in sizes so that they can be used for single-screw vessels up to the largest tonnage that is desirable for the usual freight service.

This development has been along not only the four- and two-cycle air-injection line, but also mechanical injection has been developed for both four and two cycle. In addition to this, the largest sizes, both four- and two-cycle, have been built double-acting, which gives a reduction in the weight and a reduction in the first cost. This type of engine has also proved to be very desirable for auxiliary service on shipboard, and all modern motorships have Diesel electric units to furnish electric power for auxiliary service.

The Diesel engine has also proved very advantageous for use on dredges, and is used for direct drive on main dredging pumps, also for driving the auxiliary equipment by means of shafting and clutches and by having an engine connected to a generator so that the various auxiliary equipment can be driven by motors. Some of the larger dredges have Diesel engines coupled to generators, and all of the auxiliaries including the main dredging pump driven by electric motors. This arrangement allows full power to be applied to the dredging pump at low heads, which is very advantageous.

The Diesel engine has now invaded the railroad field and has been used in Europe on smaller locomotives and railcars for about a dozen years. The use for railcars has just started in this country, and a number of Diesel engines have been built for use on switching locomotives. Practically all of these have been electric drive; that is, the Diesel engine is coupled to a generator, and regular electric motors are used on the driving axles.

While the peculiar tractive-effort characteristics of the Diesel locomotive make it especially desirable in switching, and where the freedom from smoke and noise is also of advantage in populous districts, it has been found that the operating costs are very low, which makes the use of the Diesel engine for main-line locomotives very desirable, and it is actually coming into use for this particular service.

### Diesels Desirable in Aeronautic Field

In addition to this, there are special cases where use of the Diesel engine seems very desirable, such as for aeronautics. While at present the weight of the Diesel engine is a drawback for use in this service, the fact that it can use a very safe fuel is a very desirable feature for aeronautic use.

In general, the Diesel engine as it stands today has reached practically the same state of development as other power equipment such as the steam engine and the turbine. The main problems have all been solved, and efficient, reliable service has been demonstrated in a great many lines of use.

While, as mentioned, the main problems have all been solved, an advance could be made if more complete information could be obtained in regard to some of the fundamental things connected with the operation of a Diesel engine, such as more complete knowledge of the nature of the combustion; the characteristics of the products of combustion at the high temperatures and pressures obtaining in a Diesel engine; the characteristics and nature of the ignition of fuel at these high temperatures and pressures; more complete information in regard to the transfer of heat from this mixture to the walls; a coordination of the information now existing in regard to the transfer of heat through the walls to the water jackets; a more complete knowledge of the desirable characteristics of the walls and other parts that are exposed to the high temperatures so as to resist not only the temperatures but also the natural wear.

These problems of the Diesel engine are along much the same lines as has been the case from the first, the most important one being the combustion characteristics of the engine, which with the design of the engine, especially the parts in connection with the combustion space, and also the materials used for this part of the engine, have an important bearing on the size and output limitations.

Those three things also have a bearing on the maintenance of a Diesel engine, and the maintenance further depends on the lubrication, and the cooling, and the nature of the cooling water used. For special cases such as for railway work, the output limitations will require special investigation, and also the question of weight will have to be carefully gone into.

In regard to the special uses for aeronautics, the weight of the Diesel engine is a vital factor in this case, and the output limitations will have to be especially investigated to secure the light weight desired and as high speeds will have to be used, special investigation will have to be made of the characteristics of the

fuel consumption at these high speeds. In regard to the solution of these problems, research in various degrees is now being carried out by industrial concerns and government departments.

For instance, in regard to the aeronautical use of the Diesel engine, the National Advisory Committee for Aeronautics has conducted very interesting and complete tests on the output limitations, fuel consumption, and weights of the Diesel engines for this use.

Now in the building of a modern Diesel engine, the manufacturers avail themselves of the special knowledge of the metallurgists and of the steel works for the furnishing of the crankshaft for the Diesel engines. Standard parts, such as standard studs and nuts, are bought of concerns who specialize in these particular things. Gages, thermometers, lubricators, piping, and the valves and fittings for this piping are all bought from specialists; also the seamless tube for high-pressure piping, seamless air receivers, and riveted air receivers are the product of specialists.

It is when Diesel engines are in actual service and being operated by the user that the problems which have to be solved are developed. In England there was an association of users of steam equipment, known as the Manchester Steam Users Association, which made periodic inspections of the steam plants of all the members and made a paintaking investigation or research in connection with every failure of a boiler or engine part, and the effect of this cooperative research was very beneficial to the users of the boilers and steam machinery and had a profound influence on the design ot this equipment. The Diesel engine users in England have had for years an association where they could compare notes and look into the problems of the individual members and by this cooperative effort improve the operating results.

### Research Interests Many Lines

In view of all this, such problems as come up regarding improvements of the Diesel engine are of interest not only to the Diesel engine builders but also to these other industries, such as the petroleum industry which furnishes the fuels and lubrication for these engines, and to the many lines of industry which are users of this equipment.

In addition to this, the solution of some of these problems would be of benefit to still other industries; for instance, the transfer of heat from gaseous mixtures to the walls of the Diesel engine involves a careful investigation of the problem of heat transfer, which would be of advantage not only to Diesel-engine builders but to builders of steam locomotives, boilers, radiators that are used in the heating of buildings, and to the builders of radiators for cooling automobiles.

In view of the cooperation of a number of industries in supplying materials which go to make up a modern Diesel engine, it would be desirable for these industries to cooperate, and also for the Diesel-engine builders themselves to cooperate, and also the various other industries that would be benefited by special research on problems specifically brought up by the manufacturer of Diesel engines in the solution of such problems as may appear.

Just how this research should be conducted or supported is a question that should be taken up and settled to insure the quickest and best development of the Diesel engine. Cooperative effort along various lines is now seen commercially among manufacturers who are cooperating to educate the public in regard to the use of cement. This is also true of the hardwood lumber merchants, brick manufacturers, and a number of others.

In England the Government authorities have seen the desirability of assisting and advising in the research necessary to industrial life, and as far as this has gone it has proved very beneficial.

In this country we have the Bureau of Standards, which has done a great deal to assist our industries in solving some of their problems and improving their processes. Various government bureaus have departments of research. The Bureau of Aeronautics of the government has a wonderful research department which has accomplished a great deal, and both the army and the navy have conducted considerable research into their various problems.

Some of the larger industries in this country maintain extensive research departments, such as the General Electric Company, Westinghouse, the Western Electric, American Telephone and Telegraph, American Radiator Company, and General Motors Corporation.

A good example today of cooperative research is the Nela Park Laboratories of the General Electric and Westinghouse companies, which devotes its entire attention to the improvement of the electric incandescent lamp and the methods of its manufacture. The modern incandescent lamp illuminates this research problem, and its cheapness and efficiency today show how desirable the activities of such a cooperative research can be.

However, it is only the largest concerns that can afford to carry on such research as is now desired, and in this country government agencies cannot be expected to solve all the problems of industry, nor would this be entirely desirable. Also, a great many industrial concerns do not have the resources to do this as thoroughly, completely, and quickly as is desired, nor can the existing facilities for research and apparatus and personnel which are available at the various colleges be called upon or expected to do this work unaided.

A good example of this cooperative research has already been set by the petroleum industries, which have already inaugurated a very extensive program of research, coordinated by the American Petroleum Institute, which has arranged to coordinate a great part of the technical activities of the oil industry.

It would seem from all of this that the best solution of this problem of Diesel-engine research would be for industry as a whole to cooperate in supporting such research as was desired, and in the author's opinion this research could best be conducted and directed by such a disinterested body as The American Society of Mechanical Engineers.

## Discussion

R. J. S. Pigott.[2] After an association of some 14 or 15 years with the Research Committee, the first thing that occurs to me when it is mentioned is, "Where is the money?" Perhaps you may not realize it, but over two-hundred million dollars a year is expended in the Government and private laboratories. There are some large units, such as the General Electric Co., which alone spends between seven and eight millions a year; the American Telephone & Telegraph Co., which spends a little more than that; Western Electric, with probably two or three millions; Westinghouse, with two or three millions; Aluminum Company of America, two or two and one-quarter millions. And then there is an enormous total amount of money spent by the smaller groups, eighty or ninety millions of dollars a year for research work.

In addition to that there are various trade associations spending a great deal of money on research work, this money coming from their own membership. There are a number of very large research endowments, none of which, however, is directed toward industrial research; for instance, the Rockefeller Foundation, 165 million, which is used exclusively for research in the medical profession; Mellon Institute, which is devoted to chemistry; and also the Carnegie Institute, which covers pure science which

[2] Consulting Engineer, Public Service Production Co., Newark, N. J.; Chairman, A.S.M.E. Standing Committee on Research.

none of the other groups has attempted. They have a twenty-two million dollar endowment.

The smallest of all is the Engineering Foundation, which has about six-hundred thousand dollars, and that amount is insignificant compared to the problems coming before it.

So far as the Society is concerned, we have no fund from which to draw, except to draw the money from the Engineering Foundation. For that reason we have started a campaign of our own, which I am not at full liberty to mention as yet. Whether that will be successful, I do not know. If we are successful in getting such an endowment, this question of research for industrial purposes will be solved. Until that time we must pursue our labors by the same method that we have during the past 15 years. We need funds and we need the cooperation of those interested in the furtherance of this work.

In our experience with several different groups, I might exemplify it by mentioning the Fluid Meters Committee. This committee was made up first of a small group of users, and later it was found that the information could be obtained only through the manufacturers. The textbooks did not have it; the manufacturers themselves had what little information there was that was up-to-date.

We brought into the committee a large number of manufacturers, but toward the end of our work a great many more manufacturers were on the committee than any other class. At first the attitude was somewhat colored by suspicion. Each manufacturer thinks, "Well, am I going to get as much out of this as the others, or can I get a little more than they are getting for the amount I am putting in." If we could get the proper cooperation, then there would not be that suspicion.

However, they found that the things they were doing were not secrets at all in their particular business; they were already known to the others or else they were not worth anything. There are many problems facing you now that could be solved through cooperation and common action. By individual effort you do not get the large spread of specialized skill to bear on the subject, and you do not have funds enough to make it a commercially feasible expenditure.

The characteristics of the problem before you are twofold. Fundamental research covers investigation in the physical properties of materials. As an example, I might refer to the investigations of Professor Schweitzer in relation to the oil-spray atomizers and the action of various oils, etc. That has nothing to do per se with any particular design of engine.

If the work were performed in connection with a particular design, that would be a matter of applied research. As a matter of fact, the kind of research that you in general have to tackle, and that we in the A.S.M.E. can assist in, is applied research, because it shows up so well as bringing back money commercially; if you have to go out and get money from industry, you must show a rather quick commercial return. You will find with rather few exceptions that our work has been largely applied research rather than fundamental research. The exceptions are in the development of standard steam tables and investigations into the physical properties of refrigerants and also some of the work on oil sprays.

It is curious that the steam tables should have brought in the largest amount of money, $63,000 having been collected on that work, and when the work is finished $15,000 or $18,000 more will have been collected. This represents one of the most valuable single contributions. The reason why it has been so well supported is that not only the steam-turbine manufacturers but all of the public-utility people and the boiler manufacturers require good steam tables, especially in this day when the pressures are going up. For that reason we have had considerable support from all of those groups. Most of the work has been carried on in the Bureau of Standards and at Harvard, equally divided between college equipment and government equipment.

As to the methods used in the A.S.M.E., they are of interest to you because you are looking for a path by which you may arrive at the solution of your research problems. It seems that the first thing you can do, if you are unable to provide sufficient funds individually to do a real job on this very expensive pursuit, you will have to get together as a trade organization or through some committee organization.

After we have undertaken a project, the first thing is to make an examination of what has already been done, correlating that information, and laying the foundation for future research. For example, on fluid meters we spent nearly nine years before the first section of the report was brought out. During those nine years there was some quarreling among the manufacturers and users as to what was right and what was not right, but only $1500 had to be spent (on pulsating flow) to get out a textbook of up-to-date information on the theory of flow. After examining all of the literature, we found that most of the work had already been done. That is one way in which duplication of work may be avoided.

The method by which we function has been growing during the past 15 years. Our feeders may be the survey committees of the professional divisions, the National Research Council, or any individual member of the Society who may have a proposition to present. The subjects are brought in with full data, and a program is outlined, and reaches the Main Research Committee. We go back to the professional divisions and ask them for suggestions in the way of organizing the committee, and from that point on the committee is granted funds with which to operate, and they proceed on their own so far as possible.

The Main Research Committee is called upon to assist in the way of an occasional donation or establishing contact from one or two other sources, but generally the committee is provided with funds for laboratory work from the outside sources. The manufacturers have been the largest contributors, because in general they have been the ones who immediately benefit from the results. After this period of education has been completed there is not nearly so much difficulty in getting the money required to carry on these experiments.

With regard to a question that was raised this morning, we have 29 special committees under the direction of the Main Research Committee. Each of these committees is investigating a particular problem. About three of those committees are working on fundamental research, and about 30 per cent of them are joint committees. When we find that the problems reach out beyond the field of any one society, we immediately establish contact with the other groups.

For instance, on our Boiler Water Committee, we received assistance from the American Water Works Association and the National Electric Light Association. There are other joint committees I could mention. In every case we make an effort to tie up with all of these groups, whether they are trade organizations or not, if they have an interest in the problem. In that way we can get the largest number interested and the greatest prevention of duplication of effort. When you have two groups working on a particular problem, you get farther ahead than if you were working with only one group.

In the problems which have been brought out already in this conference, such as the fuel-oil specifications, the design of the Diesel engine, and the matter of spray nozzles, etc., you have already the mechanism available to go into this matter thoroughly if you want to make use of it.

W. F. Joachim.[3] The National Advisory Committee at its

[3] National Advisory Committee for Aeronautics, Langley Field, Va.

Langley Field laboratories has been carrying on research on the high-speed oil engine for the past six years. One of the major activities that was first developed was the committee's spray-photography equipment.

This is a parallel apparatus to the equipment that Professor Schweitzer has shown you. Instead of injecting the sprays into a pressure chamber against a swinging pendulum, the committee's apparatus has a much smaller chamber with large optical-glass windows, and pictures are taken of the sprays on photographic film. The apparatus may be divided into three major parts: that part which produces the illumination, the part which produces the sprays, and the camera. The illuminating apparatus consists of 25 high-tension condensers, charged by a transformer of 2-kw. capacity to about 40,000 volts. These condensers are discharged through a rotary distributor disk about 30 in. in diameter, at the rate of from 2000 to 4000 discharges per second. The electric sparks, which are about 1 in. long, occur in a reflector and are focused upon the spray chamber.

The sprays are produced coincidentally with the discharge of the electric sparks, so they are illuminated at a very high speed. The camera is on the opposite side of the spray chamber from the reflector and consists of a light tight-box containing a film drum about 12 in. in diameter, driven by an electric motor at high speed. As the sparks pass between the electrodes in the reflector they illuminate the spray nozzle first, then the tip of the fuel jet, then the fuel spray as it grows and develops, through the cut-off of the spray, and then its final development and dispersion. These spray images are caught by the film on the rotating film drum. The nozzle and fuel sprays are very well defined, even though the sprays themselves may be moving at a rate of 400 or 600 ft. per sec. and the film may be traveling at the rate of 200 ft. per sec.

With this apparatus the committee has studied the effects of injection pressure on the fuel, the effects of air pressure up to 600 lb. per sq. in. in the chamber, the effects of various nozzle designs, the effect of injection turbulence, injection tube length and diameter, the effect of various gases, various fuels, and so forth.

In endeavoring to point out some of the things that have occurred in our research activities that I believe indicate the importance of research, I want to tell you about my first attempt to design an injection valve for producing a uniformly distributed continuous spray in what might be termed a flat disk-shaped combustion chamber.

Realizing that a very fine atomization was necessary for high-speed operation, I did not want to use sprays from round orifices, and I attempted to design injection valves using annular orifices and centrifugal force. I felt that if an injection valve could be designed to produce such a high centrifugal force that the fuel would be thrown outward in a horizontal plane, practically perpendicular to the axis of the orifice, we would have developed a valve very much worth while.

The centrifugal force was produced by turning multiple grooves on the end of the injection-valve stem, after carefully calculating the velocity of the fuel, which would lead the fuel into a small chamber and thence through a round hole. The final dispersion of the fuel after its exit from the hole was calculated to produce a cone with an angle of 120 deg. We tested it and it was about 110 deg. The difference in cone angles can probably be explained by the adhesion of the fuel to the surfaces, surface tension, etc. When this injection valve was placed in the spray-photography spray chamber and the injection of the fuel made in the air under pressure, the fuel spray which was just about right for injection into a flat-top combustion chamber, as viewed in the atmosphere, closed up like a rosebud at night. It was disappointing. The result of that test was that the spray was finally directed mechanically.

In some of the committee's engine work which is carried on in single-cylinder aircraft engines, using Liberty engine parts, such as connecting rods, pistons, rings, valves, etc., we have had occasion to vary the size of round orifices in a vertical disk-shaped combustion chamber in order to determine the effect of orifices on the penetration, and the effect in turn of the penetration of the jet in this chamber. The orifices used in two of the main jets varied from $^{10}/_{1000}$ in. to $^{21}/_{100}$ in. The total distance for penetration was about $4^1/_2$ in. The $^{10}/_{1000}$-in. orifice sprays did not reach the piston. The power performance was not exceptionally good. In increasing the orifice diameter the performance improved, even though the sprays actually contacted with the piston head.

Most of us have the idea that our fuel sprays should just reach the piston crown or the cylinder wall and should go no further. The writer believes that it is true with the cylinder wall, but of the piston crown, recent results have indicated it is desirable to have the spray hit the piston and then distribute itself at that point.

Professor Schweitzer's spray chamber will give you information on sizes of injection valves which the committee is not prepared to test. The committee's work so far has concerned itself with cylinders of the aircraft size, 5-in. bore by 7-in. stroke, and by carefully programming the work and carrying it on with the spray-photography equipment, using those results to construct injection valves and fuel pumps, the performance obtained on the single-cylinder aircraft engines has improved at a rapid rate.

In 1922 and 1923 the cylinder pressures in these single-cylinder units ranged from 1600 lb. to 2000 lb. per sq. in. The reason for this was that at that time the committee's spray photography was not in operation. We needed more research. In the year succeeding, the cylinder pressure was reduced, first to 1000 lb. per sq. in. and then to 800 lb. per sq. in., and during this last year we have obtained at 1500 r.p.m. a brake mean effective pressure of 100 lb. per sq. in., with a fuel consumption ranging around $^1/_2$ lb. per b.hp. and cylinder pressures as low as 550 lb. per sq. in.

When these performances are corrected to multi-cylinder engine operation, the brake m.e.p. is 110 lb. per sq. in. and the fuel consumption about 0.46 lb. per b.hp-hr. To obtain the same performance at 1500 r.p.m. as is obtained in engines around 600 r.p.m. is a considerable feat, and it could not possibly have been done without the research facilities at Langley Field and the money with which to back it up. The writer would like to say that Professor Schweitzer's equipment is capable of doing the same thing in a somewhat different way for the oil-engine industry and would like to urge that each one here avail himself of the opportunity to carefully inspect the Pennsylvania State College equipment and get behind the project.

# Diesel-Fuel-Oil Specifications

By G. H. MICHLER,[1] NEW YORK, N. Y.

*The author gives examples of the various specification requirements encountered by the oil refiners, and points out the impossibility of carrying several grades of Diesel fuel oil at distributing points which are not also refining centers. Unless Diesel engines are constructed which can operate efficiently on a standard grade of oil of broad specification, ship operators will be unduly restricted to limited points of fuel supply and may be precluded from operating in the most desirable trade services. He suggests that three specifications would be sufficient: a minimum gravity of 24 deg. A.P.I., a maximum sulphur content of 1.5 per cent, and a minimum flash of 150 deg., closed cup.*

I HAVE BEEN hoping for some time to have an opportunity to present to Diesel-engine engineers and manufacturers one of the problems facing the petroleum industry today in its endeavor to meet the varying demands made upon it for Diesel oil for the many types and makes of Diesel engines now in use. I therefore welcome the opportunity afforded to present a picture of our problems with the earnest hope that this audience may feel they are worthy of consideration and may cooperate with us, after obtaining a closer understanding of the oil-suppliers' situation, toward a simplification and standardization of Diesel-oil specifications. This cannot fail to operate to the mutual advantage of Diesel-engine designers and builders, Diesel-engine operators, and the suppliers of the fuel for these engines.

Let me say at the outset that I do not believe the petroleum industry has any clearer understanding of your problems than you have of ours. It is only by an exchange of ideas from each side, for which this meeting furnishes an admirable opportunity, that each party interested in the development of the Diesel engine can appreciate the limitations of the others.

## Growing Ascendency of the Diesel Engine in the Marine Trade

The growing importance of the Diesel engine as an economical power unit cannot be overestimated. In one of its principal fields, the marine trade, its growing ascendency over steam power plants is attested to by Lloyd's marine-construction figures for the year 1927, which reported that for the first time in history world-wide construction of Diesel ship tonnage exceeded construction of steam tonnage, the comparison being as follows:

| | No. | Steamers, deadweight tons | No. | Motor vessels, deadweight tons |
|---|---|---|---|---|
| American | 11 | 71,900 | 8 | 18,670 |
| Foreign | 364 | 1,422,000 | 277 | 1,590,848 |
| | 375 | 1,493,900 | 285 | 1,609,518 |

It will be noted that in Europe where the construction of motor vessels is considerably more advanced at the present time than in this country, motorship construction during the year surpassed steamer construction by about 200,000 deadweight tons. This represented a considerable advance in Diesel construction over 1926 in which 925,837 deadweight tons of steamers were constructed as compared to only 701,777 deadweight tons of motorships.

When we consider that the fuel consumption in these large units bears a ratio of 1:3 as compared to fuel oil burned by steamers under boilers to develop the same horsepower in comparable tonnage, the importance of the Diesel engine as a factor in conserving the future world oil supply can be appreciated. Its advantage to the operator, particularly of freight ships, on long trade routes, is decided. His fuel consumption is materially decreased, making available more space in the ship for freight-earning cargo and requiring him to make fewer stops for fueling purposes. A good illustration of this is furnished by the recent development by some shipping companies of a fast round-the-world freight service by Diesel ships which, in some instances, practically bunker for the entire round at one port.

Everything apparently justifies the operators' investment in a comparatively high-priced piece of mechanism (in this country at least), but there is, as usual, a fly in the ointment. In this case it is the various types of Diesel oil required by different engine builders, and passed on by them to operators as a basis of performance guarantees.

## Various Types of Diesel Oil Demanded

Let me cite some examples: A couple of years ago a motorship made her maiden voyage from a United Kingdom port to the United States. The following is comparison of oil supplied the vessel in the United Kingdom and oil supplied by our company at New York:

| | United Kingdom sample | New York sample |
|---|---|---|
| Gravity at 60 deg. fahr. | 26.7 | 30.2 |
| Flash, Pensky-Martens closed cup, deg. fahr. | 175 | 175 |
| Viscosity, Saybolt, at 100 deg. fahr. | 98 | 50 |
| Sulphur, bomb method, per cent | 1.34 | 0.4 |
| Carbon residue, per cent | 3.05 | 0.4 |
| Asphalt, Italian tar test, per cent | 45 | 6 |
| Ash | none | none |
| B.t.u. per lb. | 19,125 | 19,400 |
| Water and sediment | trace | trace |

At the time of delivery, our knowledge of requirements of marine Diesel engines led us to believe that the oil furnished by us was very much superior to that furnished on the other side, and we believe that most Diesel-engine manufacturers would be of the same opinion. This is apparently borne out by the specifications issued by marine-Diesel-engine builders from time to time.

In actual operation of the vessel, however, serious trouble was encountered, and all of the trouble was laid to the oil by the operators of the motorship. As an experiment, we mixed 40 per cent of a heavy residue oil with Diesel oil, which had the result of reducing the gravity, increasing the viscosity, sulphur content, and coke residue, and very materially increasing the asphalt content by what is known as the Italian tar test, also reducing the B.t.u. per lb. In other words, the oil was brought to what we consider a poorer quality and made to conform more nearly to the grade of oil delivered in the United Kingdom, which appeared to operate successfully. Whether the trouble was due to the grade of oil delivered or mechanical troubles of the engine we are not in position to say. Under any circumstances, the operators claimed that by blending what we considered an inferior oil, their troubles were overcome. This is only one illustration of the difficulties we have encountered.

## Various Specification Requirements of Ship Owners

One of the largest customers of the company which I represent who buys a considerable volume of Diesel oil for his ships at

[1] Standard Oil Company of New Jersey.

Presented at the First National Meeting of the A.S.M.E. Oil and Gas Power Division, The Pennsylvania State College cooperating, State College, Pa., June 14 to 16, 1928.

North Atlantic and U. S. Gulf ports insists on various specifications for different ships, although all of them were engined by the same company in Europe. For some of his vessels he requires a maximum sulphur content of 0.75 per cent, and a minimum A.P.I. gravity of 26 deg. For other vessels he limits the maximum sulphur content to only 0.5 per cent and stipulates that gravity shall not be below 27.5 deg. These specifications are drawn in accordance with the guarantee of the engine builder. Vessels with engines of the same make have operated successfully for years on the West Coast on an oil with a sulphur content of over 1 per cent, and gravity at times as low as 24 deg. For several years our company had a contract with another ship operator who required Diesel oil of a minimum gravity of 33 deg. A.P.I. Builders' specifications were again given as the reason.

Another of our contract customers requires the following minute specifications of Diesel oil for delivery to his ships:

| | |
|---|---|
| Viscosity at 100 deg. fahr. Saybolt Universal, sec. maximum | 100 |
| A.P.I. gravity, deg. | 25+ |
| Flash point, Pensky-Martens closed cup, deg. fahr. | 150+ |
| Ash, per cent, not more than | 0.05 |
| Hard asphalt, insoluble, per cent, less than | 1 |
| Coke, per cent, not exceeding | 1.5 |
| Hydrogen, per cent, not less than | 11 |
| Carbon, per cent, not less than | 86 |
| Oxygen, per cent | none |
| Cold test, deg. fahr., not more than | 46 |
| Water, per cent, not to exceed | 0.5 |
| Sulphur, per cent, not more than | 1 |
| B.t.u. per lb. | 19,000+ |

It is natural that Diesel-engine builders should wish to insure a supply to their engines of fuel oil ideally suited for their best performance. It is further natural that in the course of evolution, through which any new type of machinery must advance toward perfection, there should be a wide variation in the ideas of different manufacturers as to what constitutes a suitable fuel for their particular engine. One present phase of evolution is that manufacturers are endeavoring to construct engines which will operate on heavier oils. In doing this it seems that these engines will not operate on lighter grades of oil such as are considered more desirable for other engines. Each manufacturer seems to have a different idea of the grade of oil required for his particular engine. Sulphur is sometimes blamed for all troubles encountered, and some manufacturers, as mentioned previously, are requiring that oil should be used containing not more than 0.5 per cent of sulphur. It is our view that to limit sulphur to this low percentage is unnecessary, and further it is our view that a great many of the other specifications demanded are unnecessary. During the early period of development of the Diesel engine, such varying requirements in fuel specifications were perhaps excusable. Is it not a fair question to ask today, however, whether the Diesel engine has not developed to a point where such minute and variable specification restrictions are no longer either necessary or desirable? Their continuation can have only one result, and that an unfavorable one, to the further progress of the Diesel engine: higher cost of Diesel fuel oil.

### Diesel-Oil Problems of the Petroleum Industry

To clearly appreciate the reason for this statement requires an understanding on the part of the engineering fraternity of the problems of the petroleum industry.

In a great many cases the exacting specifications now required cannot be met, or if they can be met the oil can only be delivered from refining centers, as the specifications demand running a special batch of oil, carrying it in separate tankage, and delivering through clean lines or barges so that the oil will not become contaminated with what has heretofore been considered a standard grade of Diesel oil. Take, for example, unnecessarily restrictive sulphur limitations. They may require the fuel-oil supplier to manufacture a special batch of Diesel oil from low-sulphur crudes, which either may not be available when delivery is wanted or else are considerably more expensive than crudes of a higher sulphur content that would be suitable for the manufacture of Diesel oil of a more liberal sulphur specification.

### Impossibility of Carrying Several Grades of Oil at Points Not Refining Centers

We do not believe that consideration has been given to the fact that it is impossible to carry several grades of oil at distributing points which are not refining centers. If the oil industry attempted to do this it would have to invest millions of dollars in increased tankage in order to carry separate grades of oil at different points where there might only be a demand for the special grade required once a year. It will be readily seen that this does not fit in with refinery operations, nor does it fit in with tank-steamer deliveries. It is of course impractical to carry several different grades of Diesel oil on a tanker making delivery from a refinery point to an oil-distributing station. Imagine a distributing station on the Atlantic seaboard where storage sufficient for the volume of business done is replenished by tanker deliveries from the nearest refining center. Imagine at the same time having contracts with shipping interests, one of which calls for a minimum gravity of 33; another of which prefers 24 gravity and does not under any circumstances want to exceed 28; one of which has a sulphur limitation of 1 per cent; another sulphur maximum limitation of 0.5 per cent; and still another which has ten or a dozen minute restrictions with reference to viscosity, ash, hard asphalt, coke, hydrogen, carbon, oxygen, etc. Suppose, further, that against each one of these contracts only one vessel per year calls for bunkers; a tremendous investment would have been made for separate tankage, lines, and transportation from the refining point against each of the contracts made, and perhaps one delivery of, say, 2000 barrels of each grade would represent the return on the investment.

We feel that Diesel-engine manufacturers overlook the fact that crude petroleum is produced in a great many sections of the world. All of these crudes vary in their characteristics. In the United States foreign crudes will be received from Peru, Mexico, Colombia, Venezuela, Trinidad, or the Argentine, and in addition to these foreign crudes Atlantic Coast refineries may be receiving crudes from Pennsylvania, Illinois, Kansas, Arkansas, Oklahoma, Wyoming, Texas, or California. Some are primarily asphaltic-base crudes, some naphthene- and some paraffine-base, and all vary in their other characteristics. Furthermore there may be some variance in crudes from different sections of these various producing divisions.

Consider for a minute the operation of an oil refinery on the Atlantic seaboard. It will receive daily by pipe line and tank steamers crudes of widely varying characteristics from different parts of this country or imported from other countries. The problem is to extract from these crudes various grades of finished products, aviation naphtha, gasoline, lubricating oils, greases, wax, kerosene, gas oil, Diesel fuel oil, light fuel oil for metallurgical work, bunker C fuel oil, and asphalt, not to mention a large assortment of specialties. You can readily appreciate the number of stills, lines, and tanks required to handle such a volume of products from different kinds of crude oil. Let us go further still and imagine the result of a dozen or more of different sets of specifications being required for each one of the long list of finished products—the result is obvious. It means multiplying refinery equipment and expense to a point beyond all reason. The cost of finished products must compensate for the unreasonable extension of equipment. It is perfectly true that there are

a great number of different grades of lubricating oil, which is of necessity a highly specialized product, but you do not buy lubricating oil at a Diesel-fuel-oil price.

### Considerable Latitude Required in Drawing Diesel-Oil Specifications

It is therefore clear that there must be considerable latitude in drawing up Diesel-oil specifications. An exacting specification drawn up to meet a Diesel-engine fuel oil that might be made from Mid-Continent crudes would quite likely not be met with Diesel-engine fuel oil produced from California, Venezuela, Mexico, or Texas crudes, nor could such a specification be met by refiners who are running a great number of mixed crudes. In other words, if an attempt is made to segregate crudes to produce Diesel oil only from a selected crude, the cost of the product would be high.

As we see it, the successful development of the Diesel engine is dependent on a supply of Diesel-engine fuel oil at the lowest possible price. The main obstacle in the future to a reasonable price is the lack of a standard Diesel-oil specification with sufficient flexibility to permit refiners to utilize crudes from various sources and to carry one grade of Diesel oil in tankage at different points. Unless this is done, the future progress of the Diesel engine is going to be very materially handicapped. This handicap will be twofold: in the first place, the cost of manufacturing, handling, and storing a variety of different grades of Diesel oil may cause the price to mount to a point where it would destroy the economy which rightly belongs to the Diesel engine due to its low fuel consumption. In the second place, unless Diesel engines are constructed which can operate efficiently on a standard grade of Diesel oil of broad specifications, ship operators will be unduly restricted to limited points of fuel supply. This feature might very easily preclude their operation in the most desirable trade services.

From the standpoint of the oil companies the question of specifications is considerably simplified if they are limited to three: minimum gravity, sulphur content, and flash. With regard to the first, it is our feeling that a minimum gravity of 24 deg. A.P.I. should be generally satisfactory. We believe that a maximum sulphur content of 1.5 per cent should be acceptable. Minimum flash of 150 deg. closed cup has always been the standard. We should welcome an expression of opinion from you as to the suitability of these specification limits, and whether you do not feel that further restricting specifications are unnecessary.

I know you are all interested in the advancement of the Diesel engine. I am sure you agree that that advancement depends upon a suitable future supply of Diesel-engine oil at a reasonable price. I am equally sure that you have not been in a position to realize the fact that varied and restrictive specifications present a formidable obstacle to low-priced Diesel oil. I have endeavored in what I have said to show you that that is the case. The more liberal the specifications of oil demanded for Diesel engines, the greater the security of an adequate supply of fuel oil for them at a reasonable price in the future. To this extent the success of the Diesel engine is in the hands of its designers and builders.

## Discussion

J. J. Broshek.[2] The Navy is a large consumer of Diesel oil, principally as fuel for the engines of submarines, of which there are about eighty in service at the present time. Contracts for the oil are made by the Bureau of Supplies and Accounts in Washington, and all of it is required to be in accordance with Navy Department Specification 7-0-2 of May 1, 1925, only one grade of fuel oil for the Diesel engines of submarines being provided for.

General requirements in the specifications provide that the fuel shall be a hydrocarbon oil, free from grit, acid, and fibrous or other foreign matters likely to clog or injure the burners or valves, and, if required, shall be strained by being drawn through filters of wire gauze, 16 meshes to the inch. The oil must comply with the following five detail requirements:

1 The flash point shall not be lower than 150 deg. fahr., Pensky-Martens closed tester
2 Water and sediment combined shall not amount to more than 0.5 per cent
3 The total sulphur content shall not exceed 1.50 per cent
4 The viscosity shall not be greater than 200 sec. at 32 deg. fahr. by the standard Saybolt Universal viscosimeter
5 The ash shall not exceed 0.1 per cent.

The requirement of 150 deg. fahr. as the minimum flash point is standard for all grades of fuel oil used in the Navy except in the case of very heavy oils, when the flash point is required to be not less than the temperature to which the oil must be heated to give a viscosity of 8 deg. Engler or 30 sec. at 150 deg. fahr., Saybolt Furol.

A limit of 0.5 per cent of water and sediment is believed to be ample. This item is not included in the three specifications which are recommended by Mr. Michler, but it is considered a desirable one.

The sulphur content has been the subject for much discussion and thought, and only as recently as 1924, one year before the specifications now in use were issued, a sulphur content of not in excess of 1.0 per cent was required for Diesel oil; but oil with this comparatively low sulphur content was hard to get at a reasonable price, so the limit was raised to 1.5 per cent. There was a general belief that sulphur in the fuel had a decidedly corrosive effect, but with existing designs of engines there has been practically no complaint from vessels on this score. Examination of a large number of submarine engines has shown no pitting or corrosion that could be attributed directly to sulphur in the fuel.

Fuel for the Navy, whether Diesel or bunker oil, is never purchased under a gravity specification; the limiting factor for naval requirements is viscosity. For use on submarines the oil must flow readily even at a low temperature, and this quality cannot be covered by a gravity limitation since oils of the same gravity may have entirely different viscosities. At the fuel-oil testing plant in the Navy Yard at Philadelphia, there were recently tested two oils with identically the same gravity, 18 deg. B.; one, an Asiatic petroleum, had a viscosity of 4 deg. Engler at 90 deg. fahr; the other, an East Coast oil, had a viscosity of 4 deg. Engler at 189 deg. fahr.

The ash content is specified at less than 0.1 per cent and is kept low, because if present in any quantity it might cause serious injury to the working parts of the machinery. With the Diesel oils ordinarily supplied this requirement should present no difficulty.

To insure that the specifications are complied with, three representative samples are taken from each lot; one sample is tested by a Navy inspection office, one is for the contractor supplying the oil, and the third is for reference to the Bureau of Standards in case of a dispute as to the quality.

The Navy has had no trouble in obtaining fuel meeting the requirements of these specifications at a reasonable price; contracts are usually made for six months or a year and provide for deliveries of estimated quantities at certain designated ports both on the East and West Coasts.

[2] Commander U. S. N., Navy Yard, Philadelphia, Pa.

O. H. Weise.[3] The author has indeed rendered a splendid service in bringing to the attention of the Diesel-engine builders the lack of standardization of Diesel-fuel-oil specifications, and in the construction of engines which should burn the same qualities of oil so as to avoid the necessity of storage of various grades of fuel oil suitable for Diesel engines.

The shipowners operating Diesel-engined vessels have interests common with the petroleum industry in desiring a standardization of Diesel-fuel-oil specifications and should welcome the formulating of such a standard in order to insure the procuring of suitable oils at a more reasonable price, which such standardization would no doubt bring about. At the present time every Diesel-engine builder has specifications for fuel oils which in many instances have been found to meet the requirements of their engines, and in other cases grades of fuel oil have been arbitrarily selected which would be more beneficial to the life and operation of the engine, thus avoiding complications which would necessitate costly experimental work in developing fuel-injection systems in order to make their engines suitable for burning a heavier grade of fuel oil. Such divergence of opinion of Diesel-engine builders has brought about a condition which requires a considerable variation in the qualities of fuel oils required for Diesel engines, and which burdens the purchasers as well as the petroleum industry.

The above statements are borne out by the examination of the questionnaires submitted by engine builders with their bids on main and auxiliary engines recently opened by the Shipping Board.

The lowest grades of fuel which the various builders claimed they could use in their engines successfully varied between the following characteristics:

| | |
|---|---|
| Viscosity, Saybolt Furol, 60 deg. fahr. | 56 to 1000 |
| Acid | 0 to $2^1/_2$ per cent |
| Sulphur | 1 to 4 per cent |
| Ash | 0 to 1 per cent |
| Residue | 0.05 to 35 per cent |
| Coke | 0.20 to 5 per cent |

It may be of interest to know what fuels were used on the tests of the main and auxiliary engines built for the Shipping Board during the initial program which is tabulated below:

| | 1 | 2 | 3 | 4 | 5 | 6 |
|---|---|---|---|---|---|---|
| Baumé at 60 deg. fahr. | 26.8 | 24.9 | 21.1 | 25.6 | 20.3 | 19.70 |
| Viscosity, Saybolt Furol, at 77 deg. fahr. | 46.5 | 53.0 | 50.8 | 19.0 | 67.2 | 202.0 |
| Carbon, per cent | 86.5 | ... | 85.6 | 85.8 | 87.6 | 86.99 |
| Hydrogen, per cent | 12.4 | ... | 11.99 | 12.5 | 11.6 | 11.43 |
| Sulphur, per cent | 0.66 | 0.76 | 2.53 | 1.06 | 0.40 | 1.12 |
| Oxygen and nitrogen (Diff.) | 0.28 | ... | 0.95 | 0.62 | 0.38 | 0.46 |
| High H.V. | 19,374 | 19,180 | 18,780 | 19,164 | 19,002 | 18,954 |
| Low H.V. | 18,188 | 18,020 | 17,706 | 18,071 | 17,917 | 17,883 |
| Average temp. of fuel during test, deg. fahr. | $62^1/_2$ | 145 | 140 | $73^1/_2$ | 88 | 72 |

In establishing a specification for Diesel-engine fuel oils, the lowest quality should be established so that the owner of a Diesel-engine plant could obtain the advantage of low-priced fuels, which should enhance the economic value of the Diesel engine.

In the case of marine Diesel engines, the chief saving lies in the annual fuel bill, and therefore the lowest quality established as satisfactory would give the greatest saving, which naturally is of paramount importance. There is also the advantage that by setting a fairly low limit on the quality of fuel oils, the engine builders would be encouraged to strive toward the construction of engines which would meet conditions required for the use of this grade of oil, which would also be a stride forward toward the development of the Diesel engine.

The author did not mention viscosity, which appears to be the chief characteristic of fuel oils giving the engine builders concern. These oils must have a viscosity low enough to readily flow to the fuel pump and through the small piping between the fuel pump and fuel valves, so that if the highest viscosity permissible at the fuel pump is established, there is little reason to consider gravity.

The author's selection of the maximum sulphur content of $1^1/_2$ per cent seems reasonable, and in addition to the foregoing characteristics, ash and coke should be limited, as coke has a tendency to gum up the cylinders and piston rings, while ash, if found to any great extent, will have a detrimental effect in causing excessive liner and piston wear.

It has been rumored that one of the Standard Oil groups in the East has been carrying on experiments to develop a Diesel oil by treating ordinary bunker C by some process in order to reduce its viscosity, and it would be of interest to have the author give such information as he may be willing to disclose relative to the success that has been attained with these experiments, and also how the cost of this oil would compare with that of ordinary boiler fuel.

[3] U. S. Shipping Board, New York City.

Ernest Nibbs.[4] Many expert chemists who have grown up with the oil industry frankly state that they know comparatively little about the complex structures forming what are known as crude oils. In refineries, similar processes on different crudes result in differing products; different processes on similar crudes also differ in the results; and similar processes, except for small changes in temperatures and pressures, will produce different results from similar crudes. When it is considered that oil companies endeavor to market all their product, adjusting their processes best suited both to their raw material and the market of the moment, it is not to be wondered at that the Diesel-engine manufacturer as well as any other consumer receives a consideration exactly in proportion to the value of the oil company's product for which he provides a certain market.

Meanwhile the Diesel builder produces a Diesel engine. It is tested thoroughly, marketed, and after a time the customer comes along and says his engine will not burn the only oil he can obtain in such and such a place. Sometimes he says, "I can get burnable fuel, but I want to use the cheapest possible." Another says, "The engine must use oil picked up at any bunkering port in the world." And so the engine builder responds, and tests various kinds of fuel procured from many various fields, only to find that some unexpected results occur. By experience he finds that oils above a certain viscosity number have to be heated, and that goes into his specification; other oils, even if heated, give him trouble with wax in spray valves or carbon in valve passages; others seem to delight in depositing a sticky, resinous, asphaltic substance on and behind piston and rings, while some cause steel and iron parts to corrode extensively. Very naturally he specifies characteristics which he has found will give good service in his engines; but as all engines are not alike, as many fuel specifications exist as there are engines.

Mr. Michler proposes three qualities only: maximum specific gravity, maximum sulphur, and minimum flash point. With numbers 2 and 3 I am in agreement; the third for the reason that the insurance societies insist on a minimum flash point of 150 deg. fahr., and this requirement is of the nature of one imposed on two parties by a third party; the second, because up to 1.5 per cent sulphur my experience leads me to anticipate no trouble; but the first does not appear to me to be sufficiently fundamental or embracing.

Will specifying specific gravity alone or in combination with maximum sulphur and minimum flash point prevent an oil's being

[4] Chief Engineer, New London Ship & Engine Co., Groton, Conn.

supplied that will not flow at ordinary temperatures? Will it limit the amount of water that may be in the form of a mixture or an emulsion? Will it prevent too great a proportion of bottom ends being blended with a high-grade distillate? Will it insure a fuel that will not settle out into its original parts when in storage? I do not think it will, and yet all these points are important. Consider tar, asphaltum of the hard and soft varieties, resins, waxes, and coke; think of the various tests and names of the tests designed to define these constituents; the Italian tar test, which I confess was first called to my notice by Mr. Michler; the test by the Nolde method; the California tar test; the various degrees of purity of the petroleum ether used in dissolving the tar content, and likewise that of the benzine also used as a solvent. Therefore the first step to any fuel specification is to further standardize nomenclature of the various tests. Many of these are standardized already, the A.S.T.M. having done good work in this connection, but those in connection with tar and asphalt need some attention. Likewise the terms "tar," "pitch," "asphaltum of the hard and soft kinds," "asphaltic residues," etc., require definition and general adoption. After this has been done, the hardest part remains, viz., specifying "Diesel fuel" that will be fair to all engine builders, to the operators and owners of engines, and to the oil producers. It involves many things: whether the specifications are to be international and (or) national, national and (or) regional; whether the fuel to be specified is intended to be consumed by marine or stationary internal-combustion engines where ignition is by heat of compression only, including hot-bulb engines, or consumed by engines excluding these latter; whether the classes of fuel, if classes there be, shall limit in both directions or only one.

Here are the analyses of two different fuel oils, both of which are supposed to be suitable for Diesel engines (the latter of which will be pumped to a ship whether bunker fuel A, B, C, or Diesel oil is ordered):

| | | |
|---|---|---|
| Specific gravity | 0.9371 | 0.9395 |
| Baumé | 19.5 | 19.1 |
| Flash | 235 deg. fahr. | 220 deg. fahr. |
| Viscosity at 77 deg. fahr. Saybolt Universal | 950 sec. | 93 sec. |
| Viscosity at 122 deg. fahr. Saybolt Universal | 250 sec. | 50 sec. |
| Carbon residue, Conradson | 6.02 per cent | 1.50 per cent |
| Asphaltic matter, A.S.T.M. precipitation No., using petroleum ether | 20 | 4.8 |
| Water (distillation method) | 0.70 per cent | 0.42 per cent |
| Remainder after distillation by Engler method up to 620 deg. fahr. | 68 per cent | 42 per cent |
| Low heating value | 17,805 B.t.u. | 17,264 B.t.u. |
| Ultimate Analysis (percentages) | | |
| C | 84.76 | 87.34 |
| H | 11.64 | 11.04 |
| Sulphur | 0.83 | 0.37 |
| Ash | 0.06 | 0.02 |
| N | 0.48 | 0.06 |
| O and undetermined | 2 23 | 1.17 |

Both are not really good. They can be utilized, although the first requires heating to handle properly, and the second, though very fluid, has some high-molecular-weight compounds, probably aromatics, that are hard to burn.

The M.A.N. Company consider, in general, that viscous oils should be burnt with a small charge (about 5 per cent) of a superior grade of fuel; if this be not done, then in time the operator will pay excessively for wear and tear and maintenance due to unburnt fuel at light loads, besides having paid more in the first case for extra installation features, comprising special heaters in tanks, supply-line pumps, pipes on engines, special cleaning and filtering arrangements, and stowage for different fuels. Simplicity and reliability are the great needs of today in the marine world; many intricacies and complications are unavoidable, and we should therefore avoid those we can, especially in modern ships which can carry sufficient fuel for round-the-world trips from selected ports.

In order to present an alternative to Mr. Michler's proposal I submit the following as reasonably insuring a fuel that I believe would give satisfaction for guarantee purposes and continued operation for marine and stationary installation without pressing unduly hard on oil refiners for output or consumers for cost; and I would point out that specific gravity is not included in the requirements.

| | Marine | Stationary |
|---|---|---|
| Flash point, insurance-company requirement, deg. fahr., not less than | 150 | 150 |
| Heat content, operators' requirement, B.t.u. per lb., low heating value, minimum | 17,500 | 17,500 |
| Water content, operators' requirement, per cent, not over | 0.05 | 0.05 |
| Viscosity, operators' and builders' requirement, Saybolt Universal at 70 deg. fahr., not over | 200 sec. | 200–700 sec. |
| Sulphur content, operators' and builders' requirement, per cent, not over | 1.5 | 1.5 |
| Distillation, test builders' requirement, remainder after heating to 660 deg. fahr., per cent, not more than | 40 | 60 |
| Coke, builders' requirement, Conradson test, per cent, not over | $2^1/_2$ | 5 |

The engine builders are just as keen as the oil producers and engine operators to combine and specify a Diesel fuel such that all three industries may be run on a basis which will permit them all to obtain a fair return for their labor.

J. W. Morton.[5] There are two methods for utilizing liquid fuels for the generation of power: either the engines are adapted to the fuels, or the fuels are adapted to the operations of the engines. Sustained efforts are at present made in both directions, but whereas up till now engineering has been principally concerned with the first-named method, the oil industry has lately commenced to advance along the second line of procedure. For the Diesel engine, however, the results of these efforts are as yet insignificant.

I fully agree with Mr. Michler that an endless number of fuel-oil grades are just as perplexing to the Diesel-engine designer as it is for the oil refiner to have to furnish a special grade of fuel for every motor vessel in port.

For large horsepowers, two means are at hand for the designer: either increase the number of cylinders for a given bore, or increase the bore for a given number of cylinders, in order to obtain the desired horsepower. The shipowner is especially interested in smaller weight and space, resulting in lower first cost and larger-cargo earning capacity. The designer is interested in his cylinder dimensions, whether he can satisfactorily and completely burn his fuel-oil charge. The operating engineer is generally interested in the simplicity of his engine or engines, so that they will burn almost any kind of oil without changing all his valve settings, heating the oil, etc. Thus a uniformity in Diesel-oil specifications is a factor that interests more than one party.

I do think it is wrong for any builder to specify a certain grade of fuel oil; first, because the engine should be built so as to take care of a certain fluctuation in fuel Baumés, and secondly, it involves storage of maybe just as many grades of fuel oil as we have engine builders. With the present-day non-corroding steel

[5] Camden, N. J. Mem. A.S.M.E.

suitable for valves, I do not think sulphur plays such an important role that it is necessary to restrict its limit. I agree with Mr. Michler that a Diesel engine should more or less be able to "digest" all kinds of "food," within certain limits of course. Once, however, the engines are out of the hands of the builder, it is principally a question for the shipowner, as the real problem is one of upkeep, maintenance, and possible delay.

So far, certain regulations have been laid down regarding oils, and they have been divided into more or less useful and serviceable fuels. But the present aim of Diesel engineers is to build engines in such a way that all liquid fuels, including the most inferior and especially residues from the oil industry, may be used without any particular chemical or physical preparation. And this feature is responsible for the high degree of economy of the Diesel engine.

A preliminary condition for the use of any liquid fuels in Diesel engines is an exact knowledge of their chemical and physical properties. Strange to say, no sufficient attention has been paid up till now to the chemical and frequently also to the physical properties of liquid fuels with regard to their applicability to various classes of internal-combustion engines, and above all to the Diesel engine.

For the chemical properties of liquid fuels with respect to their use in the Diesel engine, the following factors are of importance:

1 General chemical composition for ascertaining:
  *a* Ignition and combustion and the equipment required for same
  *b* Effect of a possible presence of sulphurets on engine parts that come into contact with either the fuels themselves or with the combustion and exhaust gases
  *c* Possible effect of the presence of asphalt components, especially in case of their incomplete combustion
  *d* Effect of the presence of free carbon.
2 The ash contents, i.e., purely inorganic incombustible combinations or incombustible residues of salts from organic acids which adhere to the engine parts after combustion and cause wear and tear.
3 The heating value for approximately judging the type of fuel and determining the consumption and thermal efficiency.

Of the physical properties of liquid fuels the following are important:

4 The specific gravity, for an approximate estimate of the fuel and heating value and for determining the space required for fuel consumption and fuel requirement.
5 The flash and the combustion point, for an estimate of the fuel, the danger of fire and the requirements for storing.
(Points 4 and 5 do not concern the work of the engineer.)
6 The boiling curve, for ascertaining the composition in quality and quantity of the boiling points of its various components.
7 The viscosity at various temperatures, for ascertaining the degree of fluidity and the contrivances necessary for the feed and conveyance to and within the engine and for determining atomization by air or mechanical pressure into the combustion chamber.

As regards the technical treatment of oils, to this must be added the presence of water and mechanical impurities, which can be reduced to the lowest possible minimum for permanent work by separation, evaporation, or filtering devices.

The burning of heavy oils in an oil engine is a point of great interest. It is true that solid impurities may be fairly readily separated from the oil by mechanical means such as filters, settling tanks, and centrifugal separators; but it is the hard asphaltum case formed during the combustion that is the troublesome element. Hard asphaltum can be completely burned and is burned in some oil engines, all that is required being sufficiently congenial conditions of temperature and time coupled with sufficient air. The secret of burning asphaltum is to obtain as perfect combustion as possible. The indication of good combustion is low fuel consumption on an i.hp. basis, and generally speaking the engine with the lowest fuel consumption per i.hp. will most readily burn hard asphaltum. The fuel-injection system associated with the lowest fuel consumption on an i.hp. basis will generally be the system most suitable for using boiler oils with hard asphaltum content; but at the present day there seems to be little to choose between the best systems of either air or mechanical injection as regards fuel consumption per i.hp. Obviously, however, the engine with the lowest consumption per b.hp. will burn a minimum of oil and therefore is subject to a minimum of abrasive matter in the oil. This latter may appear unimportant at first sight, but it must be remembered that there are well-known Diesel engines burning 0.44 lb. per b.hp. and others burning 0.36 lb. per b.hp. under service conditions, a difference of 25 per cent. It is here that some solid-injection oil engines will show a distinct superiority.

Broadly speaking, therefore, it may be said that any contrivance or construction, such as improved shape of combustion chamber, which will tend to reduce the fuel consumption will also tend to reduce the formation of asphaltum coke. The foregoing is an illustration of the necessity for obtaining the best possible fuel consumption not only on the grounds of economy of fuel but also because it means perfect combustion with consequently improved operating conditions of the cylinder parts.

Most of our fuel-oil specifications are incomplete, I think. The more readily the heat units can be converted into work, the higher the price that can be paid for the fuel. The connection or ratio between the hydrogen and carbon atoms in the fuel oil is a good measure for its suitability in oil engines, but these are generally omitted in the ordinary specifications submitted when bunkering. The hydrogen content is a direct measure of the formation of a volatile "oil gas," assured by the great heating-up of the oil. The more susceptible the oil is to formation of this gas, the better it is suitable for oil-engine service.

This ratio, as specified by some well-known European shipowners, is expressed by the percentage of the carbon and hydrogen atoms combined in the fuel, i.e.,

$$\frac{\text{H}}{\text{C}} = \frac{\text{Per cent of H in oil} \times 12}{\text{Per cent of C in oil}}$$

The best all-around results are obtained when this ratio is as near as possible to 2, and it should not fall below 1.6.

The use of "boiler oil" for oil engines is principally a question for the shipowner, as the real problem is one of upkeep, maintenance, and possible delay. Oil engines can be run on boiler oil satisfactory if care is taken to rid the oil of water, sand, and other earthy matters by heating and centrifugal force. The heating is also necessary to enable the oil to be pumped and to permit of proper atomization, and excepting for a slightly higher fuel consumption, it is, so far as running is concerned, a perfectly good oil to use.

Both ash and hard asphaltum are very undesirable and must be avoided on account of the abrasive action within the cylinder, which spells "repairs," and it resolves itself into an economic question whether the saving in fuel cost warrants the greater detention and repairs. Whatever policy is adopted, it is certain that all motorships should be capable of burning oil fuel in the event that Diesel oil is not available at some bunkering station.

It is interesting to note what the author says about the im-

portance of the sulphur content of the oil. Where damage has occurred, it might have been caused by other constituents of the oil. It is reasonable to suppose that sulphur could not form sulphuric acid within the cylinder because of the temperature's being too great.

I think I am right in quoting that from the separation of crude oil 15 per cent is classed as gas oil and 45 per cent as boiler oil. The latter percentage is sure to increase at the expense of the former through the ever-increasing demand for the lighter distillates, particularly gasoline and thus we come to the crucial question: What is a shipowner to do in a few years' time with an engine which is restricted to the use of an engine oil that is difficult to obtain? Builders must prove to owners and superintendents that the use of boiler oils does not necessitate repairs if the oil is properly rectified.

The ash content in oil used in Diesel engines should be as low as possible, since ash causes wear on the cylinder liners and piston rings. A figure of 0.05 per cent should never be exceeded, and this is higher than desirable. In a few motorships boiler oil is now being exclusively employed for the Diesel engine, and the best results appear to have been achieved when arrangements are made for purifying the oil by means of centrifugal separating machines. The main object of their employment is the elimination of all water (which is less easy of separation in settling tanks than is the case with Diesel oil), as well as the ash content so far as possible, together with mechanical impurities. In all cases where boiler oil is employed it must be heated by steam coils in the tanks or by other means, while steam heating should also be provided in the gravity tank. The centrifugal machines are comparatively small plants driven by electric motors (or steam turbines) at a high speed of rotation. It may be estimated that about 50 per cent of the ash content in the oil can be removed by centrifuging, while the water can be totally eliminated. Asphaltum is not removed by passing the oil through a centrifugal separator, but this has no detrimental influence in the Diesel-engine cylinder.

The flash point at which oil can be carried on motorship has been reduced to 150 deg. fahr., so that ships may bunker at practically any port they like to visit. Settling tanks should be high and of small horizontal area and provided with heating coils fitted vertically for about two-thirds of the height of the tank to insure rapid and uniform heating of the whole of the oil in the tanks. The heating surface necessary is approximately 2.5 sq. ft. per ton of tank capacity. If viscous oil is likely to be used, heating coils should be fitted in the main fuel tanks. The heating surface necessary is about 0.7 sq. ft. for deep tanks and 1.5 sq. ft. for cellular double-bottom tanks per ton of tank capacity.

Chemists and engineers, by the help of analysis of deposits in the cylinders and exhaust passages and by signs of wear and tear obviously resulting from the use of the fuel employed, have been able to determine the constituents forming the oils which are responsible for these undesirable manifestations, and as a result of this experience are now able to prepare specifications of oils suitable for use in Diesel engines; but since these cannot be had at every bunkering station, their use is very much restricted and the importance of such specifications is somewhat nullified, and as already said, a broad specification should be adopted, sufficient only to exclude oils which would be liable to cause danger or detention, etc. to the ship, should an unsatisfactory oil be bunkered.

To summarize conclusions: Oil for marine purposes has come to stay; coal, aided by the as yet undiscovered perfect condenser tube which will permit the use of water-tube boilers with really high pressure, may still put up a good fight. The itinerary which a ship must follow is a factor in determining the most suitable machinery, but is lessening in importance as the provision of oil increases in those countries which do not produce oil. Specifications will help us to realize what we want, but will not enable us without experience of similar oil in similar engines to indulge too freely in prophecy. It should warn us off the rocks of ash and hard asphaltum, which cause wear and low hydrogen, which means low efficiency. More economical use must be made of existing supplies. As engineers we are equally ready to build and to operate with equal technical efficiency steam engines or oil engines, and any system of transmission of power, mechanical, electrical, hydraulic, or Magnus currents, which may appear most suitable to the business in hand. But commercial efficiency as between ship and ship may vary very widely with the various types of machinery, and it is on the commercial efficiency of our gear that we must rely for our future successes.

T. B. Danckwortt[6] and M. S. Reynolds.[7] The difficulties encountered by the petroleum industry in meeting the varied demands for Diesel-engine fuels have been presented by Mr. Michler in a very clear statement, with which we are in full agreement, as Atlantic Seaboard and Pacific Coast conditions with regard to facilities for fuel distribution are practically identical. Because of the fact that many Diesel engines are manufactured on the eastern coast, and hence designed with the use of eastern fuel oils in mind, we have encountered some difficulties in the application of western fuel oils to Diesel-engine operation which would be of general interest. Until a few years ago the problem of obtaining suitable fuel for Diesel engines was a simple one, but the enormous automotive-industry demand for gasoline has resulted in changed refining conditions so that the lighter grades of gas oil are no longer available in as large quantity for Diesel-engine use. The increased number of Diesel engines operating has also been a factor. The situation has become further complicated by the advent of a new type of engine, the high-pressure solid-injection type, some forms of which are very susceptible to slight variations in the physical characteristics of the fuel used. The essential requirements for the complete combustion of fuel of any type are sufficient oxygen, time, and initial temperature, and for optimum operation these factors must be combined properly by the correct and timely distribution of the fuel spray which has a penetration ability conforming to the requirements imposed by the density of the air, the shape of the combustion chamber, and controlled air-turbulence action. As a general rule, paraffin-base fuels burn somewhat more readily and rapidly than asphalt-base fuels of similar characteristics. For this reason, some of the smaller-sized engines of the solid-injection type manufactured in the East and particularly adapted to eastern fuels, give unsatisfactory performance on California fuels. On investigation, it was found in each case that the design of the combustion chamber and injection system was unsuitable for the complete combustion of California fuels, and after redesigning the engines in this respect the flexibility as to speed and permissible variation in fuel was greatly improved and in several instances the horsepower was increased 40 per cent. Because of these experiences we consider that the engine manufacturer should feel it his duty to test each new engine type and size with both paraffin- and asphalt-base fuels so as to be certain that his engine will be suitable for operation on either of these types; as well as the intermediate varieties of fuel, and hence that the purchaser will not be restricted in his choice of fuel and field of operations.

At the present time the types of Diesel engines used on the Pacific Coast and operating on California fuels are as follows:

1 *Air-Injection Type.* Air-injection engines, when properly

[6] Diesel Engineer, Union Oil Company of California, Los Angeles, Calif.

[7] Research Engineer, Union Oil Company of California, Los Angeles, Calif.

adjusted, can obtain perfect combustion with asphaltic fuel oils, regardless of gravity, viscosity, or other characteristics within wide limits. Because of the possibility of adjusting the pressure, quantity, and temperature of the injection air to obtain the best fuel economy, fuels, ranging in gravity from 12 deg. to 40 deg. A.P.I. can be used successfully in this type of engine, in spite of the comparatively short and late injection period, although in general the closed type of injection valve has somewhat better atomizing characteristics for the heavier fuels. Of course, the atomization and flame-propagation characteristics of the fuels change with the physical properties, such as gravity and viscosity, but the possibility of controlling the air-turbulence energy by the injection pressure and by the timing permits wide variation in the physical characteristics of acceptable fuels. All the conditions for efficient combustion, namely, fine and uniform atomization, air turbulence, good distribution of the fuel spray, excess air, and high compression, may be met without restricting the engine to the use of special grades of fuel.

2 *Precombustion-Chamber Injection Type.* Diesel engines of the precombustion-chamber injection type vary widely in their design and operating characteristics. In general, engines with small restrictive passages between the precombustion chamber and the main combustion chamber usually have insufficient air turbulence and heat conduction to the precombustion chamber, and this results in rapid carbonization unless the dimensions of such antechambers, including the injection device, have been developed especially for operation on our particular fuel. In other words, engines with such restrictive passages are usually poorly adapted to operation on fuels of varying characteristics.

The type of precombustion injection engine with a plain cylindrical neck between the precombustion and main combustion chambers gives a timed air turbulence before and during combustion which is adequate for the complete combustion of asphaltic fuel oils, and thus the fuel flexibility of these engines approaches that of the air-injection type. When well designed and properly adjusted, they can operate on a wide range of California fuels from 14 deg. A.P.I. up, regardless of flash point or viscosity. This system of injection is well adapted to small- or medium-sized engines of low or high compression and either two- or four-cycle. Many engines of this general type are now operating satisfactorily on Pacific Coast fuels.

3 *High-Pressure Fuel-Injection Type.* In this method of injection the fuel is forced directly into the cylinders through nozzles of very small diameter by means of high hydraulic pressures. Engines of this type are therefore very sensitive to variations in the physical characteristics of the fuel, since changes in the viscosity particularly influence the atomization and penetration characteristics of the injection spray. It is frequently found that the efficiency falls off markedly with a variation in the gravity of the fuel beyond a range of about 4 deg. A.P.I. unless the nozzle size is changed. This sensitivity toward fuel variation is marked even in the largest sizes of engine, and becomes still more serious in the small sizes. With proper adjustment of the injection by the use of suitable nozzle types, fuel pressure, and timing, the high-pressure solid-fuel-injection type of engine is well suited to Pacific Coast fuels of 24 deg. A.P.I. gravity and lighter, and the fuel economy obtained is very satisfactory. This economy, however, has been attained at the expense of sensitiveness to fuel variation, with the result that the responsibility for permanently efficient operation has been place on the oil companies instead of being assumed by the engine designers. European practice has shown that engines of the solid-injection type can be designed with greater flexibility as regards variation in fuel by giving particular attention to air turbulence with the use of open combustion chambers and high injection pressures.

A tabulation of the gravities of California fuel oils which have been used successfully in engines of different types can serve only as an approximate indication of the fuel flexibility of the various engine groups, as this flexibility depends so largely upon adjustments, loads, and minor variations in the design. However, as it may serve as a rough classification of engine characteristics with special reference to operation on Pacific Coast fuels, the following list of engine types and of fuels which have been successfully used in them is presented:

1 Air-injection engines, large and small sizes, two- or four-cycle, medium fuel pressures, uniform and controlled air turbulence, high compression; 12 to 40 deg. A.P.I. gravity.

2 Precombustion-chamber engines, two injection sprays, air or solid injection, medium fuel pressures, medium to high compression, cylindrical neck, four-cycle, controlled air turbulence; 14 deg. A.P.I. gravity and up, depending on type and size.

3 Precombustion engines, one injection spray, air or solid injection, low and medium fuel pressures, two-cycle, four-cycle, open neck, controlled air turbulence, low or medium-high compression; 16 deg. A.P.I. gravity up to gasoline, depending on type, size, speed, and load conditions.

4 High-pressure fuel-injection engines, two injection sprays, opposed-piston types, high compression, high fuel pressures, two-cycle, open combustion chamber, air turbulence; 18 deg. A.P.I. gravity and up, depending on size and speed.

5 High-pressure fuel-injection engines, one multiple-hole spray, high compression, high fuel pressures, two- or four-cycle, open combustion chamber, air turbulence; 20 to 22 deg. A.P.I. gravity and up, depending on size and speed.

6 High-pressure fuel-injection engines, one multiple-hole spray, medium or high compression, high fuel pressures, four-cycles, or two-cycle, open combustion chamber, no air turbulence; 24 deg. A.P.I. gravity and up, limited range for each engine, depending on size and speed.

7 Medium- and low-pressure fuel-injection engines with restricted antechamber, one injection spray, high compression, two- or four-cycle, cups, tubes, etc., partial air turbulence; 26 deg. A.P.I. gravity and up, depending on type and size.

What has been said about the combustion difficulties encountered on the Pacific Coast with Diesel engines of medium size applies with even greater force to the small engines which are now appearing in increasing numbers, as the sensitivity toward fuel variation increases as the combustion chamber becomes smaller, the piston speed greater, and the explosion pressures higher. Although this class of engines is still in a critical stage of development, the successful operation of foreign engines of this class on the Pacific Coast for many years has established the feasibility of building small engines which will operate satisfactorily on a wide range of fuels. Much research on engine design in relation to fuel flexibility remains to be done in order to insure a permanently cheap fuel supply to the small Diesel-engine users. To illustrate the type of service in which these engines are used and the economy which may be obtained, the following example is given:

A 2-ton Diesel boat, 21 ft. in length and equipped with a 4-hp. engine using regular Diesel fuel oil which costs $2^3/_4$ cents per gallon at Los Angeles Harbor, can run about 800 miles for an expenditure of only $1 for fuel.

From our experience with western fuels in Diesel engines, we are in complete accordance with Mr. Michler's proposal to simplify the specifications for Diesel fuels by omitting such items as carbon residue, asphalt, surface tension, etc. As long as the functions and importance of these properties have not been established by fundamental research, definite specifications for such characteristics must be considered as premature. The elaborate specifications originating with some Diesel-engine manufacturers are considered to be the result in most instances of experience in limited markets rather than of careful experimental work. Mr. Michler proposes to restrict the specifications to minimum gravity, sulphur content, and flash point. In our

opinion, the specifications for the ordinary grade of Diesel fuels (that is, excluding the heavy industrial fuel oil which can at present be used successfully in only a limited number of engines) should contain the following items:

1 Gravity. This is important as an index to the class or grade of oil, although fundamentally the property is of less importance than viscosity. A minimum gravity of 24 deg. A.P.I., as proposed by Mr. Michler, should be acceptable at the present time to both the Diesel-engine manufacturers and the petroleum industry.

2 Flash Point. As the flash point may be decreased by the presence of a limited amount of low-boiling material in the oil, it is not as significant as regards the burning characteristics of the oil as the fire point, which is the temperature at which the fuel vapor continues to burn. Until the relative efficiency of fuels of varying fire point in engines of definite compression pressure has been thoroughly determined by extensive experimental work, it is felt that no specification should be arbitrarily chosen for this property. To insure safety in handling the fuel oil, it is felt that a minimum flash point of 150 deg. fahr. in the Pensky-Martens closed cup should be specified, as has been common practice in the past.

3 Water and Sediment. This test was not mentioned by Mr. Michler, but it is felt that it should be specified to protect the buyer from the delivery of contaminated oils. An acceptable oil should have a water and sediment content not exceeding 1 per cent.

4 Viscosity. The viscosity of a fuel oil is of more fundamental importance than the gravity, as it measures directly the characteristics of the oil as regards flow through nozzles or lines. While the specification of 24 deg. A.P.I. as the lowest gravity permissible will automatically exclude oils of extremely high viscosity, it may be advisable to include a viscosity specification as a further safeguard. It is suggested that the maximum permissible viscosity be set at 100 sec. Saybolt Furol at 77 deg. fahr., following Government specifications for Navy Standard and Bunker Fuel Oil A, which, according to Technical Paper 323-B, United States Government Master Specification for Lubricants and Liquid Fuels, are both high-grade fuel oils which may be used in Diesel engines. It should be understood that this applies only to the usual grade of light Diesel fuel oil and not to heavy industrial fuel oils such as are commonly used for steam boilers but which have a restricted use in Diesel engines.

The specification for sulphur content, although not objectionable to Pacific Coast refiners if set at 1.5 per cent maximum, as suggested by Mr. Michler, is considered unnecessary, as the deleterious effect of sulphur on engine parts has been greatly exaggerated; some Diesel installations have been operating for over 20 years and under adverse conditions on Mexican fuels containing 3 to 4 per cent sulphur and still retain the original cylinders and pistons.

The limiting of Diesel fuel specifications to gravity, flash point, viscosity, water, and sediment should not work any hardship upon Diesel-engine manufacturers and should be satisfactory to the oil refiners. In considering the suggested figures for the specifications, it should be borne in mind that these may be subject to future modification as dictated by economic necessity. Even with this possibility of future change, however, the establishment of definite specifications at the present time will assist materially in the standardization of engine-fuel requirements and available types of fuel, with benefit to the engine-manufacturer and user, as well as to the oil companies, through greater economy of operating because of decreased fuel costs. The experience of our company in common with that of other members of the petroleum industry has proved the impracticability of attempting to maintain supplies of a large variety of Diesel fuels throughout the territory in which we operate, and to a lesser extent the inadvisability of supplying special fuels even to groups of consumers that happen to be located near a refining center.

As regards the future development of Diesel-fuel specifications, there is little doubt that economic considerations will force the use of progressively heavier fuels. One of the chief factors in this development is the increasing importance of gas oil as raw material for the production of gasoline by various cracking processes. The demand for gas oil as cracking stock in competition with its use as Diesel-engine fuel has already resulted in the establishment of a substantial differential in price between this commodity and heavy industrial fuel oil, and we may anticipate that this differential will tend to increase rather than decrease. The obvious remedy for the increasing cost of Diesel-engine fuels of the gas-oil type is the construction of engines which are suitable for operation on heavier oils.

One of the serious obstacles that the Diesel-engine industry must overcome is the fear of prospective purchasers that possible future increase in the price of Diesel fuel will nullify the present economic advantage of the Diesel engine. To overcome this fear, and thus insure their own future, the manufacturers must make their engines sufficiently flexible in fuel utilization to take advantage of the grades of oil economically available. The greatest increase in the use of Diesel power will come through replacement of steam plants, and when it is considered that a steam plant uses nearly three times as much oil as a corresponding Diesel plant, it is evident that such replacement will create a considerable surplus of boiler fuel. This will tend still further to increase the differential between boiler fuel and lighter fuel of the gas-oil type. With such developments, the engine that is restricted to the use of a light fuel will be penalized, and it is to the interest of the Diesel-engine industry at this time to prepare for such a contingency not only by standardizing on a simple specification for a type of fuel which will continue to be available for a considerable time, but also by developing designs of engines which are adapted to the use of heavier grades of fuel.

Harte Cooke.[8] Mr. Michler's paper gives a very interesting statement of the confusion at present existing in regard to the question of Diesel fuel oil:

I think that a general specification about as follows will cover the situation in regard to Diesel fuel oil:

Viscosity not more than 25 Saybolt Furol at 60 deg. fahr. The reason for this requirement is that fuel more viscous than this cannot be handled conveniently through piping without special provision for heating.

Flash, 150 deg. fahr. The reason for this requirement is to comply with the results of the classification societies.

Water, dirt, and foreign matter not to exceed 1 per cent. The reason for this is to prevent excessive cost in settling and cleaning the oil.

Gravity, 22 to 30 B. The reason for this is that oils heavier than 22 usually have to be heated in the system to make them fluid. Oils lighter than 30 are apt to give trouble owing to seepage past the fuel valves, causing carbonization.

In general, an oil corresponding to these specifications should be entirely satisfactory for Diesel engines.

V. L. Maleev.[9] Our experience shows that the present high-compression Diesel oil engines, particularly those equipped with the airless mechanical-injection system, can handle satisfactorily any fuel oil, provided it is clean and not excessively viscous. I agree with Mr. Michler that the specifications should be broad, and I think that the ones he suggests can be adopted by all

[8] McIntosh & Seymour Corp., Auburn, N. Y. Mem. A.S.M.E.

[9] Consulting Mechanical Engineer, Western Enterprise Engine Co., Los Angeles, Calif. Mem. A.S.M.E.

Diesel-engine builders: minimum gravity 24 deg. A.P.I., minimum flash of 150 deg. fahr. closed up, and maximum sulphur content of 1.5 per cent. However, I think that it is advisable to add one more specification, namely, limits for viscosity.

We all know that a very viscous oil is apt to give trouble by clogging small-size pipes, especially when the outside temperature drops sufficiently low. On the other hand, we also know that it is very difficult to keep tight glands in high-pressure fuel pumps, valves, and fuel needles if the oil is not viscous enough. Generally speaking, a gravity of not less than 24 deg. A.P.I. determines to a certain extent the viscosity, but not always in a sufficient way. Therefore it seems that viscosity limits should be prescribed but should be sufficiently broad, namely, a minimum of 40 sec. and a maximum of about 260 sec., both Saybolt Universal at 100 deg. fahr.

E. P. Kiehl,[10] and J. B. Hill.[11] The use of Diesel engines is growing quite rapidly, and the question of specifications for fuel is increasingly important. It would be advantageous if one type or grade of oil could be found suitable for all designs of engines, but this is not possible with present designs. It is desirable to restrict the number of oils to as few as possible and to make the specifications as broad as possible. We do not agree with Mr. Michler that fuel specifications should consist of minimum gravity, sulphur content, and flash, since we consider these three items the least important. The specific gravity only furnishes a rough index of the general type of the oil and a very rough estimate of the heat values. The flash point only measures the danger from fire in transporting and storing the oil. The amount of sulphur has little if any influence on the behavior of the engine.

The viscosity has a very important bearing on the ease of atomization and consequently on the thermal efficiency of the engine. Oils of low viscosity tend to produce smoother operation and a cleaner engine than oils of high viscosity. It should be noted, however, that if the viscosity is too low, trouble may be experienced in the fuel pump, which in a great many designs relies on the fuel oil for its lubrication. Heavy asphaltic matter probably has an influence on the performance, principally on coke troubles around the exhaust valve. The specification for this quality might be the A.S.T.M. precipitation number or some other equally simple test. Some of the troubles in Diesel-engine performance can be traced to foreign matter, and the quantities of inorganic ash, insoluble matter, and water should be limited by specification. We feel that a specification of the following points should insure better operation than the suggested specifications of Mr. Michler:

Max. and min. Saybolt Universal viscosity at 100 deg. fahr.
Maximum asphalt
Minimum Pensky-Martens flash deg. fahr.
Maximum ash content, per cent
Maximum sediment, per cent
Maximum water, per cent.

The case which Mr. Michler mentions in which a supposedly better grade of Diesel fuel gave trouble when the poorer grade did not, is, in our opinion, attributable to the fact that the engine was adjusted for the poorer grade and was capable of handling it, and the change to the cleaner and lighter oil without adjustment might have been expected to cause trouble.

L. K. Doelling.[12] As the Diesel engine is a very flexible engine and there are very few oils that cannot be burned successfully, I believe we should not make complicated specifications for a few exceptions. We have not found a single oil not suitable to be burned in a Diesel engine in the last five years.

About 23 years ago I drafted the first specification for fuel oil. It was short, but as time went on and we met with difficulties, we added to the specification. It should be remembered that at that time we built a low-pressure oil engine which is more sensitive. It was not long before the specifications covered a whole page, and we found considerable sales resistance because customers objected to the specifications for the oil.

About two years ago we drafted a new specification which is simple but apparently answers the purpose as we have not encountered any difficulties. It reads as follows:

> The engine will burn any commercial fuel oil produced in the United States or Mexico, and such crude oils or crude oil mixtures are now successfully being used in Diesel engines of similar size.

H. E. Brelsford.[13] The oil companies seem to think that "oil is oil," and any Diesel-engine company that will put an engine out without specifying the kind of oil to be used in it is certainly hunting trouble. Mr. Nibbs hinted somewhat, and quite specifically, at the variations in oil. I remember when I took organic chemistry in school we had a Russian professor, and our introduction to the hydrocarbon group was this: "Gentlemen, there are more than fifty-thousand compounds in this group, and we don't take all of them in this semester."

I think this whole thing simmers down to this:

No one today that I know of is building a universal atomizer, that is, one that will burn any oil that may be put in it in any engine in any part of the world. Over in Europe they are burning 33 or 34 B. fuel oil.

In this country you cannot control the kind of oil that a customer wants to use in his engine, and therefore a specification on fuel oil should be such that an engine builder can build an engine with an atomizer that will be entirely satisfactory, according to the specifications given for that engine. And then if any one wants to burn some other kind of fuel, the burden of making such changes or readjustments should not be up to the builder of that engine, but the expense should be borne by the customer. I think for that purpose a standard fuel oil is probably the desirable thing.

W. H. Butler.[14] One of the first things I should like to mention is that the statement that the oil companies are not in agreement is very true, and sadly true. If they were, the conditions we are facing today would not be as important as they are. If in the beginning the Diesel-engine industry and the oil companies had stood together and worked out their specifications together, and the Diesel-engine industry had built the engine around the specifications, then today we should not be trying to furnish numerous grades of oil for various engines.

For instance, there is one motorship running in New York harbor that if it were bunkered with an oil with a viscosity below 60, could not get out of the harbor.

There are two things I want to bring up, and one is the B.t.u. per lb. In test work, of course, everything is figured on B.t.u. per lb., but we do not burn the oil by the pound, but by the gallon, and why not specify the B.t.u. per gallon? We inject a definite amount of oil into the combustion chamber, and that is a volumetric measurement, not a weight measurement. If we look over some of the theoretical measurements of B.t.u. per gal. and per lb., we shall realize that condition. For instance, 32 gravity oil has 19,530 B.t.u. per lb., the weight is 7.169, and the B.t.u. per

[14] Standard Oil Co., New York, N. Y.

gal. is 140,010.57. And then we come to 20 B. oil, which has a weight of 7.772, with 19,050 B.t.u. per lb. and 148,056.00 B.t.u. per gal.

At one time our company was experimenting with some heavy oil which quite a few men present have used and tested. We showed some very peculiar results. We would take gas oil, 32 gravity, run it against this oil, which was 18 gravity, and show a 6 per cent saving in fuel. It is merely in the difference in the weight and number of B.t.u. per gallon. This was not only proved in the test which was made, but certain small boats running in New York harbor, covering a period of 18 months, showed month in and month out a 6 per cent saving, due to the weight and the number of B.t.u. per gallon.

Gravity has always been accepted as a standard specification for a Diesel fuel. Of late years this has become unimportant, for the gravity range no longer is a criterion of the function of the oil. It is our contention that viscosity should be a standard specification. In atomizing a fuel we are attempting to produce from a given quantity the greatest possible number of the smallest possible drops. As the volume decreases by the cube of the diameter and the surface decreases by the square of the diameter, then in spraying of fuel surface, tension plays a very important part. Viscosity is a fair indication of the surface tension.

If we plot the curves of various oils from the very volatile substance of the heavier oil over a wide range of temperatures, we find that the surface tension decreases with the viscosity. There has been some work done on this subject at Bayway Research Laboratory, but so far as we can find, no one has attempted previously to prove the relation between viscosity and surface tension. At one time gasoline was quoted in terms of gravity, which at present is obsolete. The same should hold for Diesel fuels, especially since cracking has become prevalent. The gravity of an uncracked stock will be 20, with a viscosity of 150 sec. Universal and a surface tension of 29.5, while a cracked stock of the same gravity will have a viscosity of 50 sec. Universal and a surface tension of 18.5. We have gone into that very carefully and have obtained a great many figures, and our laboratories are still working on it. Any further information that we obtain we shall be glad to pass on to the Diesel-engine industry.

We can give various examples of this with widely varying gravities, and yet hold the viscosity and surface tension consistently. As the Diesel-engine industry develops we shall make use of more cracked products for fuel, thereby rendering the gravity specifications even less reliable, while on the other hand, if we accept the viscosity specification no matter what the stock, we have an indication of surface tension and thereby an indication of how thoroughly the oil will atomize. This is more vital today owing to the rapid progress made in high-speed Diesel engines. The qualities limiting the speed of a Diesel engine are the ignition lag and combustion time, which are products of atomization. We are attempting by atomization to produce a homogeneous air-fuel ratio. To do this we must expose the greatest possible area to the available air, for the rapidity of combustion is proportional to surface; therefore we are not interested in the weight of a Diesel fuel, but in an indication of how rapidly the oil will atomize.

Mr. Weise, of the United States Shipping Board, asked for information on the fuel that we had been working on, and spoke of it as a bunker C oil. This was an experiment which we were working on. We put up a plant with 250 bbl. capacity, and we worked on it for two years, producing different kinds of fuel. We would take a heavy product and produce from it a very low viscosity and thereby a low surface tension. That would work very well in certain types of engines. It was tested in practically every engine made. We even sent samples to Germany, and they ran these tests in the engines of leading European manufacturers of Diesel engines. We got very satisfactory results from those tests. Today we are not going into it, because of the economic conditions in the oil companies today. At some future time, if the lighter oils become scarce and the cycle swings around, we shall go into this proposition, and practically guarantee that we can furnish an oil of 12 or 18 gravity that will meet specifications and will burn with no trouble in engines.

There has been discussion relative to the Italian tar test, which is really a lubricating-oil test, determining the sludge that can be produced in the oil. It means nothing in fuel oil. You can sludge any oil by this method, but of course lubricating oils begin to sludge at a very sticky and slimy stage, that which adheres to pipes and strainers, and it is not advisable for any fuel oil. However, this sludge is a homogeneous mixture with fuel oil and is burned readily.

Among the various complaints received, and the troubles reported by the operators of Diesel engines, we have found as a rule that the plant was as much to blame as the oil. In other words, the fuel tanks had not been cleaned, and improper methods were used in straining oils. Any oil is bound to carry a certain amount of sediment out of the tank cars, including salt water, scale, etc., and when thousands of gallons of oil are passed through the tank during a year, a certain amount of the sediment which settles, gets into the oil and is bound to cause trouble, even though that material would not show up in the analysis. Consequently, if the fuel tanks are not cleaned consistently and persistently, the operators are going to experience trouble due to that fact.

Limiting specifications will not eliminate troubles. There are lots of things about oil that we do not and will not know for a number of years. A certain company had a very peculiar complaint from one of their users several months ago, and got in touch with the writer's company. The oil was not supplied by them, but by another oil company in another locality. Looking into the matter, it was found that the specifications were beyond reproach. It was found at that time that the particular batch of oil that had been delivered and used in that engine had a high percentage of aromatics. It would not show on the specification, and there was no way in the world to determine it except by test. The various types of materials and compounds in their relation to the oils are so complicated that one batch of oil from one refinery, treated under certain conditions, will be entirely different from that from another refinery. The same is true with the by-products.

Those things are out of our control, and out of the control of every one else, but if we can get a set of specifications that are agreeable to every one, and yet fair to every one, it will solve our problem, and also advance the development of Diesel engines considerably.

Oliver F. Allen.[15] I wish to speak about the comparative cost of oil used in steam apparatus and in internal-combustion engines. It has been stated here that the ratio is 1 to 3; that is, steam equipment requires three times as much fuel as that used by the internal-combustion engine, doing the same class of work. I think that is true in the average marine and land equipment today. But we are looking to the future. Consequently we should use as a measuring stick the best performance at the present time, and that best performance represents a ratio of 2 to 1 and not 3 to 1.

I believe that when certain marine steam installations which are now under construction and being studied are put into operation, it will be found that they have practically caught up with the Diesel in some classes of service. So the question of utilizing the same grade of oil in internal-combustion engines

[15] Manager, Automotive Sales, International General Electric Co., Schenectady, N. Y. Mem. A.S.M.E.

that is used under boilers is of prime importance. For the steam plant is going to give the Diesel a race in the matter of overall efficiency.

Another point is that the performance of the small engine and the high-speed engine must not be confused with that of the larger type, such as the central-station engine and the marine engine. In every one's home there is a heating unit, a little steam or hot-water plant, and if manufactured gas is too expensive, coal is used, not dirty soft coal but the cheapest acceptable fuel obtainable. It is the same with a big power plant; the owner obtains the cheapest fuel that he can get. The Diesel station must get oil where it can get it at a reasonable price.

I had occasion recently to inquire into what is being done by the preeminent users, and found that the marine people are almost universally centrifuging, even if they get what they consider clean oil; and particularly is that true among the British owners. It also seems to be the tendency to improve the quality of the filters. For instance, Hesselman-A.E.G. are making their filters with passages finer than any opening they have in any part of the fuel-oil system, that is, the opening of any fuel valve or nozzle. I think most of the foreign manufacturers are emphasizing the importance of having clean, free-flowing fuel-oil lines, and they are not only heating the oil as it goes through the pipes into the pumps, but are heating it right up to the point of injection so as to insure adequate control of the injection itself.

Lloyd Yost.[16] The comments made by Mr. Nibbs, seem to be probably the nearest to the solution, from the engine-builders' standpoint. There are certain things in a fuel oil that must be considered from other than the purely petroleum-technology standpoint. In selling engines we must place our bids according to the specifications offered (and by bids I mean that guarantees of performance must accompany the bids) and if the engine does not perform, then the builder must make good, if he is capable of making good. That means the oil specified should be a commercial product, something that a customer can obtain—and he must not be misled. Guarantees of fuel consumption are made, of course, in terms of weight. A specification in terms of so many B.t.u. per gallon would be acceptable if one could get the purchaser of the engine to understand and accept it. I do not see that this makes very much difference to him, but it is an important point when guaranteeing the fuel consumption of your engine.

We have found out the only way to determine how a fuel oil will perform in a Diesel engine is to try it in one. At the same time we make a scientific laboratory examination, including fractional distillation. Up to this time we have distilled and tested over 1500 commercial grades of fuel oil. We have tabulated those results, and after going through them backward and forward, so far we have been unable to determine a specification that would be fair to ordinary engine buyer and also fair to the builder of the Diesel engine. In that case we must fall back upon the commercial factor, pure and simple, and refer to the oil as put out under a certain brand, and then write into the specification that this engine will perform under such guarantees "when using any brand listed on the attached sheet," which lists a great many of them, several hundred perhaps, or "oil equal to any one of those listed." That is as close as we have been able to come to it. We think this thing of an oil specification is very important, and we wish we had one, but it is necessary, as we see it, for all of the engine builders to agree—I don't know if it can be done—upon a certain specification. In testing these oils, we have found that you cannot put all fuel oils into any one classification or include them with the others and still be fair to the user. We have adopted a triple classification: (1) an oil which is satisfactory for use directly in the engine, using the standard equipment; (2) an oil which may be such as to require preheating or treatment in order that it may be used satisfactorily; and (3) an oil which may have a low heat content or other characteristics which will not allow it to make the required fuel consumption. Naturally there are some oils that are not usable in any circumstances, but those would not appear on the list at all.

[16] Manager, Research Division, Fairbanks, Morse & Co., Chicago, Ill. Mem. A.S.M.E.

J. C. Groff.[17] Mr. Michler's paper is appropriately in line with the trend of modern industry toward the elimination of overlapping of products. Further lowering of the cost of fuel oils for Diesel engines should be achieved through broadening of needlessly restrictive specifications. It is not difficult to imagine what the price of automobile fuel would be today or to what extent the enormous growth of the automotive industries would have suffered had these respective engine builders demanded rigid adherence of their products to superfine grades of fuel. Similarly, it would seem that extensive adoption of the Diesel engine, particularly in this country where it must compete with the steam plant having available a plentiful supply of low-priced boiler fuels, will be largely dependent upon its ability to operate satisfactorily upon widely varying grades of fuel oils. Only in this way can the Diesel engine take advantage of the most economical grades of fuel, and only in this way can the shipowner be assured that his vessel will be able to operate to advantage in all parts of the world.

The three limiting specifications, as suggested by Mr. Michler, in conjunction with minimum content of ash, carbon residue, sediment, and water, should be generally satisfactory. The following section is from the standard guarantee contract specifications adopted for our oil engines: "Fuel oil, before being delivered to the engine, to be passed through a centrifuge of approved type. Centrifuge to be furnished by purchaser. We suggest fuel oil of 18 deg. to 22 deg. B. gravity. Sulphur content may be any amount not exceeding $3^1/_2$ per cent."

It is presumed that the minimum gravity of 24 deg. A.P.I. has been so chosen in conjunction with an initial viscosity which will assure fluidity at low temperatures, say, 32 deg. fahr. Many motorships, particularly those carrying fuel in double-bottom tanks and not fitted with heating coils, experience difficulty in handling fuels having a high viscosity at low temperatures. Indeed, our experience has shown that handling the fuel up to the engine is much more of a problem than burning it. Proper prehandling of fuel oils by the user would seem to offer one of the most likely means of assisting all concerned in the broadening of specifications for the cheapening of fuel.

C. E. Cox.[18] I am heartily in accord with Mr. Michler's recommendation that a set of standard specifications for Diesel fuel oil be prepared and adopted, but also believe that the interests of Diesel-engine builders should be protected as well as those of the fuel-oil refiners and dealers. Broadening the specifications as far as he suggests will undoubtedly favor the refiner but will not sufficiently protect the engine builder, because there are certain properties and constituents of fuel oil not limited in his recommended specifications which may render a fuel oil unfit for Diesel-engine use, owing to the fact that they are positively injurious to the engine. While it is true that refiners and dealers in oil cannot carry a large variety of oils meeting various specifications, yet it seems to us entirely possible for them to carry a grade of oil which will successfully meet the majority of specifications presented by engine builders.

[17] Engineer, Power Division, Bethlehem Steel Co., Bethlehem, Pa. Mem. A.S.M.E.

[18] Chicago Pneumatic Tool Co., Franklin, Pa.

Almost all engine-builders' specifications for fuel are of the limiting type; that is, they do not attempt to define any limits farther than those tending in a detrimental direction. Experience has proved that certain properties of any ingredients in fuel oils if existent in excess of certain quantities produce unfavorable operating conditions. It is therefore necessary that the engine builder limit these unfavorable factors to safe values in order to be able to make his guarantees and to protect the engine owner. Fuel specifications are thus made to look very rigid, while as a matter of fact the majority of fuel oils will meet them easily. Once the dealers' and refiners' attention is directed toward these points, the ready adoption of a standard fuel will rapidly develop and the name "standard Diesel fuel oil" can be applied.

The specifications, while appearing to cover minutely every property and constituent of the oil, in fact are so liberal that few if any oils that would ever be submitted by a refiner or dealer will fail to meet them. Many products are marketed today under strict, lengthy specifications that have been complied with so long and so easily that they are seldom referred to. Portland cement might be cited as an example. There is no reason why such cannot be the case with Diesel fuel oil. On this basis, then, I believe that the specifications should be complete and yet broad enough in their limits to avoid expensive processes in producing the fuel oil. An oil dealer should know even without analysis that his oil will meet these specifications, and the engine builder will know what the worst operating conditions are that he must meet. Any hardships that may result will more likely reflect on the engine builder than on the refiner or dealer. It is assumed that the fuel oils under discussion are petroleum, and it is on this basis that we proceed.

The following properties are known to affect the operation of a Diesel engine and are the ones which we believe should be considered in defining a standard Diesel fuel oil:

1 Gravity
2 Viscosity
3 Sulphur
4 Ash content
5 Coke content
6 Water content
7 Heating value
8 Flash point.

Gravity has no influence except to supply a conversion factor for converting barrels to pounds. So far we can learn, it gives no index as to the probable properties of the oil unless the origin is known. Gravity in our opinion could be limited to a value of 24 A.P.I. very readily.

Viscosity is important, for the oil must flow readily enough under normal winter temperatures to be handled by injection pumps and nozzles; beyond that its influence is slight. Viscosity should be limited to a value of 200 at 32 deg. fahr. Giving the viscosity at 100 deg. fahr. its worse than useless, for that gives no indication of what it may be at the operating range for oils in general.

Sulphur tests have shown that a high sulphur content is not severely injurious. Limiting it to Mr. Michler's content of 1.5 per cent is therefore very liberal, and it might be raised to 2 per cent.

Ash content is important and extremely so, as the ash affects lubrication seriously, causing worn parts, sticking rings, and rapid wear. Ash should by all means be included, and should be limited to a value of not more than 0.05 per cent. It is hoped that some experienced refiner will announce that no fuel oils ever contain ash nowadays. If such is the case, then the specifications will not burden the oil refiner and yet will protect the engine builder.

Coke or carbon residue is important. Some California and Mexican oils have a very high content, the oils appearing to crack and form coke, which spoils lubrication and fouls the engine rapidly. Wear takes place and reliability is badly affected. The coke content should therefore be included and limited to 3 per cent, a value easily attainable by refiners of petroleum oils.

Water mechanically entrained will cause failure of ignition and unsteady operation of the engine. Water mixed with the oil in the form of an emulsion does not necessarily interfere with ignition, but higher temperatures are required to ignite and burn such oils. Water lowers the heating value of the fuel. A purchaser of oil should not pay for water and the cost of transporting it. Its value should be limited to 1 per cent.

The heating value of fuel oils is not so important, I believe, owing to the fact that nearly all oils run 18,000 B.t.u. or higher. When a builder is making a fuel guarantee a variation of 1000 B.t.u. is a considerable amount, and he therefore has to limit his fuel to a definite value. It would be advantageous to make all guarantees on a basis of 18,500 B.t.u. minimum, making no correction for fuels having values higher than this. This would favor the refiner as well as the engine builder.

Flash point is purely a storage problem and affects the engine operation very little. This item must be considered because of other influences. Mr. Michler's value of 150 deg. should be easily acceptable.

To summarize, we believe that such standardized fuel should be well defined as to detrimental factors, but so broadly limited as to not impose any hardships on the refiner or to cause a reflection of too strict specifications in an increased price for the fuel. The engine builder will then know what range of fuels his engine will be called upon to operate on, and can govern the design accordingly; the engine owner will be spared the trouble of buying fuel to rigid specifications, and whenever fuels are offered that do not come within the limits of the specifications, the purchaser should benefit by a differential in price. Engine builders, will be protected against having to make blind guarantees, and will have a general standard that they should be able to live up to. The mere adoption of these specifications does not imply that every batch of oil must be tested—far from it! It should not be necessary. If the refiner has kept proper check of his process, he should know that his oil is well within these specifications. There is no reason why the Diesel engine should become a disposal plant for all manner of refinery and oil-production wastes, and engine builders should not have imposed upon them all the burden of the fuel problem.

OGP-50-11

# The Economic Field for Large Diesel Engines

By EDWARD B. POLLISTER,[1] ST. LOUIS, MO.

*The author defines a large Diesel engine as one ranging from 2500 to 25,000 hp. He cites the successful performance of marine Diesels, and gives figures showing that the aggregate horsepower of such engines now being built or installed is over three times that of marine steam turbines. He points out territory far removed from coal mines and where a cheap supply of fuel oil makes the use of the Diesel engine especially desirable. Over half of the fuel oil consumed in generating electric power, he states, could be saved by burning it in Diesels rather than under boilers. Diesel generating stations cost about the same as modern steam plants, around $135 per kw. Diesels have characteristics which especially fit them for use as auxiliaries in steam and hydroelectric power plants. The paper concludes with a brief consideration of the use of large Diesel engines in industrial plants.*

EARLY in the year 1924, an engineer waiting in a railroad station in the Panama Canal Zone idly turned the pages of a *Saturday Evening Post* and saw the advertisement of an American firm claiming for the Diesel engine "instant readiness

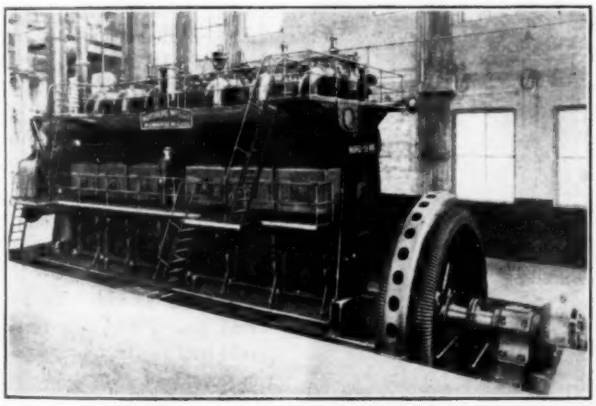

FIG. 1 3750-HP. PANAMA DIESEL BUILT BY NORDBERG MANUFACTURING CO., MILWAUKEE, WISCONSIN

for service." If true, the Diesel was just the prime mover he wanted for the proposed new 12,000-hp. Canal power station at Miraflores, to supply power in case of failure for any cause of the power transmitted from the Gatun hydroelectric station, about 36 miles distant, over a 44,000-volt transmission line.

He immediately started a serious investigation of the large Diesel. A natural beginning was the inspection of Diesel-propelled ships passing through the Canal. Quick starting and performance being convincingly established by records of ships propelled by single-screw Diesels of several thousand horsepower in round-the-world service, the safety of ships and crews depending on one engine, with non-stop runs as long as forty-five days, he set out on a visit to the Diesel firms of the United States where he was enthusiastically received.

Special automatic equipment was worked out between the Diesel-engine builders and the generator manufacturers which would permit motoring of the idle engines by the generators operating as synchronous condensers for power-factor improvement and voltage regulation, any transmission line or similar power failure automatically causing a transition from idling condition to load condition and thus providing for continuing the important power service to the Canal uninterrupted. This quite fully satisfied the claim for "instant readiness for service."

Although the desired unit size, 3750 b.hp., was larger than any Diesel which had at that time been built in the United States, it is astonishing that no less than eight substantial American heavy-machinery firms considered the large Diesel engine field sufficiently attractive to justify bidding on, an undertaking which for many involved a development expense of several hundred thousand dollars. A list of these firms follows, and all of them now have marine Diesel engines of 2500 b.hp. or larger in service.

Bethlehem Steel Corporation
Busch-Sulzer Bros.-Diesel Engine Co.
McIntosh & Seymour Corporation
New London Ship & Engine Co.
Nordberg Manufacturing Company
Sun Shipbuilding Company
Wm. Cramp & Sons Ship & Engine Co.
Worthington Pump & Machinery Corporation.

The building of the Miraflores Diesel plant was carried through to successful conclusion, three Nordberg 3750-hp. engines being supplied. This project would indicate a favorable outlook for large Diesel engines for standby service entirely aside from the

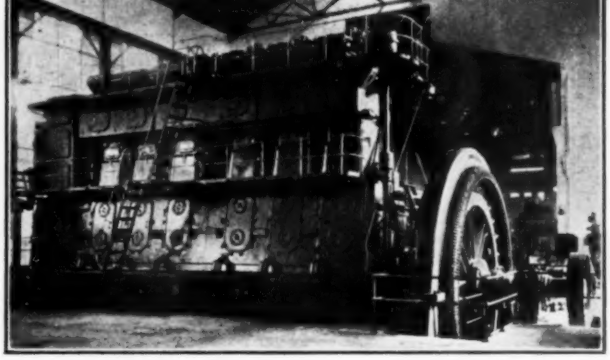

FIG. 2 3750-B.HP. BUSCH-SULZER DIESEL GENERATING UNIT, FEDERAL LIGHT & TRACTION CO., TUCSON, ARIZONA

more prominent advantage of the Diesel—its high thermal efficiency of about 33 per cent—which has not yet been approached by any other type of prime mover. But in the intervening four years only one Diesel of this size, a Busch-Sulzer 3750-hp. unit, selected by Sanderson & Porter for the Tucson, Arizona, plant of the Federal Light & Traction Company, has been purchased in this country for stationary service, and no larger units for land plants.

### WHAT IS A "LARGE" DIESEL ENGINE?

A proper question may be, "What is a *large* Diesel engine?" Diesels built by Sulzer Brothers, of Winterthur, Switzerland, of 4000 hp. capacity have been operating in European land stations for over fifteen years. In the same year that the Panama Canal invited bids on 3750-hp. Diesel engines, the Hamburg Electric Company, of Hamburg, Germany, placed an order for a 15,000-hp. two-cycle double-acting M.A.N. Diesel generating unit for in-

[1] General Manager, Busch-Sulzer Bros.-Diesel Engine Co.

Presented at the First National Meeting of the A.S.M.E. Oil and Power Division, the Pennsylvania State College cooperating, State College, Pa., June 14 to 16, 1928.

stallation in their electric generating station to carry peak loads. While this is the largest Diesel now in operation, Sulzer Brothers have developed a single-cylinder experimental double-acting two-cycle engine rated for stationary work at 2400 b.hp. at 110 r.p.m. with a cylinder bore of 900 mm. and a piston stroke of 1400 mm. A 10-cylinder engine of this size would develop 25,000 b.hp. This number of cylinders is frequently employed in marine work, and Sulzer Brothers have supplied eight 10-cylinder units averaging above 5000 hp. each for propelling ships. As 900 mm. diameter of cylinder is not the limiting size, a former Sulzer single-cylinder experimental engine having a bore of 1000 mm., somewhat larger units are not without the range of conservatism. A large Diesel may therefore be considered as of from 2500 to 25,000 b.hp.

### Marine Diesels

In considering the economic field for large Diesel engines in this country, it is important to note that the successful performance of large marine Diesels was a vital feature in the decision to go ahead with the 12,000-hp. Panama Canal power plant; and the extremely rapid adoption of the Diesel for the propulsion of ships has eliminated what might be the fear of experimental development by possible purchasers of large land Diesels. The largest motorship in service, the *Augustus*, of 32,500 gross tons, is propelled by Diesels totaling 28,000 hp. The proposed reconditioning of the Shipping Board steamer *Mount Vernon* calls for two propelling Diesels of 14,500 b.hp. each, and a total Diesel plant of 35,000 to 40,000 b.hp. These large engines can be furnished in the same American-built cylinder sizes as are now successfully operating in round-the-world marine service. The survey herewith, as of December 31, 1927, of marine engines under construction throughout the world discloses that the aggregate horsepower of Diesel engines building or being installed is over three times that of steam turbines (excluding Germany—figures not available), and that the tonnage of motorships now building is greater than that of steamships.

| | Steam Engines | | | | Oil Engines | |
|---|---|---|---|---|---|---|
| | Reciprocating | | Turbine | | | |
| | No. | I.hp. | No. | I.hp. | No. | I.hp. |
| | 327 | 556,874 | 34 | 343,700 | 352 | 1,233,956 |
| Average size | | 1700 | | 10,000 | | 3,500 |

Total gross tonnage under construction { Steam....... 1,494,532; Diesel....... 1,609,888

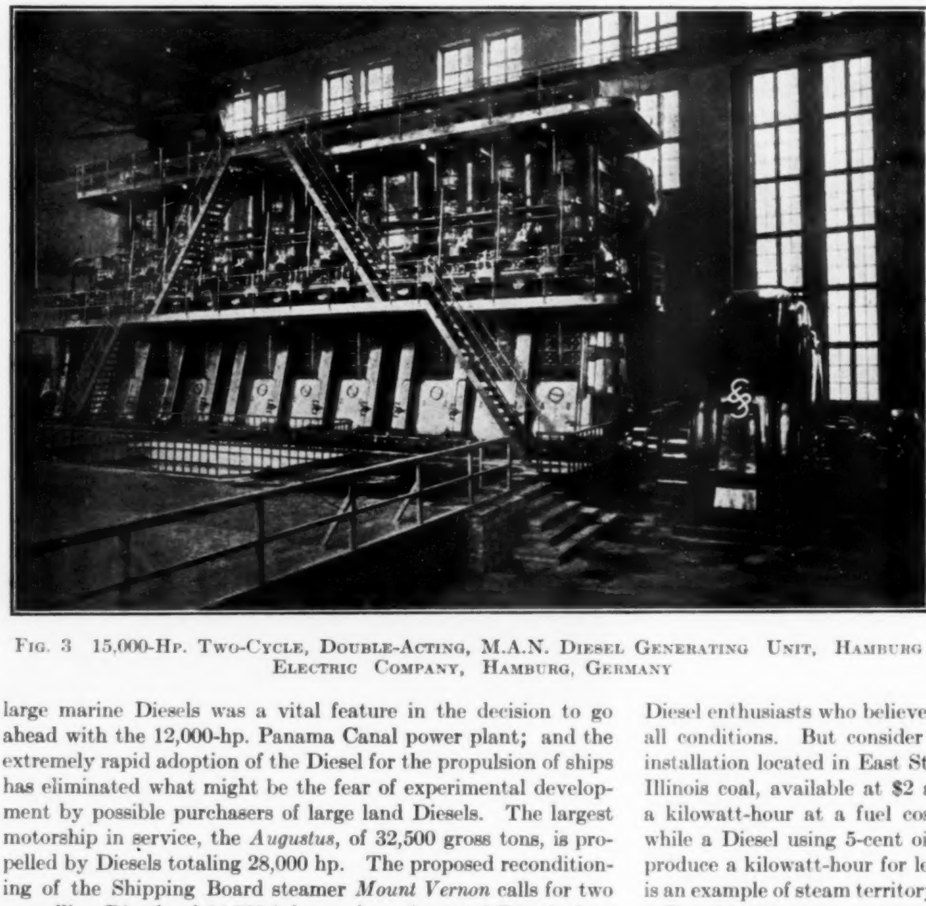

Fig. 3 15,000-Hp. Two-Cycle, Double-Acting, M.A.N. Diesel Generating Unit, Hamburg Electric Company, Hamburg, Germany

The trend toward Diesels is indicated by a statement issued in April of this year by Lloyd's Register of Shipping for the first quarter of 1928, showing a gain to March 31, 1928, of oil engines to 1,333,875 i.hp. compared with a decline of steam turbines (excluding Germany) to 277,600 i.hp., and a decline of steam reciprocating engines to 549,910 i.hp. This ratio of five to one for marine Diesels as compared with steam turbines demands the serious attention of designers of land power plants.

But, with this brief mention of marine Diesels, it is necessary, in view of the limitations of the present paper, to return to land plants, and without much encouragement from existing installations in this country, outline the future of the large stationary Diesel.

### Territory Especially Adapted to Use of Diesel Engines

As a general statement, the United States is a country of cheap coal; and as the greatest industrial developments originally centered around the coal mines of the East, the great power-plant engineering problems have been worked out without any consideration of the Diesel whatsoever. Obviously, steam plants of half the thermal efficiency of the Diesel, using local cheap coal, can produce power at less fuel costs than Diesels requiring liquid fuel if the cost of the liquid fuel at the oil field plus the cost of transportation (which is often several times the cost of oil at the point of production) is sufficiently in excess of twice the cost of local coal on a B.t.u. basis. Of course we shall always have with us Diesel enthusiasts who believe that Diesels can beat steam under all conditions. But consider a large up-to-date steam-turbine installation located in East St. Louis, and burning 12,500-B.t.u. Illinois coal, available at $2 a ton. Such a plant will produce a kilowatt-hour at a fuel cost of between one and two mills; while a Diesel using 5-cent oil brought from Oklahoma, cannot produce a kilowatt-hour for less than twice this fuel cost. This is an example of steam territory.

But this is a country of vast area, and there are large sections, especially through the Middle West and along the seaboard, remote from coal mines, and within easy reach of oil fields or a cheap supply of fuel oil transported at low costs in ocean-going tank ships. These are decidedly examples of Diesel territory.

Also, industry is moving westward with the center of population, and the demand for power throughout the great West is growing with the increase of population. This is favoring the more general adoption of the large Diesel.

The tabulation herewith of the consumption of fuel oil in generating electric power by public-utility power plants in 1927

| Division and State | Barrels | Per cent of U. S. total |
|---|---|---|
| United States | 6,782,199 | 100.00 |

shows this natural distribution of territory where oil is the logical fuel and the Diesel is the logical prime mover.

At least one-half of the greater part of these 6,782,199 bbl. of fuel oil could be saved if it were burned in Diesel engines instead of under boilers. This would be a saving of easily over $5,000,000 in public-utility fuel costs.

The comparative thermal efficiencies of Diesel-engine generating units and large steam-turbine plants are too well known to justify repeated technical discussion. There are large plants on the Atlantic seaboard (for instance, the Narragansett Power Station) where fuel oil transported in tankers is burned under boilers. The average fuel consumption per kilowatt-hour in such large modern steam plants is about 1.2 lb. of fuel oil as compared with about 0.6 lb. burned in large Diesel engines. Varying load conditions and types of equipment may, for particular installations, change slightly these figures; but they are approximately correct.

The next question to consider is whether this saving of $5,000,000 would be dissipated by fixed charges on higher Diesel plant costs or higher Diesel operating costs. While steam-plant costs are very generally known, this information is not obtainable on large Diesel-engine plants, due to lack of such installations. With so many concerns offering large Diesels in advance of actual building, prices quoted are very unstable, the market not having become established. Again, the ultimate price of large Diesel engines will only be determined after sufficient orders have been placed to produce these engines on other than single-engine orders with comparatively high cost of manufacturing.

### Cost of Large Diesel-Engine Generating Stations

Contrary to general opinion, however, based on actual selling prices of the few large Diesels which have been sold in this country, the cost of large Diesel-engine generating stations is approximately that of modern steam plants. In fact, in many cases

the cost of the Diesel plant is less, depending upon the varying costs of providing condensing water for the steam plant. Formerly Diesel engines were comparatively high in price, but today Diesels rank with the very few commodities that are being sold for less than prewar prices. Large stationary Diesels cost less than $60 per hp. and the total cost of a large Diesel generating station is normally around $135 per kw., made up about as follows for average conditions:

Estimate of Cost of a Four-Unit, 15,000-B.Hp. 10,000-Kw. Diesel Installation

| | |
|---|---|
| Real estate | $ 10,000 |
| Building, including 20-ton crane | 75,000 |
| Foundations | 40,000 |
| Four 3750-b.hp. Diesel engines, f.o.b. point of manufacture | 900,000 |
| Freight on engines at $1 per cwt | 40,000 |
| Generators and exciters, direct-driven | 100,000 |
| Freight on generators and exciters | 5,000 |
| Unloading and placing on foundations | 15,000 |
| Erection | 15,000 |
| Station piping | 15,000 |
| Cooling-water system (if required) | 25,000 |
| Fuel storage | 10,000 |
| Switchboard and wiring | 20,000 |
| Miscellaneous items, contingencies, and engineering | 80,000 |
| Total | $1,350,000 |
| Diesel station cost per kilowatt of installed capacity | $135 |

It should be noted that the installation is extremely simple, approximately only one-half of the floor space being required that is necessary for turbine installations, the building being somewhat lower, and expensive smokestack, coal and ash-hauling apparatus being absent. Fig. 8 showing the comparative floor space of a 20,000-b.hp. electric station with four units of 5000 b.hp., steam turbines—Diesel engines, is taken from a catalog of Sulzer Brothers, Swiss builders of Diesels as well as

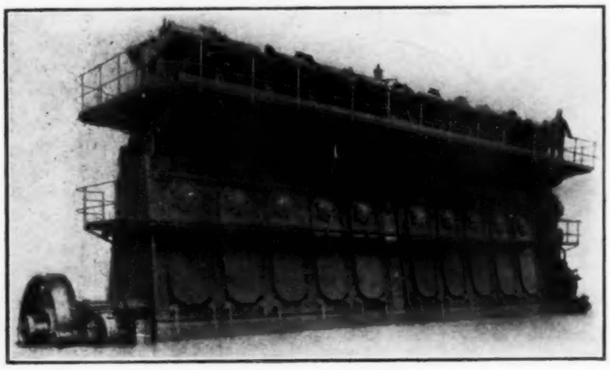

Fig. 5 Sulzer Bros. Marine Type 10-Cylinder Two-Cycle Engine, 5800–6800 Hp.

of steam turbines and boilers. The simplicity and small size of the building is quite well established by Fig. 9, which shows a 20,000-hp. 6-unit Sulzer Diesel plant installed at Shanghai, China.

As the size of the Diesel increases, the maintenance cost diminishes. The replacing of a working part on a 36-in.-diameter cylinder rated at 2000 hp. does not cost ten times as much as a similar part on an 18-in. cylinder rated at 200 hp. This is apparent and will become established in this country after more of these large Diesels have been installed.

Similarly, the same operator who takes care of a 500-hp. Diesel engine can as well take care of a single engine several times as large. There is no more to do while the engine is in operation. Adjustments and upkeep work would be somewhat greater of course, but not in proportion to the increased size of the larger engine.

And so this fuel saving would be a net saving and added to the net income of public utilities.

Here, then, is the first economic place for the large Diesel engine, in sections of the country where the price of Diesel fuel on a B.t.u. basis compares favorably with the price of steam fuel.

## Use of Diesels in Auxiliaries in Large Steam Power Plants

The task remains, however, of convincing "dyed in the wool" steam engineers, who will, of course, still insist on having steam

Fig. 6 McIntosh & Seymour 2700-B.Hp. Double-Acting, Four-Cycle Marine Diesel

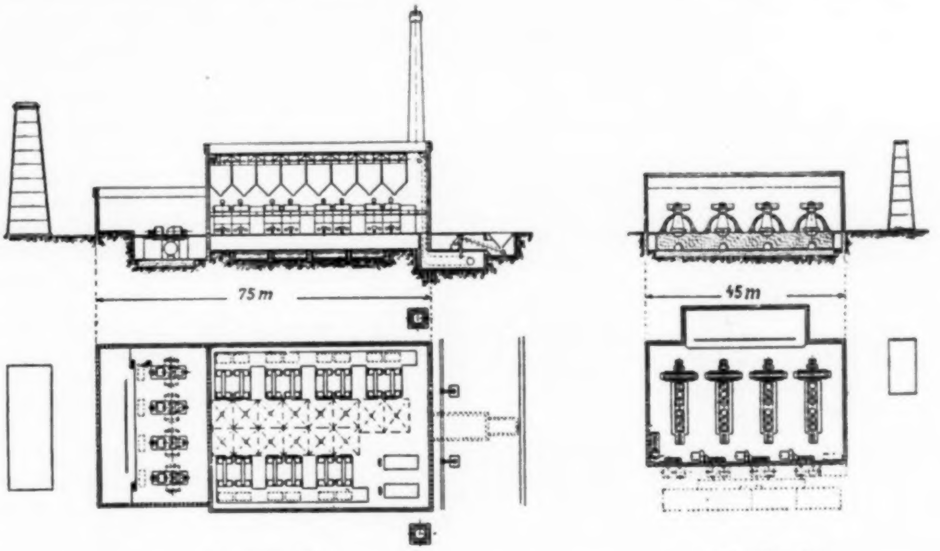
at any cost. Before reaching a decision to purchase the 3750-hp. Diesel for installation at Tucson, clearly a Diesel territory, one of these "steam" engineers organized an exploring party to see if a coal stratum could not be discovered in that locality. The geographical division of the country into cheap-coal and cheap-oil territory is a logical step in the first consideration of the large Diesel. But this is only the first step, and possibly a more important use of the Diesel is as an auxiliary to even the largest power plants, both steam and hydroelectric, because of characteristics it possesses which are too frequently overlooked. In fact, due to its limitations in size the Diesel will never be a competitor of the largest steam turbines; but it can be very advantageously used as auxiliary capacity, as follows:

1 By carrying normal peaks, permitting steam equipment to be operated at most favorable constant loads with highest efficiency
2 For emergency peaks
3 As standby and reserve to high-lines
4 Hydroelectric auxiliary.

Self-contained, with a minimum of piping and auxiliary equipment, and using easily handled and stored fuel, capable of delivering full output within a few minutes' time, simple to start up, the large Diesel generating unit, costing no more per kilowatt of installation than the overall steam plant, forms a very desirable 10 or 20 per cent of the capacity of quite large steam-turbine generating stations. The daily peak load is the bugbear of the central-station efficiency operator. It is usually of short

FIG. 7 M.A.N. TYPE, TWO-CYCLE, DOUBLE-ACTING DIESEL ENGINE, 3900 B.HP., BUILT BY THE HOOVEN, OWENS, RENTSCHLER COMPANY, HAMILTON, OHIO

duration, two or three hours only, but must be provided for either by firing up additional boilers and warming up additional turbine capacity, or operating the remainder of the day at less than the maximum efficiency loading of both. Once adopted as part-station capacity for carrying peak loads, the large Diesel will quickly become a favorite apparatus with the chief engineer and the efficiency engineer of the large power plant, as well as with the owner.



Steam Turbines | Diesel Engines

FIG. 8 COMPARATIVE FLOOR SPACE OF TWO 20,000-B.HP. ELECTRIC STATIONS WITH FOUR UNITS OF 5000 B.HP. EACH

Aside from the normal daily peak loads, there are occasional unexpected fluctuations in the load curve, especially in large cities—for instance, such as is caused by a bright day becoming cloudy. When such a sky becomes suddenly overcast with black clouds a large lighting demand, seldom felt during daylight hours, comes on quickly. For such loads, and for emergency partial breakdown of steam-power-plant apparatus, the separate, self-contained Diesel capacity serves an excellent purpose.

Eastern superpower systems are closely tied in with comparatively short distances between large generating stations. This is not the case in the West, where high-tension lines become longer and supply smaller and more widely separated communities. Further, the western part of the country is more subject to wind and sleet storms, causing damage to high-tension distribution lines which often requires many days for repairs. The pride of even small communities is humbled by a sudden return to dark nights, kerosene lamps, and candles. The support of these small municipalities as customers is almost a necessity for the proper electrical development of the western part of our country, where industrial power demands are smaller than in the East and grow at a lesser rate. Eastern holding companies who have extended their operations to the Middle West are finding out that it is extremely difficult to appease the clamorings of disgruntled small-town citizens over interruptions of high-line service. The answer is to install part of the capacity of the system in Diesel generating units placed at important feeder points and used either for constant operation, where the cost of Diesel fuel favors, with the surplus capacity in readiness in the distant steam-turbine stations for emergencies; or, where the cost of steam generation is lower, to have the distant Diesel to supply service during high-line and other interruptions, and assist in carrying peak loads.

This plan of installing Diesels is being rapidly adopted in several sections throughout the West, especially where small Diesel generating stations have been taken over by expanding holding companies, and their low-cost-production records forcibly brought to the attention of the new owners.

This system of installing Diesels at outlying points on high lines has other advantages. When a high line becomes over-

loaded, it saves increasing its capacity. Where new properties are acquired far from existing high lines and with loads not immediately justifying high-line extension, Diesel generating plants may be installed for the period of years required for the load to be built up to a point where extension of the distribution system may be profitably made. As such Diesel generating stations will produce power at costs comparable with the largest steam-turbine plants, even where steam fuel is obtainable at a more favorable cost, the rates of the large parent station may be maintained for the customers of the Diesel generating station, assisting in developing this load.

In these days of rapid improvement of steam equipment, the replacement of low-pressure boilers, turbines, and equipment which have been superseded by more efficient types, may be oftentimes deferred by installing additional capacity in more economical Diesel generating units, in many cases the partially obsolete steam equipment ultimately becoming reserve capacity.

## Diesels as Auxiliaries in Hydroelectric Plants

Another distinct field for the Diesel is as a hydroelectric auxiliary plant. During times of low water flow the Diesel may be operated with minimum attendance; depreciation is practically absent when shut down, in contrast to the heavy depreciation of idle steam equipment; the fuel is safely stored for long periods without danger of spontaneous combustion or depreciation from weathering; and the plant is compact and lends itself readily to installation in the hydroelectric turbine power house, to which the fuel is delivered by gravity pipe line. A single attendant can start even quite a large engine to carry occasional peak loads; and for more sustained seasonal operating, additional personnel can be supplied as required. The life of a Diesel operating as standby auxiliary is almost indefinite, the working parts being bathed in oil and not subject to rusting or deterioration.

Where water storage capacity is sufficient, and peak loads exceed the capacity of a hydroelectric plant, the Diesel auxiliary may be operated as a hydraulic accumulator, pumping the water back over the dam to storage during light-load periods of the day, as well as adding its capacity to the hydraulic turbines during peak loads.

Extensive study of the advantages of large Diesel-hydroelectric auxiliary plants has been made during the past ten years, and each time the lack of actual installations of large Diesels has introduced an experimental hazard which for so large an investment has prevented con-

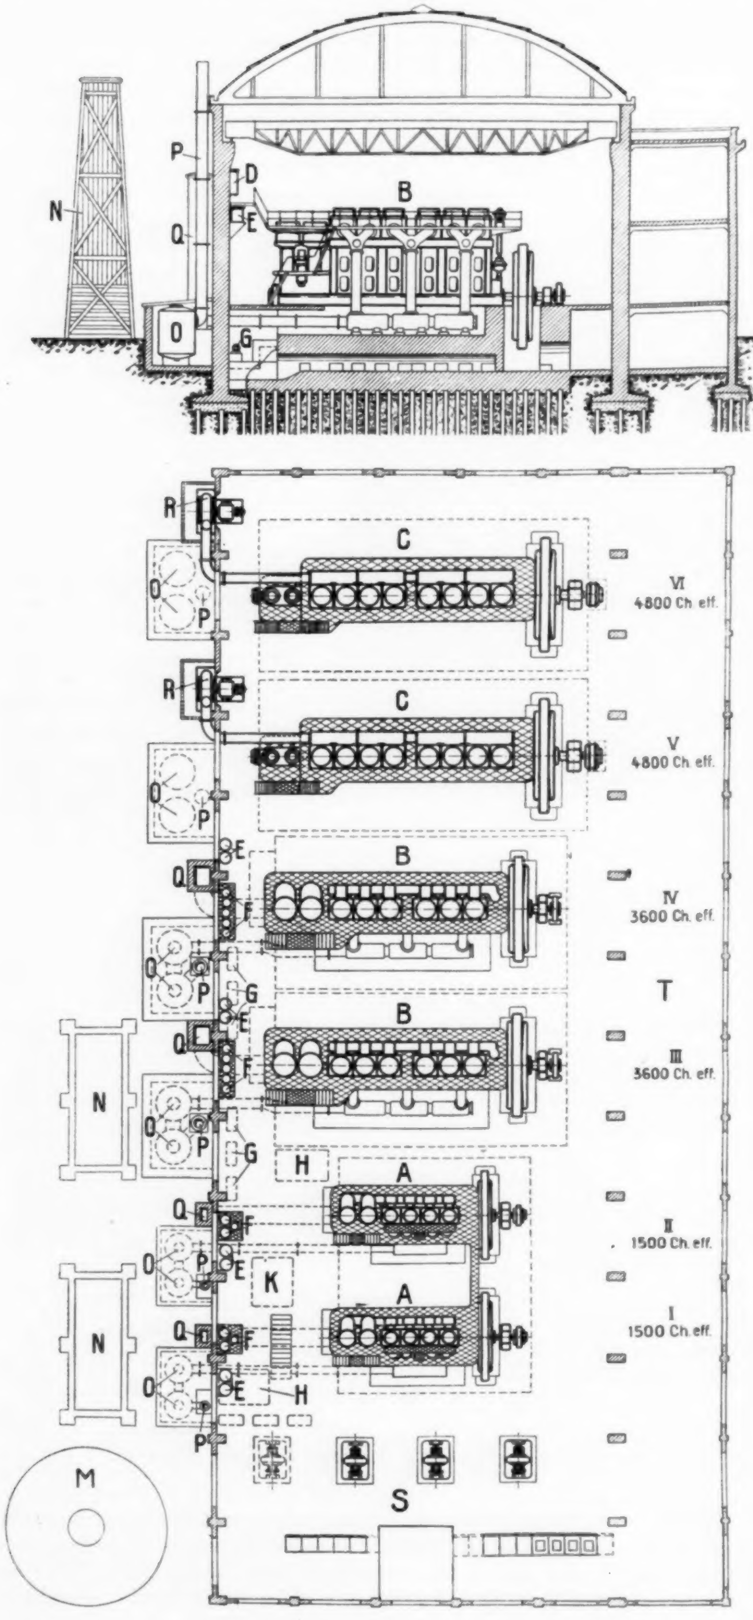


Fig. 9 20,000-Hp. 6-Unit Sulzer Diesel Plant Installed at Shanghai, China

A—1200-kva. group (1500 hp.); B—3300 kva. group (3600 hp.); C—4600-kva. group (4800 hp.); D—fuel tank; E—fuel wells; F—compressed-air bottles; G—electric pumps; H—settling tank for piston cooling water; K—hot-water tank; M—water tower; N—cooling tower; O—mufflers; P—exhaust piping; Q—suction air pipe; R—turbo-blowers for scavenging air; S—rotary converter substation; T—switchboards.

summation of such plans. This hazard has now been eliminated by the very extensive building of large marine engines, advantage of which will no doubt be taken by engineers in charge of superpower development, embracing both steam and hydroelectric power plants, with its network of distribution lines.

So far, in dealing with this subject, the use of the large Diesel engine by public utilities has been alone considered, and this is by far the largest field. To what extent the large Diesel is adopted by industry depends to a great degree on the attitude toward it manifested by the public utilities.

### Industrial Diesel Installations

If the large Diesel-engine installation has merit as a low-cost power producer it cannot be stifled, for the simple reason that industrial plants will be able to produce their own power with large Diesels at lower costs than central-station power companies can afford to supply it. Already the greater number of American Diesels of medium size—1000 to 2500 b.hp.—are installed in private industrial plants. One of these plants at the Moctezuma Copper Co., Nacozari, Son., Mexico, consists of two 2200-hp. and four 1250-hp. engines supplied by the Nordberg Manufacturing Company. At the end of 1924 this plant was reported, after some of the units had seen five years of service, to have a record of gradual reduction in maintenance cost and entirely successful operation. Investigation over a period of years of the operating results of similar engines within this range of sizes recently led the Commerce Mining & Royalty Co., of Cardin, Oklahoma, to install a 6750-hp. Nordberg Diesel plant consisting of three 2200-b.hp. engines. The installation of such plants in industries which are or should be customers of public utilities discloses a competitive situation for a long time existing to some extent between Diesel-engine builders and public utilities that is very unhealthy.

Because the Diesel engine was for many years built only in small sizes, its field was limited to small plants, both small city power-generating stations and small industrial private plants. With the development of the superpower idea, especially during the last ten years, the Diesel engine, in the minds of public-utility-power salesmen, has become definitely connected with the so-called "isolated power plant." Compared with selling electric power to replace simple non-condensing steam plants, replacing small Diesel isolated power plants has been very difficult because of the low operating costs. The electric-power salesman meeting the Diesel-engine salesman in competition for new small power plants has come to regard the Diesel as an enemy to be fought at every turn—as a menace to successful high-line development. In some cases unfair adverse claims have only served to arouse interest in the extremely low costs of producing power with Diesel engines; and in some localities the public utilities have been harassed by unfair business methods used in promoting the sale of small Diesels.

Undermining existing investment of public utilities giving good service at fair rates by agitations directed toward the installation of municipal Diesel-engine plants is economically unsound; but the menace of so disturbing comprehensive rate systems embracing large territories served by single public-utility holding companies is increasing. Fighting between two industries is usually costly to both. The great power business of the country is well organized by advantageous national electrical associations, while the thirty-five or more Diesel-engine builders are without any organization at all. The easy method for applying corrective measures would therefore seem to be, first, for the public-utility interests to promulgate proper views which would discourage costly and useless inter-industry fighting between electric-power and Diesel-engine salesmen, and, second, by installing the Diesel engine where fuel and other conditions justify the use of the Diesel, thus robbing the unethical Diesel salesman of his offensive weapon of comparing the low cost of Diesel-engine power with higher cost of steam power on which electrical rates are based. If a central station generates all or part of its power with Diesels, the principal reason for installing a municipal Diesel plant in competition is lacking; and the same line of argument applies to the isolated industrial plant.

While the Diesel was built only in small sizes this procedure could not be undertaken, but now that large units are available, the way is open. In all fairness to the merits of the Diesel engine the American power-plant engineer should give more consideration to the large Diesel, not only because of its high thermal efficiency but for other qualities which it possesses which commend it in sizes of 5000 and 10,000 kw. for installation as part capacity of even the largest power plants.

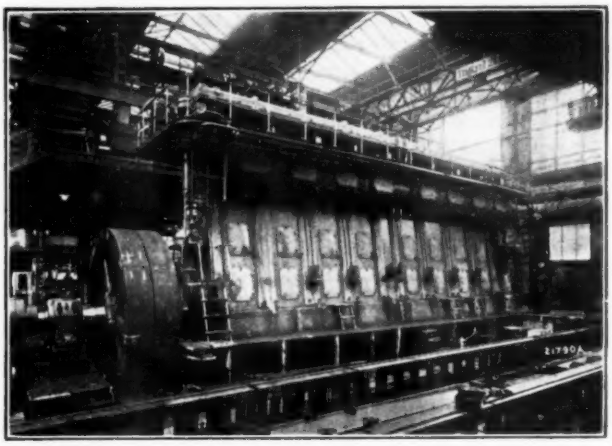

Fig. 10 Test-Bed View of 5250 B.Hp. Sulzer Land Engine, Electric Generating Station, Shanghai, China

## Discussion

Edgar J. Kates.[2] Attention has been called to the many points of contact between the local Diesel power plant and the electric central station. Referring to the fact that the greater number of American Diesels in the size range of 1000 to 2500 b.hp. are installed in private industrial plants, the author remarked that "the installation of such plants in industries that are or should be customers of public utilities discloses a competitive situation for a long time existing to some extent between Diesel engine builders and public utilities that is very unhealthy."

Certainly, oil-engine builders do not wish to stand in the way of sound economic progress. Economic laws are bound to prevail in the end, and the sooner they are allowed to come to fruition, the greater will be the benefit to all.

It therefore seems pertinent to inquire into the real function of the electric central station. Is it desirable from the standpoint of the people at large that all industry should as soon as possible receive power from centralized public utilities? Or, on the other hand, are there certain inherent limitations attached to central-station service that sometimes make a local individually owned power plant more desirable as a matter of public policy? The question of course is independent of any selfish interests. It includes other factors besides those involved in a mere investigation as to which kind of power the industrialist can buy the cheapest. In effect the question is, "How can the electric central station best serve the community?" The excuse for discussing it at this

[2] Consulting Engineer, New York, N. Y. Chairman, Oil and Gas Power Division. Mem. A.S.M.E.

time is its intimate connection with the economic future of the Diesel engine.

When the public sale of electricity was started, over forty years ago, the sole purpose was to furnish current for lighting, and for many years over 90 per cent of the current was thus used. In those days a central station's load curve showed two peaks, one of short duration in the early morning, and the other a longer one persisting through the late afternoon and evening. During the rest of the day a large part of the generating capacity was idle.

Subsequently, certain developments in the industrial field and in electrical technic, such as the improvement of electric motors and the application of alternating current to long-distance transmission, offered a solution to the problem of filling up the valley between the morning and evening peaks in the load curve. Thus commenced the eager quest for industrial power load which is still vigorously under way. This type of load was exceedingly attractive, as it made use of generating equipment otherwise idle and incurred only a small additional operating expense consisting mainly of the extra fuel. Most of the private steam plants were thermally inefficient, and the electric central station could easily afford to produce and deliver power to them at a lower price than they could make it.

Because of these advantageous factors the search for industrial power load was completely successful, and eventually the day-time valleys in the load curves of the various central stations were quite filled up. But now the pendulum has swung to the other side, and in most public-utility systems it is the industrial power load instead of the lighting load that causes the peaks and necessitates the expenditures for extensions. The industrial load is no longer a byproduct, and a correct cost analysis must allocate to it a fair share of the overhead charges.

During this period of substitution of central-station electricity for private steam-power plants the modern Diesel engine has been developed, and it has now reached a place of great economic significance. The Diesel power plant for private use enjoys the tremendous advantage over the corresponding steam plant of being highly efficient even though small. Consequently, the private Diesel plant can produce power at low cost.

Though a modern steam central station burning cheap coal *generates* electricity very cheaply, the cost of transmission makes the *delivered* cost much higher. Statistics for the United States show that the investment in transmission and distributing systems exceeds by a considerable amount that in the generating plants themselves. Furthermore, upkeep and operating costs for the distribution agencies are high, and an average of about 20 per cent of the energy transmitted is lost.

For these reasons, central stations are unable to deliver power to many types of industries at as low a cost as the power user could obtain from a Diesel plant of his own. Of course, electric power is often sold at a price which does not correspond with cost. That is because, under the system of public-utility regulation followed in most of the states, there is no obligation or even an incentive for central stations to segregate their loads into classes, determine the cost of serving each class, and apply rate schedules in accordance therewith. On the contrary, the fact that some classes of load, such as the domestic consumers, are practically non-competitive, provides an inducement to discriminate against the residence customer in favor of the industrial power consumer who can make his own energy if he wishes. With the present system of regulation this practice is generally permissible, so long as the *total* income of the central station company does not exceed a "fair return."

Such discrimination is of course economically unsound, and not only the general public, but even the central stations themselves, would benefit by its abolition. Industrial power rates that are below true cost do not promote the public interest. The low rates are not reflected in the prices of the goods marketed, since if the electric rates were higher, the manufacturer could still obtain cheap power from a plant of his own. On the other hand, the public makes good the central station's loss by paying higher residence rates than necessary.

Our national economy would be served if future large reductions in the cost of central-station current should enable all our power needs to be cheaply supplied from that source. At present there does not seem to be much hope. Generating costs are not likely to be greatly lowered; fuel engineering developments may indeed further reduce operating expenses, but they will require greater capital investment and thus greater overhead charges, with little net advantage as a result. The cost of hydroelectric power is also not subject to much reduction; the efficiency of hydraulic turbines already approaches 100 per cent, and the best sites for hydroelectric projects have already been developed. Transmission costs have an upward trend, because longer lines and higher voltages demand larger investment, cause higher expense for maintaining reliable service, and bring about greater energy losses. Transmission lines are first built to serve dense and profitable loads, and are later extended into less attractive localities.

In view of these limitations, what are the proper economic fields for central-station electricity? In the opinion of the writer the most important are:

1 The delivery of cheap hydroelectric energy to industries which are so dependent upon cheap power that all other considerations are secondary and they will be built near the hydrogenerating stations; for example, electrochemical undertakings such as the production of aluminum and the manufacture of fertilizer.

2 Furnishing electric energy to industrial establishments requiring small amounts of power, in which private power plants would not be justified. Such power should be sold at rates that will yield a reasonable profit. Typical of this field are the numerous small manufacturing plants in city loft buildings.

3 The supply of current for commercial lighting, except in a few large stores and office buildings where a private power plant would be more efficient.

4 Last and most important, the supply of cheap current to the home. This field for central-station energy offers such tremendous opportunities to serve the public welfare, and at the same time afford a most profitable income to the electric companies, that it deserves far more attention than it has received.

Over 85 per cent of the homes within reach of electric-service companies' lines are now wired up and connected. Obviously, therefore, future expansion in electric service to the home will depend not so much on connecting up to more homes as on supplying more current to the homes that already are consumers. These homes use electricity almost exclusively for light; the great opportunity lies in supplying them with current for other purposes.

Electricity can and should be made a great social servant in the home, not only for lighting, but for many other conveniences, comforts, and labor-savers unique to electricity and not sufficiently availed of at present; such, for instance, as electric refrigerators, water heating, room heating, and the operation of many small but useful electrical appliances.

The present utilization of electricity in the home is absurdly small. The average consumption is only 1 kw-hr. per day, and the load factor only 14 per cent. Think of the great expansion possible. Under these conditions the indirect costs of providing service are high, and this is sometimes pointed to as explanation for the fact that the price of electricity in the home is about ten times the cost of production.

The editorial staff of *Electrical World*, after making a survey of the light and power business, pointed out that experience with well-applianced electrical homes has demonstrated that it is en-

tirely practicable for a householder to use from 12 to 20 kw. of electrical equipment consuming between 4000 and 6000 kw-hr. annually. Such domestic installations produce a very desirable load, with a fairly even demand throughout the day and night and a load factor of 22 per cent. It was estimated that an average rate of 3.52 cents per kw-hr. could be obtained for this business and that the resulting gross income would be about $3^1/_2$ billion dollars per year, which is over ten times that now received from the entire industrial motor load.

The present inadequate use of electricity in the home is due mostly to obsolete types of rate schedules, originally designed with the idea of protecting. These should be revised with the purpose of promoting increased usage. Lower prices in the higher blocks of the rate schedules will cause greater usage and bring more profits to the electric companies; at the same time the people will derive the benefits of increased electric service. Effective education must of course accompany the changes in rate schedules.

The opportunities for profit to the electric public utilities that lie in taking on more industrial power load are trivial in comparison with those in the domestic field, and any central-station capacity released from serving unprofitable motor loads can easily be utilized for increased residential service. Thus benefits will come both to the central stations and to the public.

The chief function of the electric public utilities is to make our homes happier by supplying fully those unique services that only electricity can give. By fulfilling this purpose they will not only perform their duty to society but also reap rich financial rewards.

J. D. Bowles.[3] The Tucson Gas, Electric Light & Power Co., of Tucson, Ariz., is one of our subsidiaries. During the summer months the climate is very hot, no natural stream flow is available, water is pumped from deep wells emerging at a temperature between 75 to 80 deg., fuel oil or distillate costs from 5 to 6 cents per gallon delivered, and coal costs approximately $8 per ton delivered. These conditions combined to favor Diesel operation when power-plant additions become necessary in 1914, shortly after we acquired the property. Accordingly two 500-b.hp. Fulton Diesel units were installed in 1915. These were followed up by a pair of 550-b.hp. Busch-Sulzer Bros. engines in 1918 to 1920. Then came a pair of 900-b.hp. Werkspoor engines purchased from the United States Shipping Board, at what was then considered a bargain. All these units are four-cycle and direct-connected to three-phase 60-cycle 2400-volt Westinghouse alternators with direct-connected exciters.

The load at Tucson has continued to grow; in fact, during the last two or three years it has been growing at an accelerated rate; and when the need for additional generator capacity became urgent, I recommended against any further Diesel units of less than 2500 kw. each. Accordingly a contract was let to Busch-Sulzer Bros., of St. Louis, to build an engine rated at approximately 3750 b.hp., 124 r.p.m. at Tucson, elevation of 2200 ft. Allis-Chalmers Mfg. Co. furnished the alternator, which is a flywheel type, the rotor of the alternator serving as a flywheel for the engine. This machine is rated at 3750 kva. and is served by a belted exciter using Texrope drive. This drive, by the way, has proved entirely satisfactory and permits of an exceedingly short coupled arrangement, and by belting the exciter we reduce the cost of the installation somewhat; but, mainly, the higher exciter speed provides for better voltage regulation and the use of fewer relays for the vibrating voltage regulator. The generator voltage regulator serving this entire station, by the way, is now equipped with 32 vibrating contacts.

[3] Vice-President and Chief Engineer, Federal Light & Traction Co., New York, N. Y. Mem. A.S.M.E.

At the present time the Tucson operating requirements are about 4000 kw., and we are considering the installation of a duplicate of the present big unit in the immediate future.

The two-cycle principle was chosen for this new unit to cut down on the number of valves and consequent maintenance and loss of service as well as simplified head construction. We have found economy of this unit, so far, in all-day, every-day operation to be equal to, if not better than, the smaller four-cycle units installed in the same station. We are also using a somewhat heavier grade of fuel oil in the big engine than is permitted by the smaller engines.

There is no question of the advantage in the ease of operation and our anticipated lower maintenance costs for the big units when comparing these items with the same capacity in the multiplicity of smaller units. The voltage and frequency charts with the big unit in operation indicate superior regulation to several of the smaller units running in parallel with the big unit off the line.

The air for scavenging is drawn through an air washer to clean and cool it. With a reciprocating scavenger pump the rated capacity of this washer should be about twice its rated capacity for turbine-generator cooling. Some nuisance has been experienced at Tucson with the 3700 b.hp. unit owing to the air pulsation, accompanied by a steady thumping noise, both of which carry over the country for several miles. There is a difference of opinion among those of us who have been in intimate contact with this installation as to whether the air currents and noise are caused by the exhaust or the intake, or a combination of the two. The noise is in the form of a hollow boom like beating a large drum, timed at 124 beats per min., although the scavenger pump is double-acting in effect. We are now installing some additional muffler sections on the exhaust, the muffler being in the form of a stack which can be made up of any number of sections. At the top of this muffler there will be installed a chimney with its rim 90 ft. above the ground to correspond with an adjacent steam-boiler stack.

A concrete inlet chamber has been built which will be provided with wood baffles, and the air will enter this chamber through a stack carried well up into the air. With these added facilities, I do not anticipate any further noise or air vibration nuisance. However, our next big engine is to be equipped with an independent motor-driven scavenger blower.

There are a number of interesting features in connection with our Tucson Diesel-engine installation, such as using Zeolite-softened water for spray-pond make-up; putting this spray-pond water directly through the jacket spaces rather than through the heat exchangers of a closed system; removing the traces of oil from piston-cooling water by chemical treatment and filtration; the storage, handling, and cleaning of fuel and lubricating oils; exhaust-heat reclamation in connection with the six smaller engines, and so forth.

[Since the foregoing discussion contracts have been let for a duplicate 3750-b.hp. engine but equipped with a scavenger blower driven by a 350-hp. synchronous motor, and a duplicate alternator. This second large unit will be in operation by the early part of the coming year.—J. S. B.]

H. L. H. Smith.[4] The author says much that is of interest and gives some points that are novel. There is no doubt that in these days of interconnection between power systems there would be decided merit in having Diesel-engine units capable of operating as synchronous condensers when not needed for power generation.

As to the Sulzer Bros. single-cylinder experimental double-acting two-cycle engine with a cylinder of a diameter of 900 mm. and a stroke of 1400 mm., this is a huge cylinder, and undoubt-

[4] Superintendent of Steam Power, New England Power Co., Worcester, Mass.

edly engine builders would have to experiment with construction of such size in order that the difficult problems of cylinder-head and piston cooling might be worked out by determination of facts. The author also tells of a former single-cylinder Sulzer experimental engine having a bore of 1000 mm. The author does not make it clear whether these huge experimental single-cylinder engines were constructed by the Swiss firm or by the American Sulzer firm, but presumably they were made by the Swiss firm. It would seem to the writer to be a far cry from an experimental single-cylinder engine of such dimensions to an engine with as many cylinders as ten. It is true that the author mentions that Sulzer Bros. have supplied eight 10-cylinder units averaging about 5000 hp., but such an aggregation as proposed, constituting an engine of altogether record size, would leave one waiting somewhat dubiously for the record of successful operation and satisfactory maintenance cost and service availability.

The fact that the number of reciprocating marine engines under construction exceeds the marine turbine horsepower under construction nearly two to one does not of course establish superiority of reciprocating engines over steam turbines except under the very special economic conditions of marine power, and unquestionably it is the rather special marine power considerations which establish the ratio of practically five to one for marine Diesel engines compared with marine steam turbines.

The author gives a table of fuel oil consumed in generating electric power by public-utility power plants in 1927. In this table Massachusetts is outstanding in that it consumed 9 per cent of the fuel oil used in public-utility plants of the entire country. Massachusetts is neither a cheap oil state nor a cheap coal state, but it has water-borne transportation of either fuel so far as its coast line is concerned. Its consumption of fuel oil has varied somewhat widely and rapidly with the varying factors of oil production and freight transportation, the tendency recently having been toward lowered use of fuel oil. Specific reference is made to the Narragansett station as using fuel oil, although the most recent practice at that station does not comprise the use of oil fuel.

The author gives an interesting tabulation of estimated costs of a four-unit station aggregrating 15,000 b.hp. or 10,000 kw., using as a basis the unit engine cost previously mentioned by him of \$60 per b.hp., the estimate totaling \$1,350,000, or \$135 per kw. of installed capacity. If this installation were figured on its load capacity with one unit out of service, the unit cost would go up to \$180 per kw.

The author mentions the daily peak load as difficult to provide for in central-station operation. In these days, however, the central-station field is almost entirely that of light and power, and the old-established peak loads of a few hours' duration which characterized all electric-railway stations and do still to the limited extent in which electric railway loads have not been taken over by the general electric utility supplying light and power, and which characterized the electric-light central station in former years before the development of extensive industrial peak loads, have at the present time very limited existence.

The general electric utility today has an industrial peak load which now exceeds its lighting load. It is true that for a few weeks in the winter there is a serious overlapping, but seemingly at present it must be handled by short seasonal operation of otherwise obsolescent reserve equipment. In a few more years it undoubtedly will be handled largely by the joint effect of temporary curtailment of the heat economy of steam plants by the cutting out of perhaps two stage heaters in multiple-stage heating turbo-generators, thus allowing nearly the full throttle steam admission to go through to the condenser, the low temperature of cooling water in the winter season enabling the condensers to maintain good vacuum and also making available extra thermal capacity of generator air coolers so that the generators may carry loads from 10 to 15 per cent in excess of nameplate ratings.

The author refers to the commercial strife between Diesel-engine salesmen and electric-utilities salesmen with respect to industrial installations. More responsible consideration of the whole matter of the competitive field of electric-utility power supply and industrially generated power would seem to be free from considerations of this nature. The electric-utility industry should not be considered as antagonistic to Diesel engines, nor on the other hand can it be expected to adopt it as a means of forestalling competition with industrially generated power by means of the Diesel engine.

Joseph Pope.[5] This meeting has gone from an oil-engine meeting to a meeting of an entirely different character; its chief object now being, apparently, to criticize the central station and to find fault with the steam plant. A steam plant is not necessarily the inefficient and disreputable thing we have been told it is, and one can be built today that very closely approaches the efficiency of a Diesel generating station. Much of the discussion has had to do with the low efficiency of a steam plant with low load factor, and the suggestion has been made that the peak load be taken off with an oil engine, leaving the remaining load at higher load factor on the steam apparatus. Now a steam plant usually has a pretty well defined economy characteristic. If energy generated be plotted against fuel burned for a great number of periods of equal length but different outputs, the resulting locus is practically a straight line, crossing zero output at something more than zero fuel consumption. Practically every kilowatt-hour generated, after the combustion of this zero load fuel, bears the same fuel cost as every other kilowatt-hour. What is wanted is to get the average cost down as close to this fixed increment cost as possible. Any one who has ever run a power plant knows that, except under the most unusual circumstances, the average fuel rate on the peak watch, with lowest load factor, is always better than on the other watches. It is because there are more kilowatt-hours to divide the no-load fuel by. It is the big divisor we are looking for, and anything that results in increased kilowatt-hours helps, be it high-load factor or high peak. With the same peak the higher load factor of course wins. Load factor in itself means little in operating costs, but it means a lot in unit fixed charges.

The author refers in his paper to the cost of a Diesel plant which he estimates at \$135 a kilowatt. He also speaks about the Miraflores plant. I had hoped that he was going to tell us what it cost. There has been a great deal published about that plant, but I have never seen even a suggestion of its cost. I presume we know what the engines and generators cost, for the competitive bids were published and \$94 per kilowatt was the low bid. A statement of the completed plant cost would be very helpful to others contemplating a relatively large plant and would clear away much of the fog that surrounds estimates of plant cost.

I think that it will be generally acknowledged that oil engines and generators alone will cost \$100 a kilowatt, and that is only where you begin. If all the other necessary things can be supplied and constructed for \$35 a kilowatt, fine!—but I doubt the ability to do it very much.

The author also shows a layout of a steam station compared with an oil-engine plant. If any one were to actually build a steam plant like the one pictured, it would be the last job he would ever do for me. The capacity is 20,000 b.hp., less than 15,000 kw., and there are four turbine-generators and either seven or fourteen boilers, I cannot make out which. What

[5] Consulting Engineer, Stone & Webster, Inc., Boston, Mass. Mem. A.S.M.E.

really should go into the plant depends on the load, its present characteristics, and what they are expected to be in the future.

At most, three turbines would do, possibly only one or two, and four boilers would certainly be enough. In some cases I migh put in only two boilers, if an increase in load would warrant another in a relatively short time. You can readily see what a difference reductions like that would make in the cost of the steam plant. The same liberties cannot be taken as legitimately with the Diesel-plant equipment because the units that have been proposed are at least as large as any ever built in this country.

Referring again to the matter of peak-load capacity. There are two ways ordinarily used for providing it. The more usual is to employ old apparatus that has been in the plant for years. Its first cost was low, and it owes the plant very little now, yet it is amply good for operation on short peak runs and is just as good as anything else to stand idle for reserve. Another way now rapidly becoming popular is to buy apparatus with best efficiency points at low ratings but with large overload ability. This extra capacity can be obtained very cheaply. This is the plan being adopted by the central stations most affected by the sudden short notice demands to which the author refers. In case of such a load being thrown on the plant nothing has to be started up. The reserve capacity is already running.

I cannot see much to the idea of using an oil engine for peak purposes. I think that if an installation of an oil engine can be justified at all, it will be run practically on base load to make use of its one major advantage, economy of fuel, to the greatest possible extent. The only possible excuse for doing otherwise would be a marked disproportion in the cost of steam and Diesel fuel and a high maintenance cost for the oil engine. I doubt very much if the former would occur in this country. Perhaps it does in Germany, where, as one of the previous speakers in justifying the peak load Diesel in Hamburg has said, coal costs 63 cents per ton and oil 11 cents per gallon, although my information is that Diesel oil costs there 120 marks per metric ton (1.36 cents per pound or 8.75 cents per U. S. gallon) and coal 22 marks per long ton or $5.50 per 2240 lb.

I do not want it inferred from these remarks that I am not favorably disposed toward the Diesel engine. I recognize certain legitimate fields for it, and think it would make more progress if its proponents confined their efforts to advertising its undoubted good features instead of trying to point out the defects of other systems of power supply, concerning which they do not appear to be particularly well informed.

### Author's Closure

The comments of Mr. Edgar J. Kates throw a very interesting sidelight on the discussion. After all, the case between centralized public utilities and local individually owned power plants rests upon selfish interests; but the selfish evaluation of the relative advantages and disadvantages must, in each case, be based on more intelligent and broader considerations that the mere comparative cost of purchased power and individually generated power; at the very least, reliability and permanence of service and the effect upon other correlated uses must be considered as factors. The author had intended to point out some avenues, opened up by the Diesel engine, through which the centralized public utility could reach lower power costs, to the mutual advantage of itself and the public. Mr. Kates directs attention to another avenue to the same goal; that is, the building up of domestic load. But the intelligently selfish interests of all parties must be served, if such advantages are to be realized.

The gratifying experiences of the Tucson Gas, Electric Light & Power Company, described by Mr. J. D. Bowles, could surely be extended to many other public-service stations similarly situated. The steady growth of the unit and total capacities of this station is an indication of the development of Diesel engineering in the United States during the last 14 years. In this connection it may be of interest that, in 1912, when the plant of Busch-Sulzer Bros. was built, that company considered itself quite optimistic in assuming the largest unit it should be prepared to build to be 1500 hp.

The following will answer some of the questions in Mr. H. L. H. Smith's discussion. The large experimental single-cylinder Diesel engines, both the single and the double-acting, were constructed by the Swiss firm of Sulzer Bros., in Winterthur. The author is not in accord with Mr. Smith's belief that it is necessarily a long step from a single-cylinder experimental engine to a unit comprising ten or more of such cylinders. It all depends upon the purposes of the experiments, and the extent to which and conscientiousness with which they are carried out. Experiments started and carried out with the purpose of proving the correctness of an accomplished engineering design must not be classed with such as have the purpose of developing a piece of apparatus, and "working the bugs out of it" before introducing it to the public. The years of successful service of the many children, quadruplets to dectuplets, of Sulzers' large single-cylinder, single-acting experimental engine are a tribute to that firm's Swiss thoroughness. As to the utility of marine Diesel engines as indices of what may be expected from similar units in stationary service, while there are certain differences in the economies effected, the success of these marine engines, mounted on relatively unstable foundations, running at all sorts of angles, with propellers alternately overloaded and unloaded by waves, and developing full power continuously for weeks at a stretch, is certainly sufficient assurance of their reliability in the comparatively favorable stationary service. The multiplication of cylinders is a definite tendency of the time, with much in its favor, particularly in the matter of first cost, and little against it other than comparative unfamiliarity with the idea. It is not many years ago that even six cylinder engines met with considerable opposition from purchasing engineers for land stations.

Mr. Joseph Pope questions the author's estimate of the cost of a Diesel plant. He mentions that for the Miraflores plant the low bid on the units alone was $94 per kilowatt, and suggests that a statement of the complete cost of that plant would clear away much fog. In the writer's opinion, the opposite would result, and as an example of the unreliability of figures by themselves, the writer points out that the bids on these units included delivery at the Panama Canal Zone, many special engineering requirements, six months' supply of lubricating oil and ten months' services of erecting engineers, besides special shop tests and the expenses incident to governmental inspections and approvals. The station itself may compare with an ordinary commercial station about as the Lincoln Memorial does to the adjacent Munitions Building.

The writer is certain of the sympathetic concurrence of all builders of large Diesel engines in his assertion that they would be happy could they always get the estimated $60 per b.hp. for such stationary machines, built in the best commercial manner; and Mr. Pope will be able, on inquiry, to obtain prices on large Diesels with generators alone at less than $90 per kw.

As to the capacity of units and the resulting dimensions of stations, there is undoubtedly some economic limit to unit capacity; but looking back over only the last ten or fifteen years, who has the courage to set this limit for either steam turbines, or boilers, or Diesel engines? It was possibly unwise for the author to compare stations of equal flexibility as well as capacity, but he still contends that Diesel stations occupy less space than comparable steam-turbine stations.

# Oil-Spray Research at Penn State

By P. H. SCHWEITZER,[1] STATE COLLEGE, PA.

AN EXPERIMENTAL investigation of the fuel-injection phenomena is one of the major projects of the Engineering Experiment Station of the Pennsylvania State College. The main object of the investigation is to establish the laws that control the characteristics of oil sprays in compressed air under various conditions encountered in the injection type of oil engines.

The investigation began in 1924, and the past four years were almost entirely taken up with the building of the elaborate apparatus used in the investigation. The U. S. Navy and several engine builders helped generously in the assembly of the experimental equipment, which is perhaps unexcelled anywhere for the studying of fuel injection. The completion of the experimental program will help materially the futher development of the oil engine. Advance is expected in these two lines:

1 A more efficient introduction of the fuel
2 Its faster preparation for ignition as required by high-speed engines.

Fig. 1 shows the schematic arrangement of the set-up. The central part of the apparatus is the pressure chamber. The chamber is filled with air and oil is injected into it. The spray is observed visually through a plate-glass window which is kept free from oil fog by means of a window wiper. Illumination is provided through a similar window on the other side of the chamber. The penetration and energy of the spray are accurately determined by the pendulum shown in the middle of the chamber. The spray hits the disk of the pendulum, which deflects under the impact. The pendulum carries a small mirror at the top which reflects a beam of light through the top window, and the deflection is read on the scale above the chamber. An air-pressure gage and a safety valve, set for 520 lb., are ndicated on the diagram.

Both cam-actuated and automatic nozzles are used for the injection of the fuel. The diagram shows the set-up for constant-pressure injection. A long-stroke pump produces pressures up to 10,000 lb., which can be kept fairly uniform with an accumulator, partly filled with air, in the fuel line. Passing an oil filter, the fuel travels into the cam-actuated nozzle. A cam driven by electric motor and acting on a lever arm periodically opens and closes the needle valve, producing intermittent injections. Through a gearset the frequency of the injection can be varied, and by means of an interrupter mechanism either one shot or several in succession can be produced at will. The oil-pressure indicator records the pressure fluctuations during the injection. With the spray stroboscope, which permits the jet pass in a certain phase only, the "time distribution" of the spray may be studied.

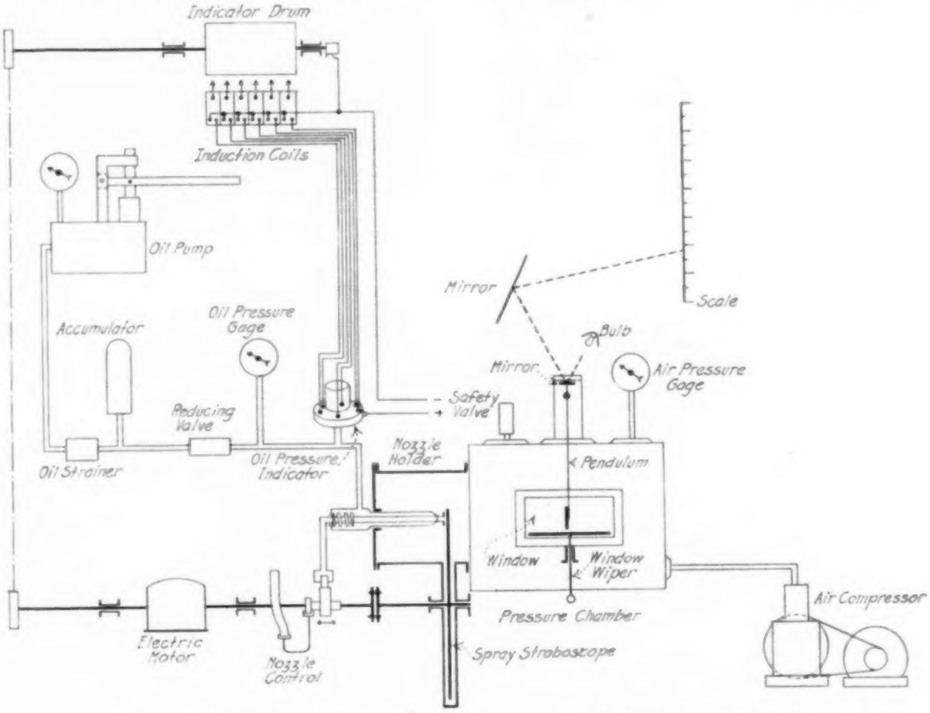

Fig. 1 Schematic Arrangement of Equipment for Fuel-Spray Research

With jerk-pump injection an automatic nozzle is placed in the nozzle holder in place of the cam-actuated nozzle and a fuel pump is driven by the cam. In this case the hand pump, accumulator, and oil-pressure gage are out of operation, but the interrupter acts on the pump itself producing one-shot injection.

Fig. 2 shows the pressure chamber, which is a rectangular casting with 28 in. × 20 in. × 20 in. outside dimensions and $2^1/_2$-in.

wall thickness, tested for 800-lb. hydrostatic pressure. The plate glass windows are 1 in. thick and are clamped between rubber gaskets in a floating manner to eliminate the initial strains. The seal is effected by the internal pressure only. The entire chamber moves on rails, which permits the study of various jet lengths. To vary the distance between the nozzle and the pendulum spacers are used.

The experimental nozzle, Fig. 3, used for constant-pressure

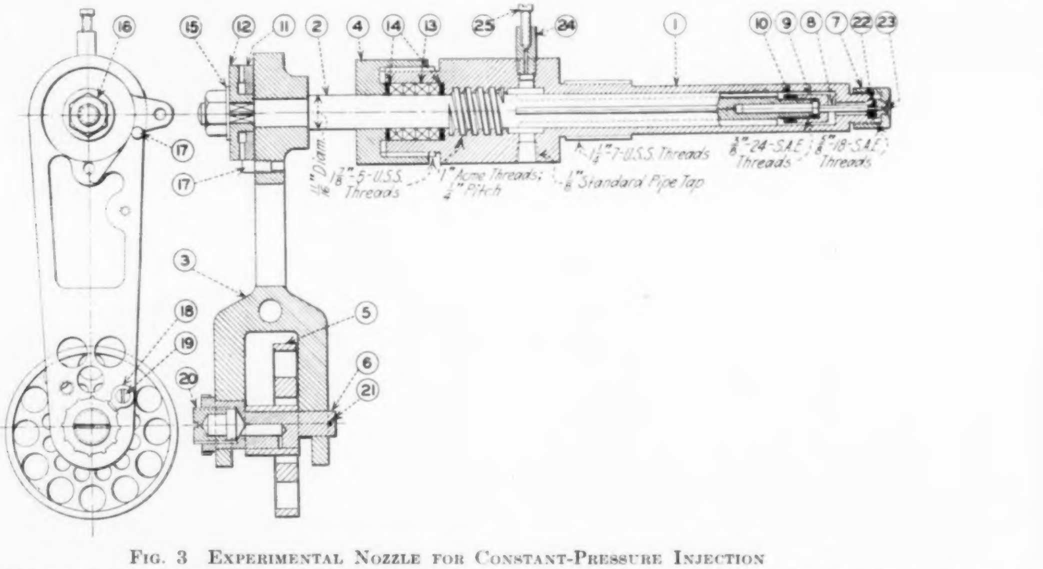

Fig. 3 Experimental Nozzle for Constant-Pressure Injection

(1 Valve body. 2 Valve spindle. 3 Valve arm. 4 Stuffing nut. 5 Roller. 6 Roller pin. 7 Nozzle cap. 8 Needle valve. 9 Valve holder. 10 Lock ring. 11 Clutch, female half. 12 Clutch, male half. 13 Packing material. 14 Washer. 15 Washers. 16 Nut. 17 Pin. 18 Roller-pin stop. 19 Screw. 20 Plug. 21 Cotter pin. 22 Valve seat. 23 Nozzle tip. 24 Vent. 25 Vent screw.)

injection, is built on the screw principle and has proved very satisfactory. The object of the unconventional design was to be able to use large cams in conjunction with small needle lifts. In this way the influence of the cam profile can be studied more conveniently. Both flat seats and conical seats are being used. With the injection interrupter, Fig. 4, single injections can be produced at a high rate of speed. The cam rotates continuously, but ordinarily it is out of engagement with the roller of the lever arm. By tripping the trigger, shown in front, the cam moves axially and stays in engagement with the roller for one revolution only. In this way a one-shot injection is produced. Setting the interrupter out of action, the injection repeats continuously.

The spray stroboscope, Fig. 5, is an aluminum disk with a slot and is driven from the same shaft which controls the injection. It is located between the nozzle tip and the pressure chamber. The slot permits the passage of the jet at definite intervals only. The rest of the spray is kept from entering the chamber. By corresponding angular adjustment of the disk, various phases of the injection, such as the beginning, the middle, or the end, can be separately studied. By measuring the amount of oil injected in the first, second, and third periods and determining the energy and penetration of various phases by means of the pendulum, the time distribution of intermittent sprays is studied and valuable information regarding after-dribbling is secured.

The dispersion or space distribution includes such items as penetration, cone angle, and spray density at various points. Absorbing the spray with felt rings made up from proper sections and determining the amount of the liquid absorbed by the weight increase is the technique to be used in studying these problems.

In order to record the pressure variations in the injection line during the short time of injection, a special indicator, shown in Figs. 6 and 7, has been developed.

The main principle of the indicator is the use of a number of pressure-registering elements instead of a single one. Each of the six diaphragms is set for a different pressure, and at the instant the pressure reaches a predetermined value, electric contact is made which is recorded on a rotating drum. The contact is maintained as long as the pressure exceeds that for which the diaphragm is set and during that time the corresponding spark needle on the drum punctures the paper at each spark, producing a row of holes. In this way a number of perforations are produced, the length of each corresponding to the time interval during which the pressure exceeds the pressure for which the respective diaphragm is set. Using six diaphragms, which deflect at, say, 200, 400, 750, 1200, 2000, and 3000 lb. per sq. in. pressure respectively, twelve points are obtained, six for the ascending and

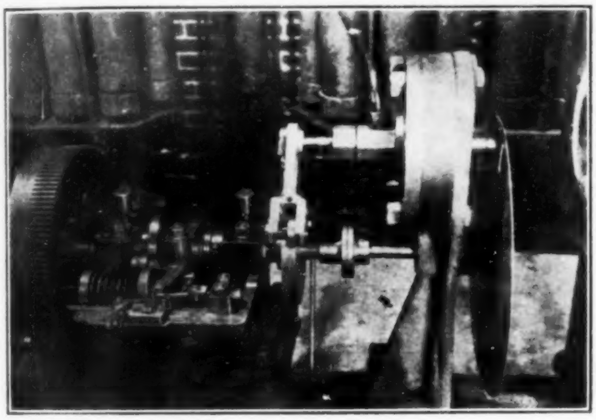

Fig. 5 Spray Stroboscope to Study the "Time Distribution" of the Injection

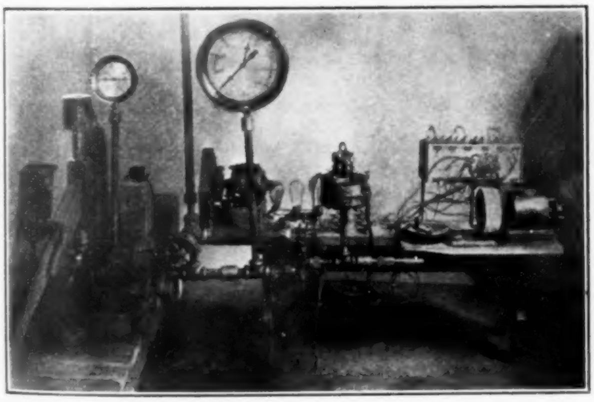

Fig. 6 Assembly of Oil-Pressure Indicator

six for the descending curve, indicating the time at which these pressures were passed during the injection. The connection of these twelve points into a continuous curve, giving a time-pressure diagram, offers no difficulty.

The recording is practically instantaneous. The electric lag—that is, the time interval between the contact made in the indicator and the mark produced on the paper—was measured and found to be about 0.0002 sec. Because the movement of the diaphragm is but a few thousandths of an inch, the inertia effect is negligible. With this indicator pressure variations of several thousand pounds within less than one one-hundredth of a second have been recorded and time-pressure diagrams obtained. Fig. 8 shows the oil-pressure indicator mounted on an engine with a duplicate spray nozzle.

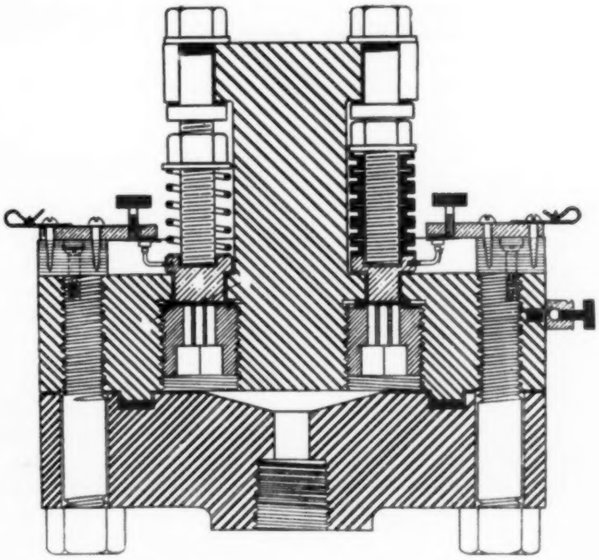

Fig. 7 Cross-Section of Oil-Pressure Indicator

Standard tests are proceeding now in three different lines: 1 Continuous injection under constant pressure. 2 Intermittent injection under constant pressure. 3 Jerk pump injection.

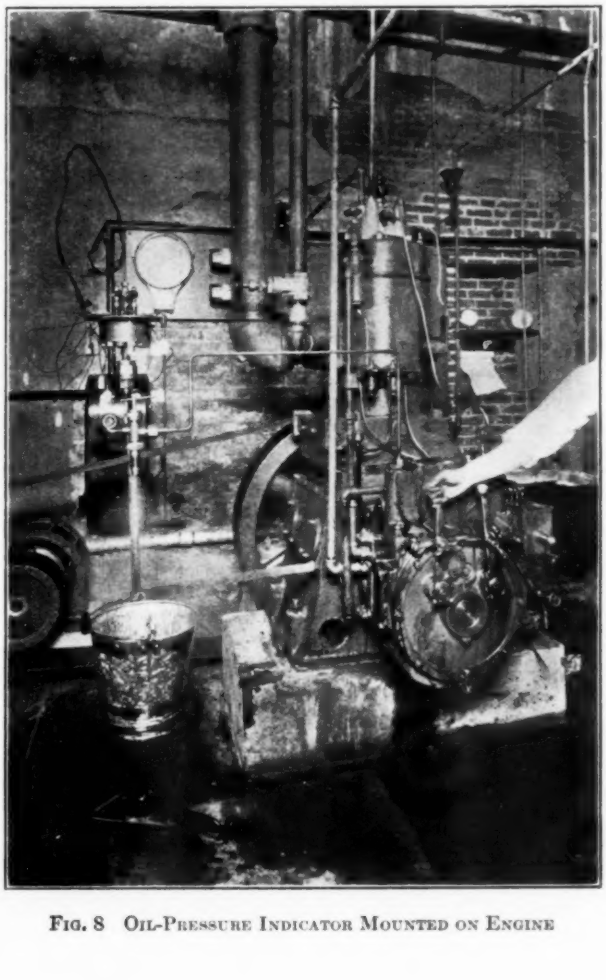

Fig. 8 Oil-Pressure Indicator Mounted on Engine

The characteristics being investigated are: 1 Spray penetration 2 Spray dispersion. 3 Time distribution. 4 Pressure fluctuations. 5 Injection lags.

The factors influencing these characteristics which are investigated are: 1 Oil pressure. 2 Pressure or density of the gaseous medium. 3 Orifice dimensions. 4 Properties of the fuel. 5 Frequency of injection. 6 Cam profile. 7 Length and diameter of the pipe line. 8 Injection pump characteristics. 9 Turbulence.

Penetration tests with continuous sprays are made by the zero method. The pendulum is loaded with a weight which just keeps it in balance against the deflecting force of the spray. If the balance is slightly disturbed, the light indicates it on the scale.

Penetration of intermittent injection is measured by the one-shot method. The pendulum acts as a ballistic pendulum in this case, and the energy of the spray is inferred from the amount of deflection. The dispersion or space distribution of continuous and intermittent sprays is determined by the felt-ring method and the time distribution of intermittent sprays by the spray stroboscope.

Paralleling the investigation of the external spray characteristics, pressure variations within the nozzle and the pipe line are studied and correlations established. The electric-spark method is also used in the investigation of the time lags, so important with the jerk-pump injections.

The project is planned to include the testing of commercial fuel-injection equipment.

OGP-50-13

# Specialization in Manufacturing Diesels

By O. D. TREIBER,[1] CAMDEN, N. J.

A MANUFACTURER is always hunting ways to cut costs, and the purchase of finished specialty products is perhaps one of the principal ways to do this. The automotive industry could not have developed to its present state without the ability of manufacturers to buy specialty finished products, although some of the automotive concerns have now grown to such a size that they manufacture many of their own specialties.

The Diesel-engine industry has today a very good supply of specialty products to draw from such as bearings, piston rings, drop-forgings, castings, crankshafts, valves, cams, springs, pistons, gears, governors, lubricators, pumps, gages, and valves, all of which are more or less common to many builders of engines. Prices of these products to the manufacturer are in many cases very satisfactory and such as to discourage the engine builders from trying to manufacture them. However, there is opportunity for improvement.

The Diesel-engine business is settling down to a more stable and well-organized business. The ability to obtain specialty products from various shops will undoubtedly have a bearing on the reduction of Diesel-engine costs and should be encouraged. There will undoubtedly be different designs of items such as fuel-oil pumps and spray nozzles. However, these generally fit about the same tools, and shops should organize themselves for producing such things, even in small quantities. At fair prices they can reasonably expect to be quite successful. There may be some parts which an engine builder can manufacture in his own plant cheaper or better than can be done in a specialty shop. This, however, is doubtful if the specialty shops will make a study of requirements and equip themselves for economical production.

The various parts of the Diesel engine can be classified into a reasonable number of groups, such as parts which are hardened and ground, parts made on screw machines, automatics, parts made from small iron castings, parts made from large cast-iron castings, parts made from aluminum. Another item is piston rings; still another is bearing shells. Another separate classification could be cylinder heads and liners. Under these classifications can be grouped practically all the parts entering into the construction of Diesel engines. It would seem to me, as an engine builder, that this section of the A.S.M.E. would contribute a factor of tremendous economical value by appointing a committee to study these classifications and make recommendations with a view to assisting both engine builder and specialty manufacturer in the economies which might be effected from specialty manufacturing.

It is necessary of course for the specialty manufacturer to study the needs of the engine builder and make what the engine builder wants and under no circumstances endeavor to sell the engine builder something which the specialty man for selfish reasons has become interested in selling.

Progress in the Diesel-engine building art has been very rapid in the last few years, but production will never be as intensive as in the automotive business. However, specialty shops can contribute their portion to the economics of Diesel-engine construction in maintaining a high-class organization of mechanics who are taught to do different kinds of jobs economically. This policy is of necessity exercised in the Diesel-engine manufacturer's shop because of the lack of high production of any given size, and if it can be worked out efficiently in the builder's plant it can also be done in the specialty shops. Take, for instance, the matter of spray nozzles. There are probably twenty-five different kinds of spray nozzles today built in as many different shops. Probably there is not sufficient production in any one shop to tool up for high production. However, should the construction of all of these spray nozzles be confined to one shop and one organization, there are a great many of the operations, such as heat treating and grinding, assembling, testing, etc., that could be done much more economically, resulting in larger savings to the ultimate purchaser.

# The Diesel Engine and Public Utilities

By ROSWELL H. WARD,[1] NEW YORK, N. Y.

THE problem of the relationship between the Diesel-engine industry and the public utilities is one which deserves the careful consideration and dispassionate scrutiny of all concerned. It is a matter of vital importance to the utility companies because the Diesel engine in its present advanced state of development is likely to be the most direct answer to the future challenge of low power rates, high transmission costs, and high fuel costs, conditions which every power producer is facing or must expect to face within the next few years.

To the Diesel-engine industry the subject is naturally of interest because the public-utility use of Diesel power on a large scale, given the proper appreciation of the scope and capabilities of the Diesel engine, can become an important force in extending the field of usefulness and the public understanding of the Diesel engine.

We have heard an author refer to the relations between the two industries as "unhealthy;" and it is the purpose of this paper to conduct a verbal diagnosis of this "invalid," this unhealthy condition, in the hope that some of the points brought to light may serve as a firmer foundation on which to base our future efforts in behalf of the broader application of Diesel power.

The Diesel engine industry and the public utilities are both comparatively young, and they are both "pioneer" industries in spite of the tremendous development which has taken place within the past few years.

In the sense that they are both dedicated to the greater development of our national power resources, the Diesel-engine industry and the public utilities are "brother" industries. At times they have lived and worked together with the utmost harmony; at other times they have indulged in the most vituperative family squabbles; and in some instances they seem to have carried on entirely oblivious of each other's presence. This rather erratic behavior is due to the somewhat conflicting points of contact between the Diesel industry and the public utilities, which can be summarized as follows:

1 Public utility use of Diesel power
2 Competition between the Diesel industry and the utility companies for industrial load
3 Competition for municipal projects.

The first view of such a complex relationship might lead one to believe that the questions concerning each individual point of contact should be discussed separately. However, it has been found that there is so much overlapping, especially so far as policies and trade practices are concerned, that we can broaden the discussion to include all of the underlying issues and that their relationships to these points of contact will easily clarify themselves as the discussion continues.

Looking at this relationship with a full appreciation of the fact that the Diesel engine has most conclusively established itself in an immense variety of power applications, the general sphere of which have been defined by Mr. Pollister and Mr. Pratt, we find a rather unequal allotment of this essentially American "pioneer" spirit. The Diesel-engine industry has, if anything, been a little bit overenthusiastic in some of its relations with the utility companies, a perfectly natural reaction, however, when they find great and supposedly progressive power producers apparently blinding themselves to the immense progress in Diesel central stations that has been made by European groups. The utility companies, on the other hand, have been backward in recognizing the Diesel engine as anything but a troublesome competitor for industrial load. The reasons for this condition can probably be summed up under the following three headings:

1 Unreasonable sales methods by both Diesel salesmen and utility-power salesmen
2 Lack of understanding of the Diesel engine by American engineers
3 Lack of uniformity and scarcity of Diesel-power cost records, especially of public-utility plants.

In an effort to clarify the sales methods of both industries the writer has carried his inquiries not only to all of the Diesel executives with whom we are ordinarily in contact, but through the courtesy of Mr. Paul S. Clapp, managing director of the National Electric Light Association, he has also been given an excellent opportunity to hear what the commercial power salesmen have to say about it. From the standpoint of the Diesel-engine salesmen the following practices of public-utility power salesmen seem to be the ones which arouse the most comment:

1 Inaccurate compilation of reports on Diesel power costs which are submitted as a basis for comparison with the utility companies' quotation
2 Misrepresentation of operation of Diesel engines in utility company plants and in private installations
3 Misleading statements as to future supply of fuel oil; criticism of Diesel engine manufacturers' advertising; presentation of contracts which do not clearly indicate the extent of charges, due to penalties, demand charges, etc.
4 Exaggerated statements as to the degree of training necessary for a successful oil-engine operating engineer
5 Misrepresentation of municipal and insurance company regulations for storage of fuel and lubricating oil.

The public utility men, in turn, sum up their composite criticism of Diesel sales methods as follows:

1 Criticism of public utilities as "soulless" corporations or monopolies; criticism of public-utility policies, rate structure, etc.
2 Criticisms based on differences in industrial and residence rates, etc.
3 Appeals for public ownership of municipal plants based on everything from costs to civic pride; extremely broad generalizations as to superiority of Diesel power.

In reference to the methods of commercial-utility salesmen, it must in full justice be said that most of the statements made by them are the result of ignorance. However, there is a uniformity in the utility companies' policy toward the Diesel engine which is strikingly absent in the attitude of various Diesel-engine builders.

The reason for the uniformity in utility expressions of opinion on the Diesel engine is principally the annual "Diesel Engine Cost Report" of the National Electric Light Association, a cost report which is compiled by a power committee of power salesmen and not engineers. *Oil Engine Power*, as some of you know, has set in motion an effort to obtain a disinterested technical scrutiny of the next N.E.L.A. Power Committee report, an

[1] Managing Editor, *Motorship*.

Presented at the First National Meeting of the A.S.M.E. Oil and Gas Power Division, the Pennsylvania State College cooperating, State College, Pa., June 14 to 16, 1928.

effort which has already met with considerable success, although there are several points which have not yet been satisfactorily settled.

There is a tendency on the part of the utility-power salesmen to regard this "report" as a sales manual; there is a lamentable lack of uniform and up-to-date Diesel-plant cost records, a point which will be elaborated later; there is a tendency to regard the Diesel engine from the utility viewpoint, as merely an industrial competitor. It will therefore be seen that considerable further work must be done before this report loses the "sales manual" taint and becomes an impartial report on Diesel costs.

The attitude of the average American engineer toward the Diesel engine is a stumbling block which has its roots deep in the dark ages. Realizing that the technical schools are partially, though involuntarily, responsible for the lack of up-to-date Diesel training of the average engineer, a survey of Diesel training facilities has been made by *Oil Engine Power*.

Another bad habit of the average engineer is his inclination to think only in terms of very large central stations. It is quite true that in various thickly populated areas we have extremely large central stations, but the cost of high line transmission, the comparative sparsity of the population in a great many sections of the United States, and a number of other factors have limited the construction of large central stations. Hence, the average electric public service or industrial plant in this country is comparatively small, and most of them are well within the range of Diesel power; yet our engineers insist on thinking in terms of mastodons when they are surrounded with prairie dogs most of the time.

The question of Diesel operating statistics has been mentioned; it is comparatively easy to get cost reports on private Diesel plants, although they are lacking in uniformity, but the very same utility group that will criticize the Diesel engineer for lack of a mass of uniform statistical data will be the first to refuse to release the cost data on its own Diesel plants.

Statistics are the basis of any impartial engineering survey; and until there is a mutual agreement on such points as rates of depreciation, interest rates, charges for maintenance, cost of installed capacity, etc., and a mutual interchange of data on private and public utility Diesel plants, Diesel statistics will continue to suffer from varying interpretations and from the limitations of the sources from which they are drawn.

If we will therefore return to the first analysis of the contacts between the utility companies and the Diesel engine manufacturers, we will find the following interrelation:

1 Concerning competition for industrial load: The natural course of business evolution and the setting up of an impartial fund of Diesel statistical data will automatically settle many of the unnecessary points of conflict which surround what should be a condition of healthy clean-cut competition. A future development along this line may be the consideration of the use of Diesel engines by utility companies themselves, who find it uneconomical to attempt to transmit power over the high line to an industrial user. If a utility company can ask an industrial prospect to install an elaborate transformer installation, it could certainly propose to the industrialist that he permit the utility to install and operate a utility-owned Diesel plant to give him the degree of reliability and economy which he has a right to expect.

2 Public-utility use of the Diesel engine is dependent on an appreciation of Diesel power which will be fostered by "cleaning up" the methods of competition for industrial load; by taking additional steps to inform graduate engineers as to the recent progress in Diesel engine design and application; by cooperating with the technical schools to bring their power plant courses up to a requisite point of "Diesel consciousness," and by gathering and disseminating broader and more authoritative cost records of large Diesel plants.

3 The question of competition for municipal plants is largely a matter of the individual policy of the Diesel engine manufacturers and public utilities concerned. Progress along the lines indicated will largely eliminate the charge of "unhealthy" methods in this market.

It will thus be seen that what appears at times to be an intricate and embarrassing conflict between two great industries is largely a series of minor misunderstandings to which a number of very logical answers immediately suggest themselves. Impartial and uniform cost reports on a large number of Diesel plants are urgently needed; a determined effort should be made to bring engineers and engineering students "up to date" on Diesel progress (a work to which *Oil Engine Power* and *Motorship* are, in the nature of things, deeply committed); and underlying all of these efforts should be a deep appreciation of the value of giving the newer business policy of cooperation between industries (even though they are competitive) a chance to prove its usefulness in this relationship.

Above all, there is the essential dedication of these two industries to a common cause: the dissemination of the emancipating lifeblood of cheap and reliable electric energy to the mass of the world's population, a tremendous and fundamental work which promises to be the greatest civilizing force ever conceived by man—a world movement in which the Diesel-engine industry and the public utilities will mutually be expected to meet the challenge of the future.

## Discussion

H. C. Thuerk.[2] We are here today not to secure information to use against your Diesel-engine industry nor are we here because we feel that by our presence we may temper some of the statements which might be made. We are here, however, because we are anxious to obtain first-hand and authentic operating information on the Diesel engine. We have been glad to work with Mr. Ward in an effort to reach a common understanding between the Diesel-engine manufacturers and our own great power industry, as we feel that we have certain common interests.

We have been trying for several years to secure authentic operating cost data on Diesel engine plants. If it were possible to have contacts in the Diesel-engine industry where we could obtain this information, I am quite sure a great deal of the present misunderstanding would be eliminated. I want to say here as a member of the power committee of N.E.L.A. that we sincerely appreciate the spirit of cooperation shown by Mr. Pollister of the Busch-Sulzer Bros.-Diesel Engine Company.

When we talk about conserving our natural resources it should be pointed out that the central stations of this country have a responsibility in this direction. We are at present furnishing approximately 60 per cent of the energy used by electrified industries. We have built up power stations, transmission lines, and distribution systems which represent a considerable investment. If large customers are taken away by competition it means that these large investments will be idle. Naturally therefore we are carefully watching all types of competition for this business in order that we may ethically protect these investments on a sound, economical basis.

It is true that the information disseminated to the electric light and power companies had been gathered by our power salesmen, but I want to point out the fact that these data are obtained from engineers. We have recently made arrangements so that one member of our power committee will attend all meetings of the oil and gas power sub-committee of the prime movers

[2] Erie Lighting Company, Erie, Pa.

committee and thus have available for our own records the data gathered by the engineers of our industry. If we can obtain from the Diesel-engine manufacturers accurate cost records on existing plants over a sufficiently long period of time, I assure you that we are going to publish that information if permission is obtained to do so.

I believe that there will always be competition between us. We shall never reach the time when members of both industries will sit back and curtail selling activities. Your industry and mine will probably always be in competition for additional power business. If we can compete on a strictly ethical basis and eliminate some of the undesirable characteristics of past experiences, I think that we shall have accomplished all that we may reasonably expect.

By cooperating we should be able to gather a great deal of statistical information on operating and investment costs which should be extremely valuable to both of us. This information will be of interest to both industries from the standpoint of competition and also from the standpoint of installing Diesel-engine units in our own generating stations.

Finally, I believe that this will be accomplished only by adopting a reasonable attitude toward each other. If we can have that reasonable attitude existing between the Diesel-engine industry and the electric industry, many of these problems will automatically solve themselves.

Hermann Lemp.[3] In my early days with the General Electric Company at Erie, Pa., I was very enthusiastic about the Diesel-engine. In connection with Mr. Henri Chatain, we completed what we considered a satisfactory 250-hp. high-speed Diesel engine, and after our work was finished we were disappointed to learn that the central stations had mentioned to headquarters that if we were to build these engines our business for central stations would cease. It occurred to me later that perhaps our sales department was at fault, and instead of advertising the fact that the small Diesel engine would be the most satisfactory unit for a small plant, it should have gone to the central station interests and told them how they might serve a much greater territory than they were serving at that time, explaining how they might establish portable Diesel-engine plants here and there, where the outlook of business would not warrant the extending of lines, substations, etc. By so doing they would create a new demand for electric service, and once this service established, feeders could then be run to take the place of the Diesel unit, which might then be moved to another unserviced territory.

I am thoroughly believing in the value of stress, and therefore think there will always be a certain amount ot honest competition between the electrical-power interests and the Diesel-engine interests. When business is operated on that basis, then the best results are to be obtained, and I believe it will be beneficial to all concerned.

Herbert W. Dow.[4] The Nordberg Manufacturing Company has many data available concerning the performance of Diesel engines in the large stations of this country. There is a plant at Moctezuma Copper Company, Nacozari, Sonora, Mexico, 9400-b.hp., which is the largest Diesel station in North America. Since this plant was put in operation seven years ago every item of cost has been recorded, and the records and the manner in which they are kept are the most complete that it has ever been my privilege to inspect.

Two 1500-kw. Nordberg Diesel generating units have been operated for the past two years by one of the largest public-service corporations in the United States. This plant has been operated on base-load service. We know what the costs of operating this station have been, and as subdivided into various items both as to prime cost and repairs. We have on various occasions asked for permission to publish this information concerning the actual costs of operating these stations, but permission has not been granted.

I personally have a feeling that the Diesel-engine builders have no right to publish such costs, for they represent vital statistics in relation to the carrying on of another industry. I am quite sure that none of us would look with favor upon having our detail operating costs in relation to the building of Diesel engines published broadcast. I believe that such data should come from users of Diesel engines, and then it would be much more authentic. We are waiting with great interest for the day when the owners of large power plants, who do know the operating costs, will either publish this information or pass it on for the benefit of the others engaged in public-service work.

Edwin H. Krieg.[5] It would appear from some of the preceding statements that there is a prevailing impression that public-utility engineers do not consider the Diesel engine. When a plant is built, it is not with the purpose of using a particular kind of prime prover, but to attain maximum financial economy. I have known of cases where steam plants were replaced by Diesels, and likewise where Diesels were replaced by steam turbines. Well-informed public-utility engineers would consider it folly to select a steam turbine where a Diesel engine would do the work better and more economically.

Statements of $135 per kw. of installed capacity and 9000 B.t.u. per kw-hr. are felt to be contradictory to values of $150 to $300 per kw. and 13,000 to 19,000 B.t.u. per kw-hr. as given in former N.E.L.A. reports. All of these glittering generalities about Diesel engines as always being the most economical lead to great misunderstanding. Greater progress would be made if the Diesel people would call to the attention of public-utility engineers the proper methods of evaluating the advantages of the Diesel in terms of dollars and cents, as there is a paucity of information and methods for such analysis.

Several speakers have referred to the data in the N.E.L.A. reports as perhaps being inaccurate. I know personally of some of the plants reported upon and am sure that the data are quite accurate.

May I again plead that the stating of generalities regarding Diesels be supplanted by an evaluation of those advantages by as accurate data as are available.

O. F. Allen.[6] When I was in Hamburg, in discussing the matter with the manager there I asked him what his comparative costs were for current from the new 130,000-kw. highly efficient plant in relation to the 10,000-kw. Diesel unit installed there. I asked him if he expected the Diesel engine to save anything over steam operation, and he said, "No." Up to that time they had no data that indicated there would be a great deal of difference in the cost, but they expected the overall cost of current produced would be a little less from the steam units.

A point that I want to bring out is with reference to capital investment and the use of capital by industrial plants. Much has been said about the industrial plant having its own installation, making its own power as compared with buying central-station power.

In the first place, the user of power wants the capital for his

[6] Manager, Automotive Sales, International General Electric Co., Schenectady, N. Y. Mem. A.S.M.E.

own business. If you study the great railroad systems that have electrified their lines during the last few years, not only in Europe, but in this country, where they had every inducement based on previous history to put in their own plants, you will note that they have not done it; they purchase their power. In other words, the generation of power is now a business in itself.

There are many cases where industrial concerns today have a certain amount of capital, which they might use in building their own isolated plants and thereby reduce their operating costs compared with using central-station power. But they do not put in their own plant, because they can earn a larger return by putting that capital into their normal business. They figure that the furnishing of power is the other man's business and not theirs. I am afraid the Diesel-engine men going out to sell the isolated plant proposition have not always realized the economic situation.

The other point is that if that investment is made, the owners are making a larger investment and will tie up more of the world's capital, on account of the reserve capacity, spare capacity, and peak-load capacity, which for their smaller plant must be relatively larger than the central-station system which would serve them.

Arthur F. Macconochi.[7] I should like to ask a question concerning the development in this country of apparatus for utilizing the waste heat from the Diesel. We are already very familiar with the application of this principle to the large number of industrial plants which have need of heat for process water and steam as well as power and which commonly employ a steam engine or turbine. In certain cases the heat balance would undoubtedly favor the more efficient Diesel, with its entire absence of smoke. Where the plant could produce an excess of power economically, some arrangement might be made with the public utility whereby an interchange could be effected (as is sometimes done in the case of the steam prime mover) to the advantage of both parties.

R. W. Wadman.[8] The question of waste heat is a very important one as it applies to Diesel engines, and it has received a good deal of attention. There are two companies in this country that are producing an ordinary water-tube type of boiler with shut-off valves and which are connected to the exhaust outlets of the Diesel engine. I know of instances where textile plants are securing all of their process water and process heat and still turning some of the exhaust up the line.

Nordberg has a plant at Rensselaer, Ind., a big building which is heated entirely from the exhaust of a Nordberg Diesel engine. It is a very simple piece of mechanism, but it has not been very well merchandized by the manufacturers of the waste-heat generators. It can be obtained, and the application of Diesel engines to industry will grow extensively as the manufacturers of Diesel engines will learn to use waste heat and apply it to the problems of their customers.

Charles E. Beck.[9] You have heard a great deal thus far about the Diesel-engine salesman, and as I am one I believe that I can speak for him. I travel constantly over a territory comprising all of the Middle Western States and have done so since the year 1911. I am satisfied that all that has been said by Mr. Thuerk of the Erie Lighting Company and by the gentleman representing the Electric Bond and Share Company is substantially correct.

Diesel-engine builders are criticized for not having operating records of their engines, but we are refused these records by public utilities using our engines. We have some good records of municipal Diesel-engine plants, but the utilities are not inclined to give them much recognition. Some of the builders have no records of any consequence at all, and despite the fact that they have many good installations. Some of the published records are incomplete and inaccurate, and again they do not always cover a long enough period.

It certainly is not the intention of the better builders of Diesel engines to antagonize the public utilities. My company, through its representatives and officials, has endeavored to work with and to assist the utilities, lend them cooperation, and in no way to interfere with their activities. They have trained engineers in their employ who are fully capable of solving their power-generation problems. It would not be far amiss to say that so far in 1928 more Diesel-engine horsepower has been purchased throughout the West by public utilities than by industries and municipalities.

The utilities have been aggravated in the West by certain engine builders and specially organized companies that go into a community being served by a public utility and offer lower rates as well as a local Diesel-engine generating plant. A community that has suffered from interruptions in the service and possibly from abnormally high rates becomes a good prospect. No obligation attaches to the city or town, and when the net earnings of the Diesel plant have wiped out the purchase price, the plant becomes the property of the city or town. A situation of this nature does not improve the feeling of the public utilities toward the Diesel engine.

One of the largest builders of Diesel engines in the United States is back of a scheme of this kind. The contention is that the greatest volume of business comes from municipalities, and it is necessary to pursue a policy of this kind because of the rate at which towns and cities have sold out to public-utility companies. The Diesel-engine salesman receives his worst criticism for the work he does in connection with this sort of scheme.

Most builders believe in selling or attempting to sell Diesel engines where they are well fitted for the conditions involved. Usually the cost of power generation is the outstanding point of consideration, and where it is, the usual practice is to abandon the prospect if a substantial saving is not possible. In towns and cities the Diesel-engine salesman finds a lucrative field where non-condensing steam plants are still in use, where old-type surface-ignition engines have become obsolete, and of course, as was previously stated, some of them start a campaign for a municipal plant where a town served by a public utility has poor service and high rates or both.

### Author's Closure

As Mr. Allen so ably puts it, power production is a business in itself, but it cannot expect to fulfil its highest obligation as a business until it supplies electrical energy to industrial and residence users at a rate which does not allow for tremendously expanded capital charges and an unreasonable margin of profit.

Mr. Thuerk is quite right in pointing out that there will always be competition between the two industries, especially so far as the smaller industrial and municipal plants are concerned.

Mr. Beck has pointed out a situation which has very largely been forced on the builders of medium-sized engines by the uncomprising attitude of the utility companies; although there is considerable to be said on both sides of this story, and obviously it is preferable if both industries can confine their activities to their respective fields.

Mr. Dow's remarks allude to a withholding of statistical data

[7] Associate Professor of Mechanical Engineering, University of Virginia. Mem. A.S.M.E.

[8] General Manager, *Oil Engine Power*, New York.

[9] Sales Engineer, Busch-Sulzer Bros.-Diesel Engine Co., Kansas City, Mo. Assoc-Mem. A.S.M.E.

which will be eliminated when the utilities make "public service" a real expression instead of a catch phrase. If the utility company has a sound and reasonable rate structure, there can be no valid reason for withholding data on power costs.

However, there are conditions of technical ignorance, biased sales policies, and misrepresentation of various types of power costs which can be constructively eliminated.

In closing, it is probably well to recall that the author's paper is based on an inquiry into the problem discussed which has extended over a period of about two years, during which the views of most of the important Diesel and public-utility executives have been obtained. A survey of technical schools has also been made in order to get at the facts regarding the Diesel training of American engineers.

The entire move for cooperation so far as is possible at this time is not based on any desire to gloss over the situation, but is primarily an attempt to infuse a spirit of "good business" and all that it implies.

# One Example of Centrifugal Pumps for Petroleum Transportation

By FLOYD E. WARTERFIELD, JR.,[1] MUSKOGEE, OKLA.

*This paper deals with the problems involved in one specific installation of motor-driven centrifugal pumps for pipe-line work. The author describes conditions prior to the installation, and gives the reasons for the selection of centrifugal pumping units, as well as actual construction and operating costs so far as possible. He also discusses the effect that the experience gained from the installation described may have on the future use of centrifugal pumps in petroleum transportation.*

RECENTLY there has been much agitation as to the relative merits of pumping equipment. A great many comparisons have been made upon purely assumed conditions. It is unfortunate that there are so few actual data available, upon which to base a direct comparison between different classes of equipment, or between different equipments of the same class. The elements entering into pipe-line "cost analysis" are, for the most part, hard to determine; and when once determined, hard to evaluate correctly. Because of this difficulty, some one or more of the component parts are only roughly approximated or else omitted entirely. Every pipe line or station presents its own particular set of problems, and it is wholly unfair to assume that whatever may serve in one case would work equally well in any other. Before a true comparison can be made between any two stations, the whole story should be told, and the existing conditions in each made absolutely plain.

In view of the foregoing statements, this paper will confine itself largely to the problems involved in one specific installation of motor-driven centrifugal pumps for pipe-line work. It has for its purpose, first, the presenting of the conditions prior to the installation; the reasons for the selection of the centrifugal units; and so far as possible, actual construction and operating costs; and second, the effect that the experience gained from this one installation may have upon the future use of centrifugal pumps in petroleum transportation.

The data and information have been furnished through the courtesy of the Oklahoma Pipe Line Company, and the installation referred to is the one known as their Henryetta Station (Fig. 1).

Initially, a 10-in. line had been built between their Cromwell and Council Hill Stations, to provide an outlet for a portion of the oil produced in the Seminole Area. The line was designed to handle 32,000 bbl. of oil per day at 480 lb. pressure. The gravity varied from 35 to 40 deg. A.P.I. and had an average viscosity of about 48 sec. Saybolt Universal at 60 deg. fahr. Some concern was felt as to whether there would ever be sufficient production for the line to operate at its maximum capacity. But, as frequently happens in pipe-line work, the line was hardly completed before it was found necessary to effect an immediate increase in the delivery to Council Hill.

The guide chart shown in Fig. 2 is introduced for the purpose of showing one method that may be employed for the rational selection of pumping equipment but will be discussed only so far as it applies to the equipment selected at Henryetta Station.

Production from a new field is almost invariably well in advance of all storage and pipe-line facilities. Seminole was certainly no exception. As is always the case in caring for a sudden increase in output, the element of time becomes the one item of paramount importance.

To attempt to determine, even approximately, the maximum production of a field, the time required for it to reach a settled figure, or even what this amount would be, is most certainly a hazardous undertaking for any one. However, it was generally believed that the added capacity, so far as this case was concerned, represented a peak load that would only be handled for a maximum of six months. At the end of this time the load would have fallen to the original value of from 30,000 to 32,000 bbl. a day.

It is customary to compare equipment, and in some instances (where ample time will permit) to select it on the basis of the "unit cost per barrel of oil pumped." Even under ordinary conditions "time of operation" is hard to determine. "Time of operation" refers to the length of time the equipment shall operate, and is a very important item in the unit cost figure. Under the stress of "do it now" it seldom, if ever, receives the consideration that it should. It is generally the case that comparative analyses, and more especially where the time for the increase is short, are forced to neglect "fixed charges" and the equipment is selected on the basis of the "time required for delivery." Unit-cost comparisons are investigated at some future date.

There was adequate pump capacity at Cromwell Station for the proposed increase and the problem was to find the quickest way in which the delivery could be made to Council Hill. It was a case of either looping the line or constructing an intermediate booster station. No line pipe was available, and even if there had been, with an adequate amount of time in which to lay it, the expenditure of $528,000 would not have been justified, for the short time it would be used. In order to effect the ultimate increase that has been realized, approximately 37.6 miles of 10-in. pipe, laid from Council Hill and parallel to the old line, would have been required. Computations for a booster station placed it at a point quite close to an existing high line, and electric power could be obtained quickly and easily.

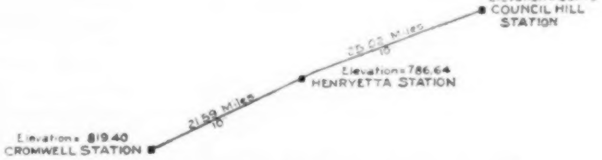

FIG. 1 LOCATION OF HENRYETTA PUMPING STATION OF OKLAHOMA PIPE LINE CO.

Immediate delivery could be made on motor-driven centrifugal units, and as a whole conditions seemed to be ideal for their use. It was realized that the operating cost would be high, but with due consideration for the time saved and the low fixed charges, it was thought that the high rate could be profitably paid for the short time the units would be in service.

Accordingly there were installed two automatic compensator-controlled 300-hp. 440-volt General Electric induction motors, driving two Byron-Jackson 6 × 17½ four-stage centrifugal pumps arranged in series and running at a full-load speed of 1750

[1] Oklahoma Pipe Line Company.

Presented at a meeting of the Mid-Continent Section of the A.S.M.E., Tulsa, Okla., December 1, 1927.

r.p.m. Following is a summary of the installed cost of the present completed station. As will be explained later, certain changes were made in the motors. The cost given does not include the expense of making these changes but is given as though the present equipment had been initially installed.

| | |
|---|---|
| 1 Pump-house building and incidental construction, i.e., small storehouse, roads, walks, grading, fencing, etc. . . | $ 3,500 |
| 2 Pumping equipment to include pumps, motors, switchboards, foundations, wire, and miscellaneous . . . . . . . . . | 16,000 |
| 3 Other station equipment, to include 5000-bbl. surge tank, gages, pipe, gates, and miscellaneous fitting and connection work . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . | 9,000 |
| Total . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . | $28,500 |

and keeping the station in an operating condition. When it was found that the pumps would deliver this quantity of oil, and that the line capacity was adequate, it was thought advisable to correct for the overload on the 600 hp. of motors by installing two of 400 hp. each and operating at 2300 volts.

The increased delivery is explained by the fact that the weather was warm and the oil run fresh from the field at a temperature of 75 deg. fahr. On test the oil showed an average gravity of 38 deg. and a S.U. time of 46 sec. In addition there was actually 155 ft. of fall between Henryetta and Cromwell that was only approximated in the original calculations. In order to protect the motors as much as possible the station was run with a wide-open header gate during the cooler hours of the day, and under

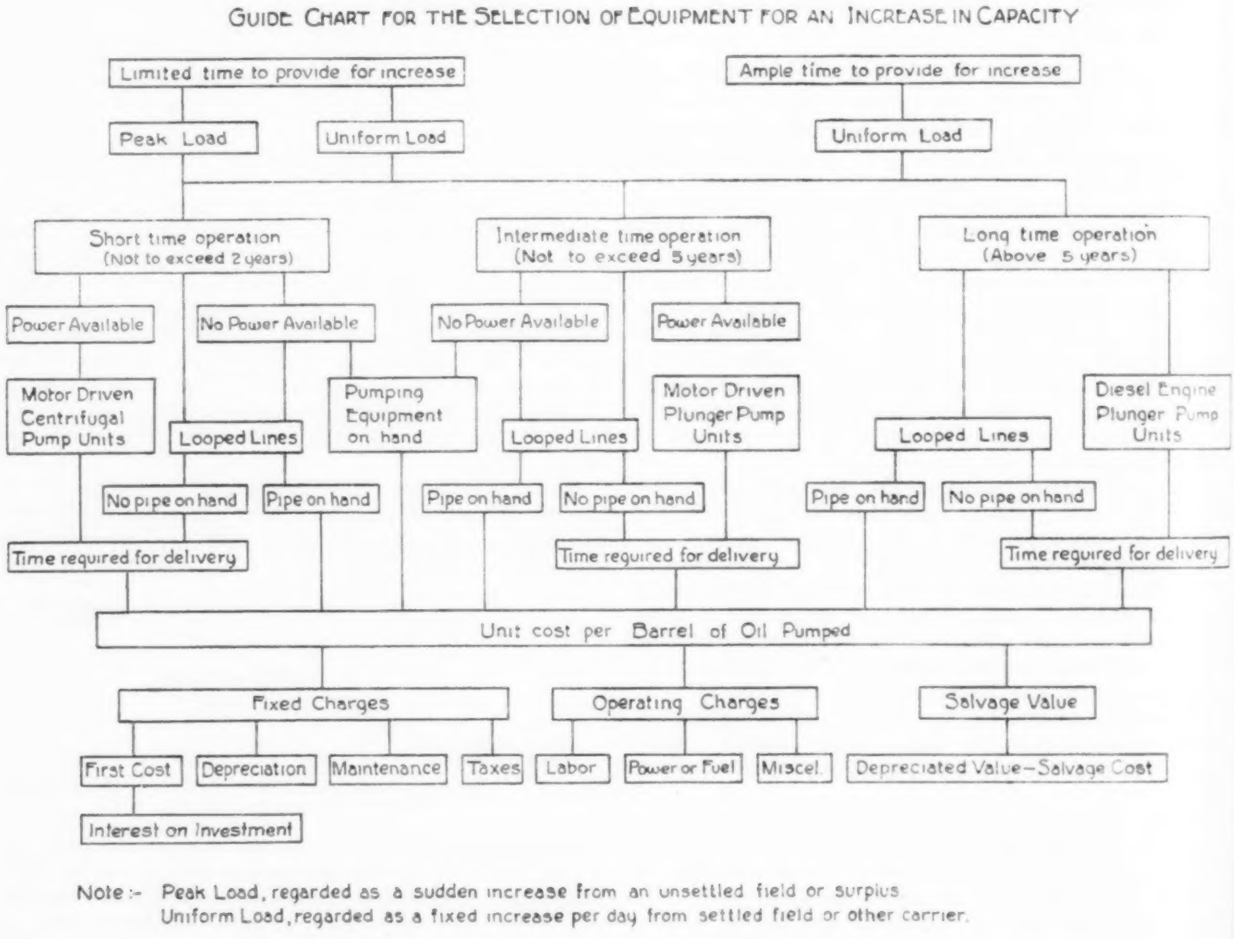

FIG. 2 GUIDE CHART FOR USE IN SELECTION OF PUMPING EQUIPMENT FOR AN INCREASE IN CAPACITY

Local construction conditions for this station were far above the average. If an estimate should be required for a similar installation remotely located and built under adverse conditions a figure of $30,000 would be approximately correct.

The installation was designed for the adverse operation usually experienced in winter pumping and was to deliver 44,000 bbl. of 38-deg. A.P.I., 75 sec. Saybolt Universal oil, at a pressure of 580 lb. Much satisfaction was experienced when the station was started the latter part of April, and it was found that the capacity exceeded that calculated for the assumed conditions. The increased delivery was very much needed, yet it could only be realized at the expense of a very severe overload on the motors. This caused no small amount of trouble in maintaining

this condition delivered around 50,000 bbl. per day at a line pressure of 535 lb. For the remainder of the time the gate was pinched down in order to raise the head and decrease the load on the motors, with a consequent reduction in delivery.

At the present time the oil has a line temperature of about 60 deg. fahr., with a S.U. viscosity of 52 sec. When the header gate is wide open, the delivery is around 51,500 bbl. per day at 580 lb., and no troublesome temperature overloads have developed such as were experienced with the 300-hp. motors.

The following is the result of a brief test made by representatives of the Oklahoma Pipe Line Company and the Oklahoma Gas and Electric Company to determine the approximate mechanical efficiency of the pumps:

TEST OF OKLAHOMA LINE COMPANY'S HENRYETTA STATION, MAY 31, 1927

*Equipment*

Two 300-hp. motors, 1750 r.p.m., 3-phase, 6-cycle, 440-volt
Two 6 × 17½ 4-stage Byron-Jackson pumps arranged in series

*Electrical Data*

SUBSTATION TESTS, 2300-VOLT SIDE OF THREE 2300/440, 200-KVA. TRANSFORMERS

| Kw. | R a/c Kva. | Kva. | Power factor | Transformer losses |
|---|---|---|---|---|
| 592 | 296 | 662 | 89.5 | 22 |

| | Avg. amp. per phase | Avg. volts per phase | Power factor | Kw. input | Hp. input | 92 per cent motor effy., b.hp. |
|---|---|---|---|---|---|---|
| High-duty pump.... | 420 | 448 | 89.5 | 290 | 388 | 357 |
| Low-duty pump.... | 405 | 448 | 89.5 | 280 | 375 | 345 |
| | | | | 570 | 763 | 702 |

*Oil-Pipe-Line Data*

| Line pressure Suction | Discharge | Bbl. per hr. 12 M. to 1 P.M | Viscosity S. U. deg. | Temp. oil, deg. fahr. | Hydraulic hp. |
|---|---|---|---|---|---|
| 12 | 555 | 2057 | 46 | 75 | 466 |

*Efficiency of pump* $\frac{466}{702} \times 100 = 66.2$ per cent

NOTE: A 5000-lb. working tank was installed and the suction pressure of 12 lb. was due to the height of the oil above the level of the pumps at this period. The header gate was pinched down and the pressure given is between the discharge of the high-duty pump and the header gate.

The actual money expended for operation during the months of May, June, July, and August is as follows:

| | | |
|---|---|---|
| 1 Maintenance: | | |
| a Material for repairs............ | $ 99.34 | |
| b Labor for repairs............... | 613.49 | $ 712.83 |
| 2 Transportation Operation: | | |
| a Station, labor, regular.......... | 3,307.42 | |
| b Casual labor and misc. (i.e. waste, lamps, brooms, etc.)........... | 470.12 | |
| c Lubricating oil................. | 50.53 | |
| d Power (1.03 cent per kw-hr.).... | 14,984.44 | 18,812.51 |
| Total........................ | | $19,525.34 |

Total barrels of oil pumped during period.............5,464,002.2
Total energy used, kw-hr..............................1,454,800
Average number of barrels pumped per kilowatt-hour.........3.75
Operation and maintenance cost alone, per bbl., cents.......0.3575

With the foregoing figures as a basis, maintenance is 3.65 per cent of the total transportation cost and is at the rate of 7.8 per cent per year on the present investment of $27,500. This rate of 7.8 per cent is not a true figure; it should be slightly higher due to the fact that the present investment is greater than it was at the time the maintenance figures were taken. It must be remembered that the maintenance cost of $712.83 applies to a time when the station was being placed in operation and that many things were done that would be avoided in the future. Considering the heavy overload that was placed on the motors, it is not unreasonable to assume that the operation was abnormal in every particular. The present 400-hp. motors have not been in operation long enough for a true figure to be determined, but indications are that it will not exceed 3 per cent of the total cost as a yearly maintenance cost.

In order to arrive at an exact cost per barrel of oil pumped it is necessary to take into account the item of fixed charges. For this purpose, the useful life of the station is assumed to be 20 years and the functional depreciation to be taken care of by setting up a 4 per cent sinking fund to provide for replacement. Interest on the total investment is at the rate of 6 per cent, and taxes 3 per cent.

PUMPING COST

(Four months operation)

| | | |
|---|---|---|
| *Fixed Charges* | | |
| Interest on investment.................. | $550.00 | |
| Depreciation............................ | 307.80 | |
| Maintenance............................. | 712.83 | |
| Taxes................................... | 275.00 | |
| | | $ 1,845.63 |
| *Operating Charges* | | |
| Labor, power, and miscellaneous................... | | $18,812.51 |
| Total..................................... | | $20,658.14 |
| Unit cost per barrel of oil pumped, cents.................. | | 0.3780 |

A comparison between the actual cost at Henryetta and an estimated cost for a motor-driven plunger-pump station of about the same capacity may not be entirely correct, but if all the items are considered some idea of the respective operating costs can be obtained.

50,000-BBL. TWO-UNIT BOOSTER STATION WITH MOTOR-DRIVEN PLUNGER-PUMP UNITS

| | |
|---|---|
| 1 Pump-house building and incidental construction....... | $12,000 |
| 2 Pumping equipment, to include two 300-hp. motors direct connected to two 25,000-bbl. triplex plunger pumps, and miscellaneous........................ | 50,000 |
| 3 Other station equipment, to include working tank and all incidentals....................................... | 13,000 |
| Total........................................ | $75,000 |

The station is assumed to deliver an average hourly amount of 2085 bbl. of 37-deg. A.P.I., 52 sec. S.U. oil through 25 miles of single 10-in. line at a pressure of 580 lb. Efficiency of the pumps, 85 per cent, and of the motors, 93 per cent. The useful life is assumed to be 20 years, with depreciation taken care of by a 4 per cent sinking fund to provide for replacement; maintenance and taxes taken at 3 per cent and interest on the total investment at 6 per cent. Computations based on 730 hours' operation at a flat rate for power of 1.03 cent per kw-hr.

| | | |
|---|---|---|
| *Fixed Charges* | | |
| Interest on investment.................. | $ 375.00 | |
| Depreciation............................ | 209.87 | |
| Maintenance............................. | 187.50 | |
| Taxes................................... | 187.50 | |
| | | $ 959.87 |
| *Operating Charges* | | |
| Regular station labor..................... | $ 525.00 | |
| Incidental labor, lubricating oil and miscellaneous material for operation....... | 300.00 | |
| Power.................................. | 3,500.09 | |
| | | $4,325.09 |
| Total........................................ | | $5,284.96 |
| Total barrels of oil pumped in 730 hours............... | | $1,522,050 |
| Unit cost per barrel of oil pumped, cents.................. | | 0.3471 |

This would indicate that the plunger-pump station would operate 0.0309 cent, or 8 per cent per barrel cheaper than the centrifugal units. However, for short-time operation, if the centrifugal units could be delivered and installed quicker, this difference can be disregarded.

That a working tank is unnecessary is a point frequently advanced in favor of the centrifugal pump. There are instances wherein this is true, but the unqualified statement will not hold for all cases. For example, the pumps at Cromwell Station were all of the plunger type, and in case of an enforced and unforeseen shutdown at Henryetta, immediate and very destructive

pressures would be built along the line. To safeguard against this emergency, relief valves had to be placed on the discharge lines from the pumps at Cromwell. There is no question that relief valves do afford some measure of protection, but by no means should they be regarded as positive insurance against accident. Further difficulty was experienced at Henryetta due to the low-duty pump pulling a vacuum and hence working at a decided disadvantage. A surge tank was the only logical solution to the troubles, and in addition to providing adequate safety, insured a well-filled pump. Positive local control has everything in its favor, and present experience indicates that a working tank will merit the added expense and should most certainly be installed.

If conditions in the future should be similar to those described for Henryetta Station, there is no doubt that a centrifugal installation would be made. In addition to some of its other advantages, the series arrangement of pumps is very desirable. When their main-line service is terminated they may be used as individual units on local-station work where only a temporary installation is required. Not only are the units compact and comparatively light, and hence can be transported easily, but they require a minimum foundation and housing space and can be installed more quickly than any other unit of even greater capacity.

A serious drawback to the centrifugal pump, and especially with small quantities at high heads, is its low mechanical efficiency. When coupled with an electric motor as a prime mover, the rate that can be paid for power must necessarily be as low as possible. Because of this low efficiency, the power companies should not be expected to compensate for it by furnishing power at a loss. Neither should the power companies penalize the pipe lines because they use the electric motor—in itself a remarkably efficient piece of equipment. It is almost time for the rate makers to adjust their demand and standby charges to fit true conditions. Apparently sufficient consideration has not been given to the fact that pipe-line work is the exact opposite of an industry. The pipe line in general begins with a peak and grades downward; the industry usually starts with a minimum and works toward the peak. It is doubtful if one rate can ever be conceived that can apply equally to both classes of loading. Centrifugal- as well as plunger-pump manufacturers naturally desire the best possible efficiencies for their products, and competition will keep them striving for improvement. Whether they succeed or fail, before the electric motor can retain its rightful place in oil-field work some change must be made in power rates. It is realized that the whole method is relatively new and that present rates may be the nature of an experiment; yet unless there is some revision, power companies are in danger of finding themselves with ample equipment on their hands for service—and no customers.

Pipe lines have been constructed wherein all stations used motor-driven centrifugal pumps entirely, but it is unlikely that this practice will meet with much favor in the Mid-Continent Field when the rates that must be paid for power are seriously considered.

The data that have been presented for this one installation should not be used as a criterion for the acceptance or rejection of the centrifugal unit. Although not entirely defined, the centrifugal pump does have a real place in petroleum transportation, and its use under certain conditions will not only be continued but increased. However, it must be remembered that each installation is to stand on its own feet, and that the selection of any pumping equipment must be made on the basis of existing circumstances.

# Progress in the Petroleum Industry

## Contributed by the Petroleum Division

Executive Committee: H. R. Pierce, *Chairman*, W. G. Heltzel, *Vice-Chairman*, P. L. Guarin, *Secretary*, Walter Samans, T. H. Kerr, and C. F. Braun

PROGRESS in the petroleum industry has its many ramifications, and the Petroleum Division in planning its review of this year's progress decided to subdivide its field and to request from a few prominent engineers a report on progress in their respective fields. The reports on these subdivisions contain valuable material that deserves the adequate treatment given by the authors, particularly because of the novelty of the matter treated and its paramount importance to several great branches of mechanical engineering. In view of this the Petroleum Division presents its Progress Report for 1927 as a symposium of reports of these subdivisions.

W. G. Heltzel, *Vice-Chairman.*

## Progress in the Production of Oil

By HOMER R. PIERCE

THE producing formations have been getting deeper and as a consequence drilling and development methods have had to change very rapidly during the past year. The deeper sands, having a higher gas and hydrostatic pressure, deliver their oil to the drill hole at a much higher rate than shallower sands, and due to the greater quantity of energy per barrel of sand-stored oil, there is a greater percentage of the stored oil recovered and at a much more rapid rate of production.

Due to the nature of this stored energy, the drainage area of a well is enlarged so that the number of wells per unit area can be cut down, thereby reducing expense in drilling; but due to the same condition the drainage to offset production is greater, and lack of adequate line protection results in loss of one's potential production to a neighbor.

Due to the greater stored energy even with the wider spacing of wells, the oil enters the drill hole at a rapid rate, and its removal from the well at a higher rate becomes more and more of a problem. The old equipment used to remove oil entering from shallower sands fails to keep the column of oil down, and consequently the back pressure on the sand low, so that one's oil seeks his neighbor's outlet when and if the latter is holding a lower producing pressure on his sand.

To meet this condition there have been numerous long-stroke high-speed pumps developed and new kinds of swabs and bailing methods tried, but due to the extreme depth of the wells, crooked-hole conditions, and the large quantity of fluid to be lifted, as well as sanding and cup trouble caused by the high rate of flow through the sand, the above-mentioned methods have proved fairly expensive in the upkeep of physical equipment, and absolutely prohibitive in waste of time where offset production could be produced more rapidly, or continuously.

### Air-Lift Method Best for Large Quantities of Oil

Consequently, the most successful and cheapest method of lifting large quantities of oil from great depth and under floating-sand conditions is by what is called the air-lift method. In some cases where the compressor equipment is installed and the wells properly tubed to give the maximum efficiency, production can be carried to its economic limit by this method of lifting, but in other cases it is necessary after the pressure in the sand has been drained to revert to the pump as a means of more completely depleting the sand.

These are problems which must be solved for each district, pool, or property, and in most cases for each well.

Some companies have realized that these problems are worthy of trained mechanical engineers, and are getting results comparable with their ability to pick engineers for the work and their ability to act on or judge the value of reports or advice of the engineers they employ.

### Pool Production or Control Necessary

The high cost of drilling wells and keeping up offset production under the present competitive conditions, together with the resultant overproduction and reduced price, have made the substantial thinking heads of the oil industry realize that pool or unit operation or some method of control is necessary. This will in the near future allow of pool operation, which in turn will demand more engineering applied to production. That is, the pool to be operated will be analyzed and drilled with a view to the conservation of its natural energy, and with a future view of restoring energy to the sand at such a time and in such a manner that the greatest ultimate production will be had at a minimum expense per barrel produced.

This will mean that from the beginning the wells will be flowed in the most efficient manner; and, as it is necessary, the gas will be returned to the rock and used as an expulsion and lifting agent, and differentials across the sand and from the sand to the flow tank or gasoline plant will be regulated so that the maximum energy in the gas will be utilized.

Hard-headed business men in the oil business are fast becoming disgusted with the wholesale waste occasioned by highly competitive drilling and production methods, and once started on the warpath they will devise some means of improving conditions, because these men are today where they are, due to their ability to handle hopeless situations in a speedy and profitable manner.

When this time comes, as it soon will, the engineers are going to have more problems put up to them than they can handle. Therefore it behooves them to be preparing now for their future task. The ability to look ahead and prepare for the future needs is just as much engineering as the solving of the problems coming up from day to day.

The problems of producing large quantities of oil from deeper horizons do not confine themselves only to the designing of flow tubings and proper ratios of pressures, but necessitate working out better joints for the various ratios of tubings and the many strength-of-material problems entering into deep-well pumping.

### Corrosion

Corrosion alone presents a wide field for investigation. Corrosion problems increase when handling deeper and more concentrated waters. This is especially true if air is used as a lifting medium.

Some of the deeper pools, which as explained deliver oil at a higher rate due to the excessive amount of energy stored in them, contain sulphur and other constituents which corrode metal very rapidly, and due to the fact that it is necessary to

remove this oil in order to keep pace with the production of neighboring wells as explained above, corrosion problems are in direct proportion to the rate of production.

# Development of Mechanical Equipment for Petroleum Production

By HOLLIS P. PORTER

THE progress of engineering in the petroleum industry has been very satisfactory during the past year. The greatest degree of improvement has been in the development of mechanical equipment, its application to the production of petroleum, and the handling and storage in field operations.

The air-gas lift has been applied very extensively to aid in flowing wells. This has been the cause of several new designs of semi-portable compressors driven by either multi-cylinder engines or electric motors. There are large, slow-speed units direct connected, being used for more permanent service.

### Problems Presented by Deeper Drilling

Deep drilling has caused many problems to be presented to the mechanical engineer. In the Gulf Coast region at Spindle Top and other fields, deeper wells are being drilled. In California, an editorial in the September number of the *Oil Field Engineer* shows that in a list of some 391 wildcat wells drilled in 1925 and 1926 the depths ranged as follows: 98 wells between 4000 and 5000 ft., 71 between 5000 and 6000 ft., 21 wells over 6000 ft., and one well recorded at a depth of 7221 ft.

In the Mid-Continent and West Texas fields there is a great amount of deeper drilling between 4000 and 5000 ft.

As a result of deeper drilling, heavier machinery is being used. Batteries of three boilers to a drilling well, each boiler having a capacity of 100 hp. and a pressure of 200 lb., is now the practice. This can be compared with the use of two 45-hp. boilers for 125 lb. pressure, which was considered sufficient in most territories a few years ago.

The mechanical engineer is being called upon to not only design better and heavier machinery, but also to direct the way to better methods and more economic practices. The use of compound slush pumps which use 50 lb. of steam per hp-hr. compared to the present simple pump using 100 lb. of steam per hp-hr. will soon be common practice, but this must be carried farther by the adoption of a type of simple condenser, if steam is to be used for drilling. Electricity will replace steam where electricity is available for drilling, and gas engines will be used more for drilling as time goes on. These improvements are now being adopted rapidly, and the mechanical engineer is called upon to apply methods of economy to the production of oil the same as he has in the past in other lines of industry.

The development and operation work of the production departments have, in the past two years, added to the organization ten engineers and technical men where there was but one before.

# Progress in Rig and Field Equipment

By GLENVER McCONNELL

THE percentage of all wells drilled to depths of 4000 and 5000 ft. has increased very greatly during the past year. This has been accomplished by the use of more powerful machinery, a higher quality of tubular goods, and better selection of wire rope and transmission equipment. Aside from this, little effort has been made to introduce new equipment that is not built according to standard designs. Very little effort has been made to reduce the power costs, although there is some tendency to adopt high-speed bearings and to improve the lubricating systems.

Much improvement has taken place in equipment designed for greater power and speed in rig hoisting requirements. Manganese-steel sheaves, larger-diameter hoisting drums, stronger steel derricks and crown blocks, and many devices for better rope service have come into use. Now efforts are being extended toward improving belting conditions for heavy drilling and pumping machinery, and more attention is given to safety requirements. The industry has practically adopted the use of steel derricks, and it is predicted that the use of timber foundations will soon be a thing of the past. The influence of the A.P.I. program for the purpose of standardizing equipment in the oil fields has been a great aid and is increasing in its importance. Pipe and tool joints are being obtained which are made according to A.P.I. standards. The result of this is that a more uniform and safe product is in general use. If the A.P.I. committees do not accomplish anything more than to bring to light the glaring defects in equipment that has hitherto been considered satisfactory, the good that they will accomplish will be invaluable. As the engineers continue to study the ways and means for standardizing on such articles of equipment as belting, wire lines, manila cordage, pump specifications, and numerous other items, they are frequently forced to admit that heretofore too little was known of the mechanical requirements of drilling and pumping equipment. The choice of power-transmission equipment becomes more difficult when it is considered that the selection of electricity, steam, or internal-combustion engines is generally governed by the means worked out for satisfying drilling and pumping requirements. Two-speed-reduction machinery is being introduced satisfactorily in some districts for pumping, but it cannot be said that for permanent equipment or for standard purposes there is sufficient accomplishment for general adoption.

Requirements for drilling machinery less expensive to operate will necessitate more consideration on the part of oil-company executives to appreciate complicated designs and arrangements that are carefully engineered. Then, too, a system of instruction will be needed for all field men in the proper care and use of equipment. Many executives are loath to consider this, but it is generally realized by engineers that a great saving in operating costs cannot be expected unless basic changes are made in much of the rig machinery now more or less standard. Haste is too much the governing factor. Production at any cost rules the instinct of a successful operator. With this condition to meet, a larger and larger number of able men confine their efforts to improving the drilling tools, the well-head control devices, prime movers, rotarys, and a multitude of miscellaneous items from burners to sand pumps. In fact, it is difficult to keep a well-trained mechanical engineer in the field long enough for him to learn what basic changes are needed and to fit himself for the task of developing a more efficient system of drilling and pumping machinery in the face of more remunerative openings in the specialty field. But the industry offers a promising future to men who will hasten the time when it can be said that highly efficient means of drilling and producing oil and gas have been accomplished.

It is predicted that within the next twelve to eighteen months when the overproduction now prevalent has ceased to exist, a great awakening to the needs of lower operating costs will be followed by such improvements in mechanical engineering in the oil fields that the gradual progress of the past will be looked upon as insignificant. The cry for competent engineers is beginning to be heard on every side. Their work in the field operating division of the industry will revolutionize present conditions.

# Progress of the Natural-Gasoline Industry for 1926-1927

By H. B. BERNARD

THE natural-gasoline industry during the past twelve months has had a tremendous impetus due to the development of new fields in California, in the Panhandle of Texas, and in Seminole and Pottawatomie Counties, Oklahoma.

The problems presented in new construction in California did not entail any novel features or anything of special interest.

In the Panhandle Field of Texas the high content of hydrogen sulphide in the gas processed in gasoline plants called for experimentation with and design of equipment to withstand the extremely corrosive action of the gas. To date the problems have not been completely solved, but great progress has been made by engineers and chemists of the industry. The gasoline produced from the gas necessitated the design of special equipment and the introduction of new processes for its treatment.

Under a recent arrangement between several operating companies in the Panhandle Field the natural-gasoline and the pipeline departments of the industry have cooperated to develop more economical methods for the transportation of crude oil admixed with natural gasoline. At this time the experiment is of short standing and consequently no results are available.

## Twofold Use of Air or Gas Lift

In Seminole and Pottawatomie Counties, Oklahoma, wherein is located what is known as the greater Seminole Field consisting of the Searight, Seminole, Bowlegs, Little River, and Earlsboro pools, the principal problem presented has been the use of the air or gas lift used, first, as a means used solely for producing oil, and second as a means for producing oil and extracting gasoline with the same equipment. As the equipment used for flowing wells and producing gasoline at the same time is practically identical with the equipment utilized for the more limited application, any summary may be confined to the twofold system.

Prior to the application of the gas lift to the production of crude petroleum, natural-gasoline plants of the absorption type had practically supplanted plants of the compression type due to the economic conditions involved and not due to the greater efficiency of the former, which is the common impression. In 1926 one of the major oil companies in the Browning Pool near Madison, Kan., constructed a compression gasoline plant built for the primary purpose of extracting gasoline but with two secondary objects in view, the first of which was to put gas pressure back on the sand, and the second to produce oil from the relatively shallow wells (about 2200 ft. deep) with the gas lift. This plant has been very successful and was the forerunner of the double application of compression gasoline plants.

Early in the history of the Seminole Field the first gasoline plants in that area were conceived (about August-September, 1926). These plants were universally of the absorption type, and made no provision for the production of high-pressure gas for flowing purposes. About sixty days later when several high-pressure compression plants using both air and gas were put in service, it was found that where gas was the medium compressed, gasoline was extracted, but as no final coolers were installed on the second stage, the gasoline production was very small. A short time later it became a more or less general practice to install an absorption-type unit on the discharge of the low-stage compressors to extract the gasoline, and this method is in more or less universal use in those plants constructed late in 1926 and early in 1927.

Considering that the condensing and cooling of a given amount of gasoline over a definite temperature range requires a given amount of condenser surface and with the view of eliminating absorbers, stills, and the numerous auxiliaries used in connection therewith, one of the major oil companies in March, 1927, put in operation a gasoline plant, designed not only to efficiently extract gasoline under compression methods but to furnish high-pressure gas for producing crude petroleum by the gas lift. Shortly thereafter this plant was put in successful operation, and it has set a model type of construction and operation which will replace the high-compression type of plant utilizing absorption equipment for gasoline extraction. One of the principal problems presented in the construction of the two-purpose compression plant was the design of a system of controls to enable the operation of each individual well under the most favorable conditions and to permit the "kicking off" of any well or wells without interference with other operations. This system was fully developed in July of 1927, and while it is undoubtedly capable of improvement, as the question now stands it is eminently satisfactory in operation both from the engineering and operating standpoints.

To permit the operation at normal pressures (250–300 lb. per sq. in.) for gas lift in the Seminole Field, and to provide for the same units to operate at 650 lb. per sq. in. for "kicking off" the wells, required the design of special cylinders, and the initial development of this equipment was found satisfactory. As the machinery is designed to operate fully loaded at the lower pressures, throttling devices on the suction for high-pressure operation have been resorted to.

The application of the principle of compression for a twofold purpose has resulted not only in economy of operation but has permitted the construction of large central plants as opposed to the construction of a number of smaller plants, with a corresponding further increase in operating efficiency and economy.

## Use of Superheated Steam for Power and Process Requirements

During the past year superheated steam was used for the first time in natural-gasoline plants for power and process requirements. This development is too recent to permit reporting on its results. The use of marine-type boilers in three plants of one large operating company during the past year has shown splendid results, in which a high steaming rate has been combined with low construction, operating, and maintenance costs. The high furnace temperatures developed in this type of equipment, however, required a careful selection of refractory equipment, but this feature appears to have been successfully worked out.

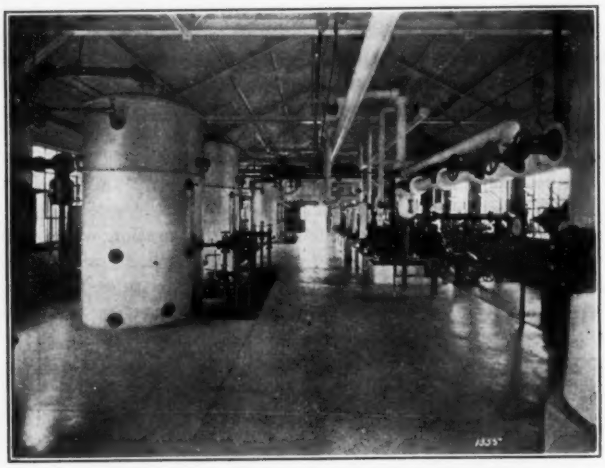
The use of base-exchange and lime-soda water-treating systems has become more general than in previous periods, as has the application of automatic controls not only in the power plant but in the process equipment as well.

In cases where economic conditions have permitted, the use of electricity for power purposes has had considerable impetus, but it is not promised that that medium will be general as local conditions must be considered.

## Gas Injection on Two-Cycle Engines

The gasoline industry is the first to apply the more recent development in internal-combustion engineering. This is the application of gas injection on two-cycle units, which makes them operate on the Diesel cycle rather than on the Otto cycle. Preliminary results point to economy on two-cycle units comparable with that expected in four-cycle operation.

The construction of large units has called forth great improvement in the design of cooling towers, which appear to have largely supplanted spray ponds. While atmospheric-type coils continue to be used for cooling and condensing service, the shell-and-tube-



Control Building, Natural-Gasoline Plant

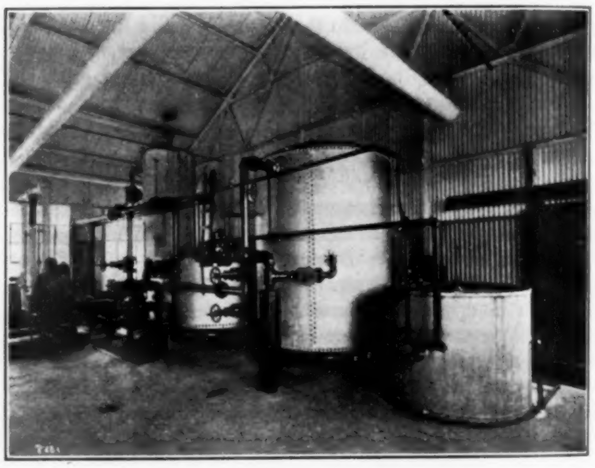
Exterior View of Control Building Above



Zeolite Treating System for Handling Water of High Turbidity

General View of a Natural-Gasoline Plant in the Seminole Field

type design is rapidly becoming preëminent. Certain advantages of the atmospheric coil and recent improvements in its design assure its continued use, and it is not expected that it will be entirely supplanted by shell-and-tube-type equipment when proper consideration is given to the local conditions surrounding individual installations.

It may be said in conclusion that the past year has been one of great progress in the gasoline industry, not only through the increased scale of its operations, but because of the greater attention given to detail of design and utilization of equipment. During the past year the three largest gasoline plants in the world were constructed, one in California and two in Seminole County, Oklahoma. The lowest natural-gasoline prices in history have demanded more efficient conception, design, and operation in all branches of the petroleum industry, and in the advance and application of engineering knowledge the natural-gasoline branch of that industry has had its due share.

# Development of Transportation of Crude Oil in 1927

By B. P. Sibole

ON THE rails, in the water, on the highways, and through the air, "Speed" has been and is the slogan. In marked contrast to this, "Conservation" has been the keynote in the transportation of crude oil, especially by pipe line. This is particularly noteworthy, because an occasional suspicion of waste has been directed to this branch of the oil industry.

All crude oil is gathered from the wells by pipe lines, and while a small portion is carried to delivery or tidewater by tank cars, most of it goes on to such delivery by pipe line. Over two million barrels (or 300,000 tons) are handled every day by pipe line. Much of it is transported in this way for hundreds of miles, and yet all of this enormous movement is carried on safely and with a very high degree of economy.

Pipe lines have been extended into new fields, but the outstanding tendency in 1927 has been the development of still further economy and measures of conservation both on new lines and on old lines already in operation. This development has been marked by conservation of oil and equipment, and economy of movement.

## Conservation of Oil

Long ago the pipe lines developed ways and means which have practically eliminated loss by leaks and breaks. In recent years the losses due to the fugitive vapors escaping have been the subject of constant attack. The floating roof continues to achieve excellent results in eliminating vapor loss from working tanks, and this year witnesses the appearance of the breather roof, which is an ordinary steel roof welded to the shell and so designed that it will rise and fall (as a diaphragm does under varying pressures) to take care of an ordinary change in volume of a tank practically full of crude oil without the safety relief valves being called on to operate. This type is for storage tanks.

The expensive lessons taught when lightning ignited large concrete storage reservoirs in California last year have resulted in the development of spires and aerials for the protection of such storage. The splendid record of comparative immunity from fire held by properly vented steel-roof storage tanks has resulted in a continuation of the tendency to build this sort of tank and replace wood roofs with steel.

## Conservation of Equipment

No radical change or improvement in materials has been made. All of these continue to suffer from the ravages of corrosion. The enormous depreciation of pipe in the ground has continued to stimulate the development of protective coating for steel pipe, which material is still the almost universal standard for pipe lines. It was just two years ago that a type of pipe-cleaning machine was brought out which has in the last year been put into very wide use. By a device of this kind, old lines can, after they are uncovered and raised, be quite effectively cleaned, permitting the outside pipe surface to receive a coating of asphalt, tar, or other protective materials. Recently such a machine has been used on new pipe as received from the mills, with the apparent object of removing the mill scale and getting a fairly clean and new metallic surface to which to apply protective coating.

While heretofore most of the corrosion of pipe-line equipment has been on surfaces not in contact with crude oil, such as the outside of pipe lines, the outside of tanks, and the inside of steel roofs on tanks, there is promise of a still more serious problem in the handling of oil from West Texas and the Texas Panhandle, as much of this oil carries with it hydrogen sulphide or its compounds.

## Economy in Movement

While reciprocating pumps driven by oil engines handle most of the oil, especially in the Mid-Continent Field, this year has been marked by the adoption of a number of electrically driven installations. Motor-driven stations have resulted in saving of man power and investment as compared with oil-engine-driven stations. For example, a small electric motor and pump can be operated by the field gager in a gathering system where an additional man might be required with an oil engine. Electrically driven pumps both for large field stations and main-line stations have been installed with economy in time, investment, and, in some cases, in man power. This electric motive power is especially attractive in handling flush oil from new fields where the quantity of oil to be handled is pretty certain to drop off rapidly after a few months.

While electric drive has been put in with reciprocating pumps—the type heretofore used almost exclusively—the use of electric motors has made practicable the adoption of centrifugal pumps for oil-pumping service. This development is something of an innovation in the Mid-Continent Field where centrifugal pumps for pipe-line stations have not been used as they have in California. The direct-connected motor and centrifugal pump has found an economic use in temporarily increasing the capacity of an ordinary pipe line of 40 or 50 miles between the established main-line stations.

Oil engines continue to replace steam equipment at some of the pipe-line stations where steam was originally installed.

Venturi meters as well as liquid meters of other types are being tried out and considered more seriously for the measurement of oil.

There is a continued tendency to replace boilers and steam pumps for more or less temporary field use, with oil- or gasoline-driven portable units.

As in many other branches of the oil industry, welding continues to be more widely used in transportation. Some pipe-line companies are almost standardizing on welded lines; others are using it more widely than ever for river crossings, manifolds, and repairs.

While conservation has been the keynote, the industry has not lacked the extension of pipe lines into new fields. Three trunk pipe lines have been built into the Texas Panhandle and two into the new West Texas fields. These new extensions in the Mid-Continent Field cover considerable mileage of pipe and are built along the same general design considered as good practice in the last few years, having steel pipe operated at about 700

lb. working pressure with stations comprising oil-engine-driven reciprocating pumps. Another line now under construction is designed with electric-motor drive.

While part of the transportation of crude oil from isolated or temporarily congested districts is handled by tank cars on the railroad, the pipe lines continue to be the principal and most economical way to transport crude oil.

The refineries located on the Eastern Seaboard will of course continue to receive the greater portion of their crude-oil supply by tanker. A number of these have been acquired during the past year, either as re-engined Shipping Board vessels or newly constructed ships. Most of these ships are provided with either direct Diesel-engine drives or Diesel-electric drives.

# Progress in Refining

By WALTER SAMANS

THE petroleum refining industry governs the progress in its methods from year to year by the existing conditions, which are ever varying. There is therefore no definite program which can be adhered to for long periods of time, and what may be good practice in one year may be superseded for very good reasons in the next year or thereafter.

The governing factor in progress is supply and demand, the same as it would be for any manufactured article. The influence of the past year's production of crude oils at approximately 20 per cent above the normal, and the uncertainty as to how long this excess production will continue, are bound to affect the viewpoint of the refiner as to the process value of existing and new equipment and the result on sale prices. Under such conditions the equipment available is put to the best possible use, and as in the case of some cracking stills at the present time, it may only be used because it is available and because of the need for disposal of cracking stock, even though the difference in market value between the raw and finished product from this type of still be insufficient to warrant cracking. The natural result of an excess in crude production is lower market prices, as storage of raw products involves considerable expense; and as lower prices of finished products also result, the profits in the business must be the real guide to the refiner in planning new investments.

In considering the progress which has been made during the last year or more, it might be well to divide the subject into five sub-headings as follows:

1 The savings in manufacture which may be obtained
2 The construction and engineering problems
3 The various processes in vogue
4 The developments in the manufacture and use of steam and power, and
5 The research work being done for future development.

### Savings Possible in Manufacture

1 As the profits of a business decline, no matter for what reason, possible savings must be obtained in every branch of manufacture, and this is no less true of the refining industry than in the production of raw materials or in the marketing of the finished products. It is not only necessary to avoid waste wherever possible, but also to increase the yield of the more valuable products.

The crude oil when received at a refinery is stored in tanks of the larger sizes. To cut down evaporation losses, tanks are provided with gas-tight roofs and with vents which restrict the escape of gas and the intake of air as the volume of the oil in the tank changes due to pumping in or to outage, and to temperature changes. The latter action is commonly known as "breathing," and takes place principally between day and night conditions. In addition, these breather vents are provided with a flame arrester, so that in case of fire nearby, or if a tank be struck by lightning and the steel is not ruptured, the flame will not be communicated to the contents of the tank. Sometimes a pressure as high as 1 lb. per sq. in. is maintained on this gas space by these control vents, in which case the roof is built in the shape of a segment of a sphere, commonly known as a dome roof and also termed an umbrella roof. In other cases breather bags, made of balloon material and housed from the weather, are connected with the vapor spaces in one or more tanks so that the breathing may take place in a closed system and gas cannot therefore escape to the air. A similar system, involving the use of a gas holder connecting to a number of tanks in a group, has been used, but the size of the lines required on account of the large volume and low pressure of the gases involved makes the initial cost very high. The principal loss in evaporation—and this applies to finished light material such as gasoline even to a greater extent than to crude—is the absorption of gasoline vapors by the air in contact with the liquid. This quantity varies from 10 to 15 gal. of gasoline for 1000 cu. ft., and as this is a high-priced product, the loss is quite important. Another method used for the conservation of such materials is the installation of floating roofs, which in effect are metal pans properly braced and provided with flexible contact shoes between the shell and the tank. A second type of floating roof consists of a series of pontoons with flexible connections at the joints and also provided with flexible contact shoes against the tank shell. These roofs float on the liquid, the idea being to do away with evaporation by eliminating the air space over the liquid. With lighter distillates under a pan type of floating roof the heat of the sun tends to boil off the lighter fractions in contact with the under side of the roof, the gases escaping at the edge of the pan. To minimize this, the roof may be insulated. Insulation may also be applied on top of the steel roofs of gas-tight tanks where the nature of the contents makes it desirable, and this will restrict the fluctuation in temperature changes, and therefore the breathing losses.

One of the largest savings that has been obtained is in the fuel used under stills, this latter forming approximately 40 per cent of the manufacturing expense. The old type of still, consisting of a horizontal steel shell set on brick or concrete masonry, with more or less structural steel, had an efficiency of from 20 to 30 per cent. The latest types of stills, whether the heating elements consist entirely of tubes or are partly shells, have an efficiency of 60 to 75 per cent. The gains are accomplished by the use of better-constructed furnaces, provided with instruments for better-regulated control of fuel and air, and take advantage of the radiant heat and convection heat in the best possible manner, which minimizes stack losses. The low rate of heat transmission from the flame to the oil inside of a still of the old type—6000 B.t.u. per sq. ft.—has been improved by the increase in velocity of the oil being heated through a pipe coil, and also by the addition of extended surface on the outside of tubes to a maximum of 25,000 B.t.u. per sq. ft., and data are in the hands of manufacturers to enable them to predict fairly accurately the results to be obtained from any given design.

Various types of stokers have been in use for some time on stills of both the old shell type and the later continuous type using forced circulation. Within the last year powdered coal has been applied to the latest type of tube stills with apparent success, resulting in efficiencies equivalent to good refinery boiler practice.

The efficient use of heat is naturally being supplemented by the proper use of insulating materials. This not only provides for layers of insulating brick, or outside insulation of settings, but

also for the covering of all piping and apparatus where radiation is undesirable.

One of the largest of fuel savings in connection with oil distillation has been obtained by the installation of tubular heat exchangers. The early days of such equipment were full of trouble for both the manufacturer and the refiner, due to the inadequate knowledge of this subject compared to steam practice, or that in other industries in which the materials were not handled at high temperatures or did not interfere seriously with heat transfer, and where corrosion was not a serious problem. For the heavier by-products of refining the heat transfer is as low as 10 B.t.u. per sq. ft. per degree of temperature difference, while for the lightest products the value may reach 70 or 80. This matter is further complicated by the limited pressure drops available as required by the process of distillation and the need for space between tubes for cleaning.

The natural low efficiency of heat transfer where oil is on one side of the tube surface and water is used for cooling makes it essential that clean water be used, and some of the refineries are putting in auxiliary coolers in which river water, which may contain a variable percentage of mud and slime, is used to cool deaereated water which operates as a cooling medium for the oil in a closed system. This cuts down the cleaning time and therefore the shutdown periods on the more expensive oil-distilling apparatus.

Naturally the introduction of instruments, both for control of fuel conditions and the specifications of the products, requires a higher class of labor, and to keep down the expense of this part of process, which in total averages 20 per cent of the refinery's manufacturing expense, the stills are built in batteries, and each unit is as large as practicable.

### Construction and Engineering Problems

2 From the construction and engineering standpoint, studies are constantly being made of the possibilities of various materials, of which a great number are on the market, and particularly is this necessary from the standpoint of corrosion. Every crude oil contains sulphur in some form, even though it be a very small percentage in some of the better crudes. Chlorides may also be present in some crudes, which results in the formation of hydrochloric acid, and this must be provided against. Any alkali added in some portion of the refining process may affect certain construction materials which would otherwise be most useful. The various alloys, both ferrous and non-ferrous, are continually studied and tested, and at the high temperatures and pressures prevalent, particularly in cracking, the physical properties of the materials used must also be considered. There must be no uncertainty in the metallurgy of a finished metal that is used in any part of the apparatus, as naturally in a large, expensive unit an enforced shutdown is very expensive.

High-pressure cracking processes have developed the manufacture of forge-welded chambers for this work. These are made in various diameters and over 40 ft. long, with thicknesses varying according to requirements up to $5^1/_2$ or 6 in. The ends are necked down and provided with flanges and covers, and a finished chamber of 52 in. inside diameter and 42 ft. long will weigh from 50 to 70 tons, depending upon the amount of machining that is done, whereas the original ingot from which the forging is made may weigh as much as 200 to 250 tons. These single forgings are being made both in this country and abroad.

Another development within the last few years on such large chambers is an electric-fused welding process in which the welding material is such that air is prevented from acting upon the material being welded. The chambers are made up of plates of the thickness required for considerable length with relation to width, and curved in the width to suit the radius of chamber desired. Chambers of this type have been in use in the Holmes-Manley and other processes and are giving satisfactory results.

Present-day refinery operators must keep pace not only with the market demand but also provide for available space for incoming shipments of crude oil, and this is governed by the kind of equipment and the capacity of tanks available. Every operation is scheduled, and the complications added by the use of pipe or tube heating coils, heat exchangers, condensers, and coolers necessitate that the cleaning of this apparatus be done in the most efficient manner. At the same time repairs must be carefully watched, and this is accomplished by a regular system of inspection, providing not only for the safety of the operators but also for the replacement of worn-out equipment when necessary. All such information is carefully recorded and studies are made for the improvement of conditions.

Protection of every kind must be provided, not only for the operators, for which no expense is spared, but also for the equipment. In consequence construction is now built for permanence and fire resistance, and every enclosed or semi-enclosed space must be properly ventilated. While the ground space occupied by equipment as now constructed may only be 25 per cent of that occupied by equipment of the same capacity some years ago, the structure has reared itself in the air, due to the natural requirements of the process; and whereas the old-type structures, with the exception of stacks, seldom exceeded a height of 25 ft., the apparatus may now extend upward 70 to 90 ft.

The protection of operators and the apparatus as a whole must be supplemented by protection from corrosion, which may occur in the materials used, particularly alloys as above noted, or also in the special coatings provided. Surface applications of metal to metal, or inert compounds applied to surfaces exposed to hot oil and vapors, are used, and in some types of stills such surface protection not only provides against corrosion but also against the adherence of carbon deposits. This is very essential in maintaining an efficient heat transfer on heating elements, for as soon as this stops or is hindered seriously the heating elements will increase in temperature until they are no longer able to carry the load, and the apparatus must be shut down.

With temperatures ranging from 800 to 1000 deg. fahr. and pressures varying from 0.5 in. or less of mercury to 1200 lb. per sq. in., it is natural to conclude that the problems of the oil refiner will never be entirely solved.

### The Various Processes in Vogue

3 The processes selected by the refiner for obtaining marketable products from the crude are naturally dictated by supply and demand, and by the economies obtainable. The quality of the product is of first importance, as nowadays the competition and the purchaser's knowledge of his requirements make it impossible to maintain sales except by strict adherence to specifications. Crude oil being a mixture of a number of combinations of carbon and hydrogen having different boiling points, may naturally be separated by distillation. Every one of these compounds, however, may be broken up into other compounds by overheating during this process, and there is a fairly definite range of pressures and temperatures under which these conditions will occur.

Before the advent of internal-combustion engines, particularly gasoline engines, there was no great proportional demand for naphthas, or what we now term motor gasoline. Cracking for a purpose was unknown, and all crude oil was distilled in batches and fractionated by gradually increasing the temperature of the oil and in an approximate way boiling off each product in turn. Impossible uniformity of heat distribution, due to the crudeness of the apparatus, resulted in overlapping of the various fractions, and the distilled products so obtained had to be rerun,

that is, again passed through the evaporating and condensing process. Each run resulted in losses that were unavoidable. The application of continuous distillation, and later the use of fractionating columns, has resulted in the modern pipe still, which produces continuously various fractions from the crude oil to desired specifications with rerunning reduced to a minimum and without scarcely any further processing except treating, and consequently with greater percentages of recovery of various products.

The heavier the products the more apt they are to crack. That is, the lubricating oils will be affected in this way at lower temperatures and pressures than kerosene and naphthas. This has resulted in the development of the vacuum distillation process, which lowers the boiling point of the liquids and at the same time gives greater yields which are claimed to be of better quality. With present knowledge in the foundry and machine shop, it is possible to produce apparatus in which a very high vacuum can be maintained and which will operate efficiently for long periods of time. The use of multi-stage thermo-compressors makes it possible to recover the steam and further improve the overall efficiency of the apparatus.

While the fractional distillations above mentioned are carried on at a pressure close to atmosphere or in partial vacuum, the development of the gasoline engine has in past years made it necessary to greatly increase the yield of the lighter fractions in proportion to the crude oil available and to the other products desired. This naturally resulted in the development of cracking processes which require fairly definite temperatures, and the maintenance of high corresponding pressures, if the cracking is to take place in apparatus of reasonable size and without evaporation. This involves high-pressure pumps for charging those fractions of the crude of which a surplus existed, mainly gas oil, and the use of digesting or reaction chambers in which the process can be completed after the oil has been heated to the proper temperature. While very little is known of what actually takes place, it was indicated that the time element was of some importance, and that the action of cracking was not instantaneous. Following this phase of the operation the pressure is released, and the mixture of gasoline obtained, together with some carbon and fixed gas, and the unaffected portion of the charge are expanded into an evaporating chamber and from there carried into a fractionating tower. This consists of a vertical shell equipped with a number of trays arranged in tiers, these trays having openings covered with caps. On each tray a certain amount of liquid collects, through which the steam and vapors have to pass, distribution of vapor through the liquid being accomplished by serrated edges on the bottom of the caps. This apparatus is commonly know as a bubble tower, and as the temperature drops from the bottom of the tower upward, the light distillates are separated from the lower-boiling compounds, so that at the top of the tower steam and practically pure gasoline vapor are taken off and led to the condensing apparatus. In such a tower used with fractionating pipe stills, other products are removed at intermediate trays; and the heaviest fraction, commonly termed "bottoms," is reduced to the lowest possible percentage. During the past few years it has been found that crude oil can be charged direct into cracking apparatus, and the natural naphtha and the cracked naphtha can thereby be removed in one operation with possibly less loss than by carrying out the fractionation of the natural naphtha separately from the cracking apparatus.

It can readily be seen that as crudes vary in their natural components and the demands of the market also vary for various finished products, the refiner has a constantly changing problem, demanding the best and most economical method of refining. During the last year the number of fractionating stills—commonly known as pipe stills due to the type of heating element—and the number of cracking stills have been greatly increased, although the excess production of crude has reduced the number of cracking stills that might have been built.

The vapor-phase type of cracking stills and the aluminum-chloride process of cracking are also in successful use, but have not had the same growth in number as the liquid-phase type of cracking stills. Vapor-phase cracking may have a special use in producing gasoline with fewer detonating characteristics.

All products as they are obtained from the first distillation of crude oil must be treated in some way. Sulphuric acid is still being used for decolorizing, but there has been considerable development in the application of clay filtration. The old method by percolating filters is being superseded on some oils by fine-clay contact treatment. The principle of this process depends upon mixing this material with the oils at proper temperatures in stirring agitators and then allowing it to settle, the number of stages of mixing and settling depending upon the refinement desired. A light acid treatment usually precedes the clay treatment.

The reconditioning of spent clay from the filtration processes has been successively accomplished by means of rotary kilns and gravity-flow driers, and in the latest plants the Herreschoff and Wedge furnaces are used, resulting in longer life for the clay.

The Edelanea process of refining, involving the extraction with liquid sulphur dioxide, is gaining headway on the Pacific Coast, and its wider use may be expected.

The use of the centrifugal method of dewaxing has become more general, and its application has been broadened.

It has been found that gasoline vapor can be treated by passing it through a fullers' earth filter, and this is superior to sulphuric-acid treatment of liquid gasoline, as the latter tends to destroy some of the anti-detonating compounds.

### Developments in Manufacture and Use of Steam and Power

4 With reference to steam and power requirements, the older types of refineries had use for a large quantity of process steam, and it was natural that their boiler plants were built mainly for this purpose, generating steam at pressures from 80 to 250 lb. and obtaining electric power by means of turbines working on 10 to 15 lb. back pressure, or using the bleeder type of turbines suitable for variable steam conditions.

The process steam required for distillation in the new type of stills is about one-third less per barrel of oil distilled than formerly, and at the same time, on account of the higher pressure required for charging pumps on crude stills and the extremely high-pressure charging pumps used on cracking stills, electric power applied through gear drives is coming rapidly into use, and more generating capacity is thereby required.

The development of high-pressure boilers and higher pressure in distribution mains for steam over widely extended plants, and the resulting improved economy, has benefited large refineries in the same way it has other industries. It has even been found desirable in some plants to generate power by means of oil engines. In the use of cracking processes the quantity of gas produced has increased, and naturally the installation of stripping plants by means of which gasoline vapors are removed from the still gas before it is burned, has made gas-engine drives possible for air and gas compressors and similar service, particularly at points far removed from a supply of steam or electricity.

The modern cracking still may require a hot-oil pump with a forged-steel liquid end handling about 180 gal. of oil per min. and operating at 650 deg. fahr., and 1200 to 1600 lb. pressure, and such pumps may be steam driven with compound steam ends, or motor driven, in which case variable-speed motors are preferable. Where steam is available in suitable pressures and

quantities, a steam pump is preferred, but as the power pumps have been found to operate very smoothly under such conditions and with some improvement in economy, they may in the end be found more suitable.

5 Regardless of where crude oil is obtained and in what quantities it may be obtained compared to the demands for finished products, the necessity of making profits against severe competition calls imperatively for continued research work toward improvement.

### Research Work Under Way

The Bergius process for obtaining products similar to those obtained from petroleum by distillation of coal under 200 atmospheres has found favor abroad, due to the peculiar situation there with reference to the crude market, and in the past year the rights on this process for this country have been obtained by the Standard Oil Company of New Jersey, although it is not expected that the process will become commercially feasible for some years to come.

In the application of radiant heat, several stills are under construction in which the oil heater tubes form the inner enclosure of the combustion chamber.

Research work is being done toward the recovery of a greater portion of the by-product gas from petroleum distillation than is now obtained by stripping processes, for use in motor fuels.

While the number of small plants obtaining petroleum products from shale oil is increasing, the proportion of these products, compared to the total market requirements, is very small.

Summarizing the entire field of refining, the last few years have indicated remarkable strides toward improvement, and the application of the latest methods in process, construction materials, and the actual use of apparatus in operation has become a highly technical subject.

# General Heat-Transfer Formulas for Conduction and Convection

By EDWIN R. COX,[1] LOS ANGELES, CALIF.

Only within the last few years has the subject of heat transfer by forced convection been placed upon a fairly sound basis, although Osborne Reynolds[2] in 1874 indicated the way. He derived by dimensional reasoning a function $dvG/\mu$ as an index of critical velocity, and plotted the coefficient of friction for pipe-line flow against this function. He also suggested that this function should affect heat transfer, but neglected to reconcile the other variables in his equation by the same dimensional reasoning. Hence his suggestion did not bear fruit for many years.

Nusselt[3] was the first to derive (1909) a complete rational equation by dimensional reasoning. In order to compare the different formulas, the following symbols have been used throughout:

- $h$ = transfer through one fluid film, in B.t.u. per sq. ft. per hr. per deg. fahr.
- $d$ = inside diameter of tube in inches
- $k$ = conductivity of fluid in B.t.u. per foot cube, per hour, per deg. fahr.
- $v$ = velocity, ft. per sec.
- $G$ = specific gravity compared with water
- $\mu$ = viscosity in poises
- $C_p$ = specific heat at constant pressure
- $C$ = coefficient, in general different for each equation, unless identified by a subscript.

With this nomenclature, Nusselt's formula becomes

$$\frac{hd}{k} = C_1\left(\frac{dvG}{\mu}\right)^{\alpha}\left(\frac{\mu C_p}{k}\right)^{\beta} \qquad [1]$$

He finds $\alpha = 0.786$. For simplicity he makes $\alpha = \beta$, thus eliminating $\mu$. This serves satisfactorily for gases but would not do for viscous liquids or even for water through a considerable range.

McAdams and Frost[4] note Nusselt's formula but make $\beta = 0$ for liquids. With $\alpha = 0.796$, this accords well with tests on water and light oils.

Rice[5] seems to have been the first to use the entire formula and finds $\alpha = 0.833$ and $\beta = 0.500$. He plots a large number of tests upon air and water and they accord fairly well. No tests were included for viscous liquids. $\beta$ is derived from Soennecken's tests with water. Plotting $h$ against $\mu$ for equal velocities, Rice finds $h = c/\mu^{0.445}$, other things being equal. But 0.445 represents the net effect of viscosity, or $0.445 = \alpha - \beta$. If $\alpha = 0.833$, $\beta = 0.833 - 0.445 = 0.388$. If we take $\beta = {}^1/_3$ and $\alpha = {}^5/_6$, $\alpha - \beta = {}^1/_2$. If we draw lines to this exponent through the points in Rice's chart for Soennecken's data, they seem to include the points well within the apparent experimental error. The writer corrected Rice's results to this exponent and the results accorded somewhat better, though not strikingly so. With $\beta = {}^1/_2$, Rice obtains a coefficient $k_0$ of 63.5. The tabulated data, using Peter's formula, shows a probable error of 2.2 per cent for $k_0$ or 15.2 per cent for a single observation. Correcting to $\beta = {}^1/_3$, the coefficient is 52.4 with a probable error of 1.85 per cent for $k_0$ or 12.8 per cent for an observation.

Rice expresses his formula entirely in c.g.s. units, some electrical, as follows:

$$W_e = \frac{Ak\,\Delta t}{K_0 D}\left(\frac{\mu C_p}{K}\right)^{\beta}\left(\frac{\rho D v}{\mu}\right)^{\alpha} \text{ watts}$$

which may be transformed to

$$\frac{W_e D}{A\,\Delta t k} = \frac{D}{B} = \frac{1}{K_0}\left(\frac{\rho D V}{\mu}\right)^{\alpha}\left(\frac{\mu C_p}{K}\right)^{\beta}$$

For translating into our units we find that

$$\frac{hd}{k} = 12\left(\frac{W_e D}{A\,\Delta t k}\right) = \frac{12}{B/D}$$

$$\frac{dvG}{\mu} = \frac{1}{77.42}\left(\frac{\rho D v_0}{\mu_0}\right)$$

$$\frac{\mu c_p}{k} = \frac{1}{241.9}\left(\frac{\mu_0 c_p}{k_0}\right)$$

$$C_1 = \frac{2804}{k_0} \text{ for } \beta = {}^1/_3$$

$$C'_1 = \frac{7000}{k_0} \text{ for } \beta = {}^1/_2$$

Hence in our units the Rice equation becomes

$$\frac{hd}{k} = 53.5\left(\frac{dvG}{\mu}\right)^{5/6}\left(\frac{\mu C_p}{k}\right)^{1/3} \qquad [2]$$

or

$$\frac{hd}{k} = 110.2\left(\frac{dvG}{\mu}\right)^{5/6}\left(\frac{\mu C_p}{k}\right)^{1/2}$$

Equation [2] would seem to be the best approximation to be obtained from the data of Rice.

McAdams and Frost[5] derive the formula

$$\frac{hD}{k} = 22.6\left(\frac{Du\rho}{z}\right)^{0.796}$$

where $D$ = diameter in in.
$u$ = velocity in ft. per sec. and
$z$ = $100\mu$.

If we take a middle point in their chart where $\frac{hD}{k} = 1250$ and $\frac{Du\rho}{z} = 150$ and draw a line through this point with the inclination $\alpha = {}^5/_6$, we find that it satisfies the points substantially as well as the 0.796 line. This would give the equation in our units

$$\frac{hd}{k} = 13.73\left(\frac{dvG}{\mu}\right)^{5/6}$$

[4] *Journal of Industrial and Engineering Chemistry*, vol. 14 (1922), p. 1101.

[5] *Journal of Industrial and Engineering Chemistry*, vol. 16 (1924), p. 460.

Presented at the Annual Meeting, New York, Dec. 5 to 8, 1927, of The American Society of Mechanical Engineers.

In plotting these data upon his chart, Rice assumes a mean value of $\frac{k}{\mu c_p} = 0.25$ in c.g.s. units, which would be 60.48 in our units. Hence $C_1$ for the McAdams and Frost data would be $13.73 \times (60.48)^{1/3} = 54.0$.

Perhaps the most elaborate and thorough tests upon heat transfer that have been published are those made by the Babcock & Wilcox Company[6] upon flue gases. The author has taken four points upon their chart, rather wide apart in velocity and temperature and converted them to our units in Table 1. These give values of $C_1$ = 54.4, 51.8, 53.2, and 52.8 with a mean value of 53.1. Comparing this with the value obtained from Rice, 53.5, and from McAdams and Frost, 54.0, the agreement is very good and indicates 53.5 as the best estimate.

TABLE 1

| | Uncored, $d$ = 2 in. | | | | Cored, $d_e$ = 1 in. | | | (1 in. diam., core) | | |

| $hd/k$ | 804 | 1233 | 668 | 1062 | 564 | 764 | 966 | 496 | 693 | 894 |
| $dvg/\mu$ | 238.5 | 421.0 | 191.8 | 337.5 | 142.6 | 214.0 | 285.2 | 114.5 | 171.8 | 229.0 |
| $\left(\frac{dvG}{\mu}\right)^{4/5}$ | 95.8 | 154.0 | 80.0 | 128.0 | 62.4 | 87.5 | 111.3 | 52.0 | 73.0 | 92.5 |
| $\left(\frac{k}{\mu C_p}\right)^{1/3}$ | 6.48 | 6.48 | 6.38 | 6.38 | 6.48 | 6.48 | 6.48 | 6.38 | 6.38 | 6.38 |
| $C_1$ | 54.4 | 51.8 | 53.2 | 52.9 | 58.5 | 56.6 | 56.1 | 60.9 | 60.5 | 61.6 |

NOTE: In the report on these tests $h$ is plotted against $W/A$ where $A$ is cross-section of tube in square feet. In the above calculations, the following assumptions have been made. Composition of flue gas (by weight): $CO_2$ = 0.149, O = 0.068, N = 0.704, $H_2O$ = 0.079. The characteristics are calculated by mol fraction.

At 180 deg. fahr., $1/\mu = 4740$, $k = 0.0148$, $C_p = 0.2506$, $k/\mu C_p = 280$
At 580 deg. fahr., $1/\mu = 3270$, $k = 0.0212$, $C_p = 0.2620$, $k/\mu C_p = 265$
At 2180 deg. fahr., $1/\mu = 1694$, $k = 0.0434$, $C_p = 0.3079$, $k/\mu C_p = 239$
The temperature of the tube wall is maintained at 180 deg. fahr.

TABLE 2 OIL COOLING

| Character of oil | Rerun bottoms | | | | Residuum | | | | |
|---|---|---|---|---|---|---|---|---|---|

NOTE: $V$, $R$, $R_w$, $R_s$, and $h$ are based on outside surface. This is reconciled by taking outside diameter, 0.625 in., in $hd/k$. $k$ is taken as 0.086. $dvG/\mu$ is calculated for inside of tube and $C_1$ applies to inside film. The logarithmic mean is used for $\Theta$ in calculating $U$.

In Table 1 are also included tests for cored tubes, in endeavoring to determine the true value of the effective diameter $d_e$ to be used in applying the formula to annular spaces or the space around a nest of tubes. The author assumed at one time that $d_e$ should be $4a/P$ where $a$ is the area and $P$ the total wetted perimeter, in $dvG/\mu$; and should be $4a/P'$, where $P'$ is the perimeter of conducting surface only, in $hd/k$. Although this gave consistent values for a nest of tubes, where $P$ and $P'$ did not differ greatly, it gave too large values for $d_e$ in double-pipe exchangers. The Babcock & Wilcox data for cored tubes would give $C_1$ = 88.5 if we used $P'$, instead of 59.0 if we used $P$. This seems to prove conclusively that $4a/P$ is nearer the true value, although the difference between 53.1 and 59.0 is great enough to indicate possibly some intermediate value, such as

$$d_e = \frac{4a}{P}\left(\frac{P}{P'}\right)^x$$

To determine $x$ would require more data than is available at present.

Another point about which there has been serious question is, Where should the viscosity of the fluid be determined? Calling the mean temperature of the fluid $t_1$ and that of the tube wall $t_2$, McAdams and Frost in some of their earlier work took the viscosity at $t_2$. Later they adopted $(t_1 + t_2)/2$ as the determining temperature and Rice also uses this value. Rice, from King's data, suggests $\sqrt{t_1 t_2}$ may be the true value. In dealing with fluids whose viscosity changes rapidly with temperature, such as heavy petroleum fractions, the writer obtained the most consistent results by taking $\mu = (\mu_1 + \mu_2)/2$ where $\mu_1$ and $\mu_2$ are taken at $t_1$ and $t_2$, respectively. This is hardly necessary when dealing with water or light oils, but when heating crude oil or cooling residuum, the distinction becomes quite important. Here $\mu_1$ and $\mu_2$ vary twenty and thirtyfold, and in fact the main problem is to determine the proper value of $\mu$ to use in the formula.

Unfortunately very little has been published in regard to the

[6] Experiments on the Rate of Heat Transfer from a Hot Gas to a Cooler Metallic Surface, Babcock and Wilcox Co., 1916, pp. 62 and 64.

conductance of oil films. In Tables 2 and 3 are given the results of some tests which are not as good as could be desired, mainly because the viscosity of the oils was not determined directly, but taken from a chart of similar oils, and the temperatures of the tube wall were not measured, but calculated. Moreover they are strictly field tests made rather hastily for a certain purpose, without calibrating instruments, or taking other precautions for accuracy as would be done in laboratory work, with which it is not comparable. The data are only included because nothing better is available.[7]

These tests were all made with a $^5/_8$-in. outside diameter No. 18 B.w.g. Admiralty mixture tube, 8.81 ft. long, 1.445 sq. ft. outside surface, enclosed in a standard $1^1/_4$-in. pipe. The oil was passed through the tube and steam or water through the annular space. Tests Nos. 59–63 are strictly stream line and are included to show the rise in value of $C_1$ with velocities less than the critical, which in these units is at approximately $dvG/\mu = 12.3$. Omitting these tests the mean value of $C_1$ is 54.7. Test No. 58 is unreliable inasmuch as the calculated value of $R_w$ is over twice as great as the value of $R_0$, obtained by difference, and, hence, a small error in $R_w$ would be magnified in $R_0$. Omitting this test, the mean value of $C_1$ would be 51.7. This is sufficient to indicate the general conformity of oil tests with those of air and water.

Assuming then that the Nusselt-Rice equation is the best available expression of the film concept of heat transfer, it remains to adapt this to a more convenient form for the practical design of heat-transfer apparatus. The most important practical considerations are cost of apparatus and cost of operation. Of the latter the most important item is pressure drop through the apparatus. As is generally known, we are able to secure almost any rate of conductance within reason if we are willing to expend sufficient power in forcing the fluids through the tubes. Hence pressure drop is a prime consideration. We may further simplify the problem by confining it to the conventional types of exchangers, either the double pipe, or the multitubular, where one fluid is forced through the inner tube or tubes, and the other through the surrounding space. In both cases the larger pressure drop is through the tubes and we may confine our attention to this. In order to relate this pressure drop to the overall conductance we must express the latter, $U$, as a function of the conductance of the inner film,

$$U = C_2 h$$

or

$$\frac{Ud}{k} = C_1C_2\left(\frac{dvG}{\mu}\right)^{\alpha}\left(\frac{\mu C_p}{k}\right)^{\beta} \quad \ldots\ldots\ldots\ldots [3]$$

where the characteristic terms apply only to the inside of the tubes. This is equivalent to assuming that if we increase the velocity of the fluid inside the tubes, we also increase the outside velocity at the same rate, and that the resistance of the tube wall is negligible. This is sufficiently approximate for most cases. If greater accuracy is required, $C_2$ may be treated as a variable and related to $v$ by tests for each group of cases.

The total heat transferred in B.t.u. per hour may be expressed as

$$H = W\Delta C_p = AU\Theta \quad \ldots\ldots\ldots\ldots [4]$$

where $W$ is pounds per hour per tube, $\Delta$ the temperature range of the fluid, $C_p$ its specific heat, $A$ the inside conducting surface in square feet, and $\Theta$ the mean temperature difference between the two fluids.

For pressure drop we have the Chézy formula

$$p = \frac{f_1 v^2 GL}{d}$$

where $f_1$ is a function of $dvG/\mu$ usually expressed by a chart, such as that of Wilson, McAdams, and Seltzer.[8] If we consider the usual range of $dvG/\mu$ for liquids, and that for gases we may, within each of these ranges, express $f_1$ in terms of $dvG/\mu$ with sufficient accuracy, as

$$f_1 = C_4\left(\frac{\mu}{dvG}\right)^{\gamma}$$

This is well within the error introduced by varying roughness of tubes. In order to use the same units in the general equations which follow, we may substitute as follows:

$$v = \frac{W}{1226\,d^2G}, \quad F = \frac{1}{\mu}, \quad \frac{dvG}{\mu} = \frac{WF}{1226d}, \quad A = \frac{\pi dL}{12}.$$

From [3] we have

$$U = \frac{C_1C_2}{(1226)^{\alpha}}\left(\frac{k}{d}\right)\left(\frac{WF}{d}\right)^{\alpha}\left(\frac{C_p}{Fk}\right)^{\beta}$$

or

$$U = \frac{C_1C_2}{(1226)^{\alpha}} W^{\alpha}F^{\alpha-\beta}K^{1-\beta}C_p{}^{\beta}d^{-\alpha-1} \quad \ldots\ldots [5]$$

For pressure drop,

$$p = \frac{f_2W^2L}{d^5G} \quad \text{and} \quad f_2 = \frac{C_5 d^{\gamma}}{W^{\gamma}F^{\gamma}}$$

or

$$p = \frac{C_5W^{2-\gamma}L}{d^{5-\gamma}F^{\gamma}G} \quad \ldots\ldots\ldots\ldots\ldots\ldots [6]$$

From [4] we have

$$W = \frac{\pi}{12}\,\frac{U\Theta dL}{\Delta C_p}$$

or

$$L = \frac{12}{\pi}\,\frac{W\Delta C_p}{dU\Theta} \quad \ldots\ldots\ldots\ldots\ldots\ldots [7]$$

This gives us three fundamental equations [5], [6], and [7]. We may consider the fluid characteristics $F$, $G$, $k$, and $C_p$; the pressure drop $p$; and the temperature relations $\Delta$ and $\Theta$ as fixed by the requirements of a given design. This leaves $U$, $L$, and $d$ subject to variation in design; also $W$, since we may use any number of tubes in multiple. Since we have three independent equations we may eliminate any two of these variables and derive a relation between the other two.

Eliminating $W$ and $L$ we have

$$U = \left\{\frac{C_1C_2}{(1226)^{\alpha}}\right\}^{\frac{3-\gamma}{3-\alpha-\gamma}}\left(\frac{\pi}{12C_5}\right)^{\frac{\alpha}{3-\alpha-\gamma}}\left(\frac{Gp\Theta}{\Delta}\right)^{\frac{\alpha}{3-\alpha-\gamma}}$$

$$F^{\frac{3(\alpha-\beta)+\beta\gamma}{3-\alpha-\gamma}}\,d^{\frac{3(\alpha-1)+\gamma}{3-\alpha-\gamma}}\,k^{\frac{(3-\gamma)(1-\beta)}{3-\alpha-\gamma}}\,C_p{}^{\frac{(3-\gamma)\beta-\alpha}{3-\alpha-\gamma}} \quad \ldots\ldots [8]$$

Eliminating $U$ and $L$ gives

$$W = \left\{\frac{\pi C_1C_2}{12\times(1226)^{\alpha}C_5}\right\}^{\frac{1}{3-\alpha-\gamma}}\left(\frac{Gp\Theta}{\Delta}\right)^{\frac{1}{3-\alpha-\gamma}}F^{\frac{\alpha-\beta+\gamma}{3-\alpha-\gamma}}$$

$$d^{\frac{5-\alpha-\gamma}{3-\alpha-\gamma}}\left(\frac{k}{C_p}\right)^{\frac{1-\beta}{3-\alpha-\gamma}} \quad \ldots\ldots\ldots\ldots\ldots\ldots [9]$$

---

[7] Since this paper was prepared it has been brought to the attention of the writer that Whitman and Morris have presented to the American Chemical Society some very valuable data on the heating and cooling of oils. It is to be hoped that this will help clear up the all-important problem of viscosity effect.

[8] *Journal of Industrial and Engineering Chemistry*, vol. 14 (1922), p. 105.

Eliminating $U$ and $W$ and solving for $L$,

$$L = \left\{ \frac{\pi C_1 C_2}{12 \times (1226)^{\alpha}} \right\}^{\frac{\gamma-2}{3-\alpha-\gamma}} C_5^{\frac{\alpha-1}{3-\alpha-\gamma}} (Gp)^{\frac{1-\alpha}{3-\alpha-\gamma}} \left(\frac{\Delta}{\Theta}\right)^{\frac{2-\gamma}{3-\alpha-\gamma}}$$

$$F^{\frac{2(\beta-\alpha)+\gamma(1-\beta)}{3-\alpha-\gamma}} d^{\frac{5-3\alpha-\gamma}{3-\alpha-\gamma}} \left(\frac{k}{C_p}\right)^{\frac{(2-\gamma)(\beta-1)}{3-\alpha-\gamma}} \quad \ldots\ldots\ldots [10]$$

Or, solving for $\Delta/\Theta$,

$$\frac{\Delta}{\Theta} = \left\{ \frac{\pi C_1 C_2}{12 \times (1226)^{\alpha}} \right\} C_5^{\frac{1-\alpha}{2-\gamma}} (Gp)^{\frac{\alpha-1}{2-\gamma}} L^{\frac{3-\alpha-\gamma}{2-\gamma}}$$

$$F^{\frac{2(\alpha-\beta)+\gamma(\beta-1)}{2-\gamma}} d^{\frac{3\alpha+\gamma-5}{2-\gamma}} \left(\frac{k}{C_p}\right)^{1-\beta} \quad \ldots\ldots\ldots [11]$$

These equations are quite general and may be used for any determinations made in the form of the Nusselt-Rice equation, and for any portion of the $f$ vs. $dvG/\mu$ chart.

For the usual range of $dvG/\mu$ found in dealing with oil or water, $\gamma$ is approximately 0.264, and for gas or air, 0.162, making the equations for pressure drop

$$p = \frac{0.00765}{F^{0.264}} \frac{(W/1000)^{1.736} L}{d^{4.736} G} \text{ for liquids} \ldots\ldots\ldots [12]$$

$$p = \frac{0.00404 \, (W/1000)^{1.838} L}{F^{0.162} d^{4.838} G} \text{ for gases} \ldots\ldots\ldots [13]$$

Hence $C_5$ becomes $\dfrac{0.00765}{(1000)^{1.736}}$ for liquids and $\dfrac{0.00404}{(1000)^{1.836}}$ for gases.

Taking $C_1 = 53.5$, $\alpha = {}^5/_6$, $\beta = {}^1/_3$, and $\gamma$ and $C_5$ as above, we have two sets of equations, as follows.

*For Liquids:*

$$U = 54.5 \, C_2^{1.439} \left(\frac{Gp\Theta}{\Delta}\right)^{0.438} F^{0.834} d^{-0.124} k^{0.959} C_p^{0.0414} \ldots [14]$$

$$W = 1247 \, C_2^{0.525} \left(\frac{Gp\Theta}{\Delta}\right)^{0.525} F^{0.401} d^{2.05} \left(\frac{k}{C_p}\right)^{0.35} \ldots [15]$$

$$L = \frac{87.6}{C_2^{0.912}} (Gp)^{0.0875} \left(\frac{\Delta}{\Theta}\right)^{0.912} F^{-0.433} d^{1.175} \left(\frac{C_p}{k}\right)^{0.608} \ldots [16]$$

$$\frac{\Delta}{\Theta} = \frac{1}{135.1} C_2 (Gp)^{-0.096} L^{1.096} F^{0.475} d^{-1.288} \left(\frac{k}{C_p}\right)^{0.667} \ldots [17]$$

*For Gases:*

$$U = 40. C_2^{1.415} \left(\frac{Gp\Theta}{\Delta}\right)^{0.415} F^{0.775} d^{-0.169} k^{0.944} C_p^{0.0563} \ldots [18]$$

$$W = 876. C_2^{0.499} \left(\frac{Gp\Theta}{\Delta}\right)^{0.498} F^{0.330} d^{2.00} \left(\frac{k}{C_p}\right)^{0.332} \ldots [19]$$

$$L = \frac{82.5}{C_2^{0.916}} (Gp)^{0.083} \left(\frac{\Delta}{\Theta}\right)^{0.916} F^{-0.445} d^{1.168} \left(\frac{C_p}{k}\right)^{0.611} \ldots [20]$$

$$\frac{\Delta}{\Theta} = \frac{C_2}{123.3} (Gp)^{-0.0908} L^{1.092} F^{0.485} d^{-1.272} \left(\frac{k}{C_p}\right)^{0.667} \ldots [21]$$

These equations are convenient for ascertaining the net effect of varying one condition while all others remain constant. From Equation [14] and Equation [18] it is evident that, other things being equal, the smallest practicable tube will give the highest transfer rate. If, then, we know the cost per square foot of an exchanger when made of tubes of different sizes, and we multiply each unit cost by the corresponding $d^{0.124}$, the products will be proportional to costs per B.t.u. per degree per hour, and will indicate the optimum size.

Having ascertained the most economical size of tube for a given purpose, the only other feature we can alter in a given set of conditions is the pressure drop. The most economical pressure drop $p_m$ is the one which affords the minimum annual cost $Y$. This is made up of two components $Y_1$, the annual charge on the investment including interest, depreciation, and upkeep, and $Y_2$, the annual cost of pumping or forcing the fluids through the exchanger. Since the surface required is inversely proportional to $U$ and $U$ is directly proportional to some power $e$ of the pressure drop $p$, we may write

$$Y = \frac{C_6 q}{p^e}$$

$C_6$ is best determined by direct test upon an exchanger of similar type. If this exchanger handles $q_0$ gallons per minute with a pressure drop of $p_0$ and a yearly investment charge of $Y_0$, and we wish to design one to handle $q$ gallons per minute, we have

$$Y_0 = \frac{C_6 q_0}{p_0^e}$$

or

$$C_6 = \frac{Y_0 p_0^e}{q_0}$$

Similarly we may determine the pumping charge. Since the power required is proportional to $pq$, we may write

$$Y'_0 = C_7 p_0 q_0$$

and determine $C_7$ by

$$C_7 = \frac{Y_0'}{p_0 q_0}$$

The complete annual cost is then

$$Y = \frac{C_6 q}{p^e} + C_7 pq$$

Differentiating $Y$ with respect to $p$ and equating to zero, we have for a minimum

$$\frac{dY}{dp} = -\frac{eC_6 q}{p^{e+1}} + C_7 q = 0$$

or

$$p_m = \left(\frac{eC_6}{C_7}\right)^{\frac{1}{e+1}}$$

Taking the value of $e$ determined in Equation [14], $e = 0.438$, $\dfrac{1}{e+1} = 0.695$, and

$$p_m = 0.564 \left(\frac{C_6}{C_7}\right)^{0.695} \ldots\ldots\ldots\ldots\ldots [22]$$

In many cases it is desirable to know the effect of adding to the length of an exchanger or to know how much to add to secure certain temperatures. For this, the simpler equation, eliminating $p$, is more convenient. This applies to either liquids or gases:

$$L = \frac{26.8}{C_2} W^{1/6} \frac{\Delta}{\Theta} F^{-1/3} d^{5/6} \left(\frac{C_p}{k}\right)^{2/3} \ldots\ldots\ldots [23]$$

The temperature relation $\Delta/0$ is directly proportional to $L$ and is not greatly affected by moderate changes in the flow rate.

In general, Equation [1] seems to rest on a sound basis. The value of $C_1$ obtained from Rice (48 tests by Soenneken, Stanton

Clement and Garland, Pannel and Jordon) 53.5; from McAdams and Frost (63 tests by Clement and Garland, Wishnew, Trowbridge, Webster, Barton and Safford, and Voss) 54.0; from Babcock and Wilcox, 53.1; from oil tests collected by the writer, 51.8; all tend to confirm the general accuracy of the exponents $\alpha$ and $\beta$ under a wide range of conditions. However, the value of $C_1$ (53.5) is only accurate as a general average. Minor variations in $C_1$ in each group of cases are still to be explained. It is quite possible that $C_1$ will be found to vary with some other dimensionless combination, such as $\mu_1/\mu_2$ or $\mu_3/\mu_4$, where $\mu_3$ and $\mu_4$ apply to inlet and outlet temperatures, or $L/d$. Other combinations which have not been tried are $V^2/(2g)L$, $LvGC_p/K$ and $WC_p/Pk$.

## NOMENCLATURE

$A$ = inside surface of exchanger, sq. ft.
$a$ = inside cross-section of exchanger, sq. in.
$C$ = coefficient in general
$C_1$ = coefficient in Nusselt-Rice equation
$C_2$ = ratio of one film transfer rate to overall transfer rate, $U/h$
$C_p$ = specific heat at constant pressure
$d$ = inside diameter of tube, in.
$d_e$ = effective diameter = $4a/P$
$e$ = exponent of $p = \alpha/(3 - \alpha - \gamma)$
$F$ = fluidity = $1/\mu$
$f$ = coefficient of fluid friction
$G$ = specific gravity compared to water
$H$ = total heat transmitted, B.t.u. per hour
$h$ = heat transfer rate for one fluid film, B.t.u. per sq. ft. per deg. per hr.
$k$ = thermal conductivity, B.t.u. per ft. cube per deg. per hr.
$k_0$ = Rice's coefficient (c.g.s. units)
$L$ = length of path in exchanger, ft.
$P$ = perimeter of wetted surface, in.
$p$ = pressure drop, lb. per sq. in.
$q$ = flow rate, g.p.m.
$R$ = thermal resistance of fluid film = $1000/h$
$t_1$ = mean temperature of fluid
$t_2$ = mean temperature of tube wall
$U$ = overall heat-transfer rate, B.t.u. per sq. ft. per deg. per hr.
$v$ = velocity of fluid, ft. per sec.
$W$ = flow rate, lb. per hr.
$Y$ = annual charge
$\alpha$ = exponent of $dvG/\mu$ in Nusselt-Rice equation = (approximately) $^4/_5$
$\beta$ = exponent of $\dfrac{\mu C_p}{K}$ in Nusselt-Rice equation = (approximately) $^1/_3$
$\gamma$ = exponent of $dvG/\mu$ in $f = C(\mu/dvG)$ = (approximately) 0.264 for liquids ($dvG/\mu$ between 40 and 400) and 0.162 for gases ($dvG/\mu$ between 400 and 4000)
$\Delta$ = temperature range of fluid
$\Theta$ = mean temperature difference between hot and cold fluids, or between tube wall and fluid
$\mu$ = viscosity in poises.

# Discussion

Lawford H. Fry.[9] The paper may be of interest to physicists but it does not present its final conclusions, if any, in a form which will bring much comfort to the practising engineer who, having a given rate of flow of fluid through a tube and knowing the entering temperature, wishes to determine the total amount of heat transferred between fluid and tube over a given tube length, or, which is the same thing, wishes to know the temperature of the fluid leaving the tube.

Equation [1] for heat transfer per square foot per hour involves specific gravity, conductivity, viscosity, and specific heat at pressure. It would be of considerable assistance in checking the author's work against other experimental data, if he gave the values he uses for these four properties of the fluids with which he is concerned. These values vary with the temperature of the fluid and must therefore vary as the temperature of the fluid drops in flowing along the wall. It therefore appears that in Equation [23] which is intended to apply to a flue of material length $L$ some statement should be made as to how the values of the properties of the fluid should be averaged so as to give mean values applicable to the length $L$.

The Hedrick-Fessenden type of formula[10] which deals with the drop of temperature along a flue instead of attempting to arrive at the coefficient of heat transfer for an element of the flue surface, seems to be much better adapted to engineering use. The present writer has shown[11] that with this type of formula it is possible to find coefficients which are applicable to a wide range of practical conditions. In the writer's work coefficients were determined empirically, but their rather wide usefulness indicates that their structure probably corresponds somewhat closely to the theoretical requirements.

If Mr. Cox intends his work to be of practical value to others, it is hoped that he will supplement the information in his paper by the information necessary to enable the results of the formulas to be measured against experimental data.

W. H. McAdams.[12] The attempt of the author to clarify the complicated and exceedingly important problem of heat transmission for turbulent motion, particularly in the case of viscous liquids, by the use of the Nusselt formula (his Equation [1]), is a step in the right direction. It is unfortunate that he did not have available the work of Whitman and Morris, presented last September at the meeting of the American Chemical Society in Detroit, but which has not yet appeared in the journal.[13] Whitman, like Cox, reduced Rice's value of $\beta$, using 0.37 instead of Cox's value of 0.33. Whitman made 106 runs in heating and cooling three different oils, and 12 runs on water, and furthermore he actually measured pipe-wall temperatures and experimentally determined the viscosity-temperature curve of the various oils. In terms of the Nusselt coefficient $C_1$, Whitman's results are of

[13] Since the above discussion was presented, the paper of Morris and Whitman has appeared, *Jl. Industrial and Engineering Chemistry*, vol. 20, no. 3, March, 1928, p. 234.

the same order of magnitude as Cox's. Furthermore, Whitman emphasizes the fact that the method of averaging the viscosity, to be employed in the Nusselt formula, profoundly affects the correlation of data. When employing film viscosities, Whitman found that the coefficient $C_1$ is approximately twice as much for cooling as for heating, but when viscosity at the bulk temperature was used the value of $C_1$ for cooling was 0.75 times that for heating. He therefore adopted the latter method.[14]

Therefore, the method of averaging to be employed in determining film viscosity is subject to discussion. It is unfortunate that Mr. Cox does not give viscosity-temperature curves which he used for his oil, so that his data can be compared with the results of Whitman and other investigators, by methods of averaging the values of $\mu$ other than his own.

From the article one gathers the impression that its author is inclined to present the Nusselt equation as a general equation for heat transmission between pipe walls and fluids in turbulent motion. If this is the purpose, it is desirable that the equation be tested on at least a large portion of the other data available in the literature. Thus, there seems no reason apparent on the face of the record for discarding the data on heat transmission of Fessenden and Haney[15] in favor of the Babcock & Wilcox results. Furthermore, adequate correction should be made for gas radiation[16] which was not negligible at the higher temperatures employed by Babcock & Wilcox. It seems doubtful whether we are yet in a position to set up a truly general equation for heat transmission in this case.

In the opinion of the writer, it is safer, in the present state of our knowledge, to use the Nusselt equation for correlation of data by plotting logarithmically the dimensionless group $hd/k$ against $DvG/\mu$, using a separate curve for each type of fluid. Where possible, one should plot separately the data for each fixed value of the group $\mu c/k$. The intercepts[17] of the various curves thus obtained will give the influence of this group on the Nusselt coefficient $C_1(\mu c/k)$. This variation in $C_1(\mu c/k)$ may then be treated graphically or algebraically. Where this amount of data is not available, a single plot for a given fluid or fluid type may be constructed, in which each experimental point has indicated on it its corresponding value of the group $\mu c/k$. Points corresponding to equal values of this axis may then be connected; where minor variations in this axis exist it is usually possible to correct for such variations by inspection. This method of correlation of data is exceedingly helpful and is probably the safest one to employ until we are surer than at present of such matters as the true influence of $\mu c/k$ axis, the proper way to average viscosities, the possible influence of other variables, the absolute values of thermal conductivities of liquids, and the influence of temperature thereon, and the like.

With reference to the author's method of determining optimum conditions of operation of heat-exchange equipment from the point of view of economic balance, it would be well to point out wherein his method differs from that of Lewis, Ward, and Voss,[18] except for the correction for length over diameter made by them and for slight variations in the numerical values of the constants. It would be interesting to know how the results of the two methods of design compare in specific illustrative cases.

[14] Whitman states that a still better correlation was possible b employing $\mu$ corresponding to a temperature "at a point one-fourth the thickness of the film from the main stream." Since this method would require trial-and-error work on the part of the designer, Whitman decided to employ bulk viscosity, allowing for the fact that $C_1$ for cooling was 75 per cent of $C_1$ for heating.

[16] "Heat Transmission by Radiation from Non-Luminous Flames," by H. C. Hottell, *Ind. & Eng. Chem.*, Aug., 1927, vol. 19, no. 8, p. 888.

[17] That is, the ordinates corresponding to $DvG/\mu$ = unity.

[18] *Ind. & Eng. Chem.*, vol. 16, 1924, p. 467.

The author fails to emphasize the point that uncertainties in $C_1$ and $\beta$ have very little effect on the determination of the optimum conditions of operation. Most fortunately, from the engineering point of view, the proper operating conditions can be predicted with a precision far greater than would be anticipated in view of the variations encountered in the direct use of the Nusselt equation.

Willis H. Carrier.[19] The important contribution that the author has made in this paper is that he has shown the application of the rationalized Osborne Reynolds formula through a very wide range of densities and viscosities both for liquids and gases, and has substantiated this in several important cases by experimental data. Similar investigations have been made by others whom he mentions, particularly Rice and McAdams. He is able to use the same type of formula for gases with densities varying as widely as that of hydrogen and chlorine and also for liquids having viscosities varying from that of water to heavy oils, for the latter of which he gives some new and interesting data. It is by this experimental study of the extremes in density, viscosity, and specific heat that he is able to determine with a considerable degree of accuracy the law of these variations in their relation to heat transfer, and for this reason the paper has a great deal of interest to the engineer or physicist who is making a research on the general laws of heat transfer.

The author also makes some very useful and practical suggestions as to the design of surface for the greatest overall economy depending upon the nature of the fluid handled.

D. R. Harper.[20] This paper is a much needed contribution in the line of making more readily available for engineering application, that vast storehouse of general scientific work which has been done on the subject of heat transfer. The excellent illustration of general principles the author has given, in bringing together experiments over a wide range of viscosities, should increase the confidence of engineers in these relations. The paper contains little which is an actual contribution to the fundamental literature in this field, but it does translate into British units much which has not been so well known to date as it should be, partly because of its places of publication, partly because of nomenclature and units unfamiliar to mechanical and refrigerating engineers.

W. Trinks.[21] This is a most valuable paper. Nowhere in it, however, is anything said about radiation. Those of us who have wrestled with oil stills know only too well that the gases which touch the oil still on one side radiate their heat to the tubes and that, therefore, we cannot separate radiation in oil-still work. I believe, coming from California, and being in the gasoline business, Mr. Cox may be interested in oil stills. We should never forget that radiation influences the gas side, at least.

R. J. S. Pigott.[22] This paper is an important contribution for the following reasons:

As is well known there are variations in heat transfer in condensers from possibly 200 B.t.u. under cold-water conditions and poor air removal, up to as high as 800 or 900 B.t.u. under conditions of warm condenser water, minimum air leakage, and proper design of the condenser.

In the feedwater-heater group, there are variations from 300 to as high as 1800 B.t.u. Nobody seems to know definitely

what the heat transfer coefficient ought to be. In the case of oil coolers values are even less definite. Of course, $\mu/\rho$ is kinematic viscosity and the quantity $ds\rho/\mu$ indicates the effect of diameter (which is the size factor) times the speed of the fluid, divided by kinematic viscosity. One thing is quite evident; that is, nobody has paid much attention to the viscosity of the fluids as yet. That is the one remaining factor which is the reason why there have been no concordant results. It just so happened without knowing anything about this paper that I started some of my staff working out test results. We found in the first check plots that water-heater and condenser tests can be plotted largely on a single line if the viscosity of the fluid is taken into account. That is on the assumption that the controlling resistance is on the water side of the transfer apparatus. Under conditions of very large air leakage in the steam and cold water, the resistance may be on the steam side, but ordinarily there is not much air dilution. We do not know quantitatively just what effect dilution of the steam with air has on transfer. That is the next thing to be investigated after we check up the liquid side. There is no question that our calculations all the way down to actual purchase will be tremendously affected by getting consistent line-up of B.t.u. transfer coefficients on a basis of this sort. Too few people have been regarding the Reynolds number as being of value in the design of heat-transfer apparatus.

The Author. The paper deals solely with heat transfer by conduction, as affected by forced convection.

Radiation was not dealt with as it is properly a separate subject. However, it may be said in this connection that the author has been able to check boiler tests quite closely by deducting the radiation from the total heat generated and assuming that the remainder determines the furnace temperature. This is in accordance with the old saying, "We cannot eat our cake and have it." Since radiation is instantaneous and combustion requires an appreciable, although very minute, interval of time, heat radiated cannot appear as sensible heat of the gases. If it did we would have accounted for more than the total heat generated. It has often been noted that furnace temperatures as measured never quite reach the calculated. If the deduction is made for radiation in this manner, the results will check quite closely. Since the radiation depends upon the furnace temperature, this cannot be calculated directly, but may be determined by trial and error or by plotting a curve. No doubt there is some radiation beyond the furnace proper, but this is small compared with the heat conducted.

Mr. Fry questions the convenience of this formula for determining the final temperatures, given the initial, flow rates, and other conditions of a given exchanger.

This is a special case and by no means as simple as the conventional problem which is merely to determine the amount of surface, size and length of tubes, and number in multiple, necessary to affect a given heat exchange. The properties of the fluids are determined by taking the mean between the inlet and outlet temperatures, then the mean between this temperature and that of the tube wall. The final mean determines the fluid properties. In the case of viscosities which vary greatly, a preferred method is described in the text. To solve Mr. Fry's problem it would be necessary to resort to the method of trial and error. He suggests the Hedrick-Fessenden type of formula as better adapted to a problem of this sort. As the author recalls it, this is of the form $T_1/T_2 = (T_3/T_4)^{\alpha}$ where $\log \alpha = Mx$, $M$ being an empirical constant and $x$ the length. Several years ago the writer endeavored to check by means of this formula some tests upon an oil to oil exchanger in which a number of intermediate temperatures had been obtained. Determining $\alpha$ from the four end temperatures and calculating intermediate values these did not check well with the observed values. Curiously enough, when fluidities were substituted for temperatures, the check was quite close. The fluids were crude oil and residuum, where viscosity plays a very important role. It is possible that a formula of this type might be quite useful in determining intermediate temperatures and in extrapolating for additional length. Whether it would be practical for exchanger design, the writer is not prepared to form an opinion. It might prove to be as difficult to determine the coefficient $M$ for different fluids and flow rates, as to calculate $U$.

Mr. Pigott also brings up an important special problem, namely that of condensing vapors. Here the conductance depends mainly upon a film of condensate clinging to the tube wall. As it is impossible to determine the velocity of this film, the subject cannot be treated by the above formula. McAdams and Frost found that the conductance depended upon both the conductivity and viscosity of this film. In the case of steam condensers, the problem is still further complicated by the presence of air. For this case Orrok's empirical formula[23] is probably the most reliable. In condensing gasoline, particularly natural gasoline, a large amount of non-condensible gases greatly affects the rate. Very little work has been done on determining this effect.

The author fully agrees with Professor McAdams that more work should be done on investigating the effect of viscosity and how it should be averaged. The author did not publish the chart by which the viscosities used in Tables 2 and 3 were obtained because it was not believed that these tests were sufficiently reliable to justify any but the most general conclusions. It is well known among oil men that oils of the same gravity from different fields may have quite different viscosities. This applies even to oils from different wells in the same district. The author also plotted the tests in Tables 2 and 3 using body viscosities, and obtained not only different curves for heating and cooling, but greatly differing curves for heating light and heavy oils. This would necessitate two complete families of curves, involving an elaborate series of tests, and would be wholly empirical. Hence it would not indicate a general law for forced convection. In regard to the Babcock & Wilcox tests, one cannot read the description of these tests without being impressed by the comprehensive nature and range of the tests and the elaborate precautions taken to insure accuracy. To question them would require a rather overwhelming burden of proof.

As to radiation, Ray and Kreisinger[24] found that in a Heine boiler the ratio of heat radiated to that conducted was from 3 to 15 per cent. If we allow for the radiation in the furnace proper, this 3 to 15 per cent is practically covered and the remainder of the heat transmitted may be safely assumed to comply with the Nusselt-Rice equation.

It has by no means been the idea of the author that the subject was finished and the book closed. On the contrary the purpose of the paper has been mainly to collect and correlate the progress so far made and to prove, if possible, that this rests upon a solid foundation. If this has been accomplished, further progress, which is inevitable, will be rather in the line of refinements making for greater accuracy.

# The Gas Lift as Applied to Oil Production

## Description of the Central-Plant System—Results of the Gas-Lift Process—Factors in Operation—Limitations of the Process

By F. W. LAKE,[1] BREA, CALIF.

The gas lift, as a method of producing oil, has reached a high state of development, and its application has been widespread during the last two years. In theory and practice it is similar to the operation of natural flowing wells. It is a development of the air-lift method of raising water, applied under different conditions and hence necessitating a different set of principles and methods of operation. This is due not only to the differences in the physical characteristics of air and water and gas and oil, but also to the essential objectives of the two operations. Water air lifts are designed for the delivery of a quantity of water in such a manner that the power efficiency is as high as possible and hence the cost of lifting near to or less than that incurred by mechanical pumping. Oil gas lifts are designed not for a high power efficiency but for obtaining the maximum net income from a producing property. For 25 years previous to recent developments, the gas lift had been attempted infrequently, but with few satisfactory results which could not be duplicated. Recent experimental work, however, has been conducted in such a manner that the underlying principles have been discovered and the process can now be applied with precision.

### The Central-Plant System

As usually applied in the most efficient systems, dry gas is compressed to the required pressure at central compressor

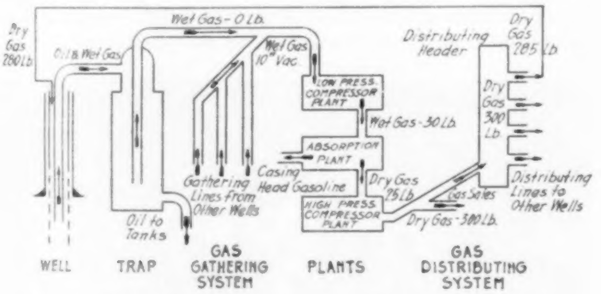

Fig. 1 Flow Diagram, Gas-Lift Central-Plant System

plants and is then pumped to a centrally located distributing header or manifold. If certain wells require pressures widely different from the majority, these should be taken into consideration in designing the compressor plant so that a certain volume at one pressure may be pumped to the main distributing header, while a different volume at a different pressure can be pumped to distributing headers serving the odd wells separately. From the distributing header, individual lines are run to each well, and by the application of meters and valves on each line the required volume of gas can be continuously delivered to each well on the system from the central point. The gas is usually introduced into the casing head between the casing and tubing, and is pumped down to the bottom of the tubing. As it enters the tubing it mixes with the oil to a certain extent and is also dissolved in the oil. No mixing device, flow piece, or jet is necessary. Usually a few perforations are drilled in the tubing a few feet from the bottom to allow the gas to enter the tubing through an opening separate from the oil opening without causing any unnecessary back pressure. The oil-gas mixture rises in the tubing, similar to natural flowing conditions, and enters the trap or separator. Here the oil and gas are separated, the oil flowing to the flow tanks and the gas entering the gathering system.

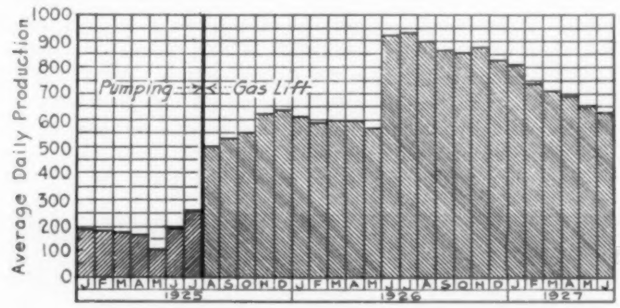

Fig. 2 Production-Decline Curve, Brooks No. 2 Well, Huntington Beach Field, Union Oil Co. of California

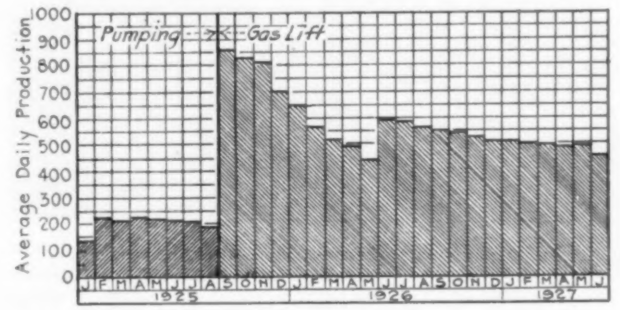

Fig. 3 Production-Decline Curve, Chapman No. 6 Well, Richfield Field, Union Oil Co. of California

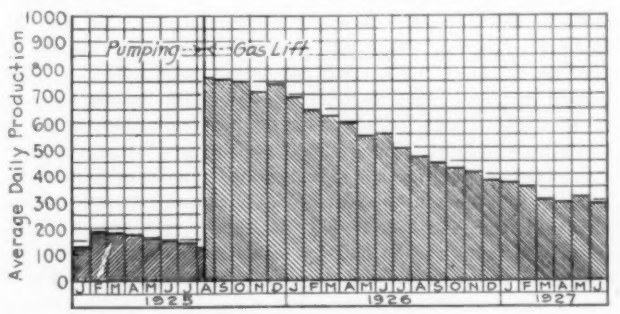

Fig. 4 Production-Decline Curve, Morse No. 3 Well, Richfield Field, Union Oil Co. of California

Through the gathering system, the gas is pulled in from the various wells by a compressor plant and is delivered to an absorption plant where the gasoline content is removed. The dry gas is then delivered to the gas-lift compressor plant, the excess being sold or used as fuel on the lease. The gas-lift system is thus a closed circuit, the gas being alternately compressed and ex-

[1] Superintendent of Production, Union Oil Co. of Calif.

Presented at the Seattle Meeting, Seattle, Wash., August 29 to 31, 1927, of The American Society of Mechanical Engineers, 29 West 39th St., New York, N. Y.

panded as it does the work of lifting the oil. Fig. 1 is a flow diagram of the gas-lift central-plant system.

In the event of a leaky casing or low-pressure sands, the process can be reversed and the gas pumped down the tubing, the oil-gas mixture then flowing up between the casing and tubing. This practice is not advisable unless conditions necessitate its use, as it is usually low in efficiency and does not give the maximum results possible.

### Results of the Gas-Lift Process

One of the results of the application of the gas lift to oil production is the increased daily rate of production. This increase may vary from a small percentage to as high as several hundred per cent. Fig. 2 shows a production-decline curve of the Union Oil Company's Brooks Well No. 2 in the Huntington Beach Field. This well was completed at a depth of 4545 ft. in November, 1922, with an initial production of 2000 barrels of oil daily. It had declined to less than 200 barrels daily in the first half of 1925. The first gas-lift installation raised the production to 600 barrels daily for nine months. At this time a change in the operation was made with the result that the production increased to more than 900 barrels daily, from which point the well has

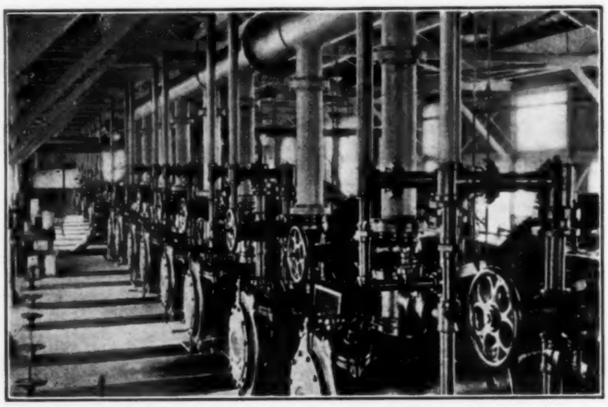

Fig. 5 Typical Compressor Plant, Compressor End

(Nine compressors direct connected to 165-hp. gas engines are employed. Five are used to pull in the gas from the field as low-pressure compressors operating from 10 in. vacuum to 30 lb. gage, and four are used as high-pressure compressors boosting the gas to pressures of from 25 to 200 lb. per sq. in. for gas-lift operations.)

had a gradual decline to the present. Fig. 3 shows a similar curve on the Union Oil Company's Chapman Well No. 6 in the Richfield District. This well was completed at a depth of 4147 ft. in May, 1921, with an initial production of 2100 barrels daily. It had declined to about 200 barrels daily in the first half of 1925. The gas-lift method raised the production to 850 barrels daily. The decline was more rapid than necessary, due to the original method of operation. In June, 1926, when a change was made in the adjustment of the well, the production increased from 440 barrels daily to almost 600 barrels daily. From this point the decline has been commensurate with the decline in reservoir pressure, which is to be expected. Fig. 4 shows the production-decline curve of the Union Oil Company's Morse Well No. 3 in the Richfield District. This well was completed at a depth of 4340 ft. in April, 1922, with an initial production of 4300 barrels daily. It had declined to an average of 150 barrels in the first part of 1925. The installation of the gas-lift process raised the production to more than 750 barrels daily, from which point the well has had a slow decline to the present. These curves illustrate a few of the increases in the rate of production which are possible in certain instances by the proper installation of the gas-lift process. More important but not quite as apparent is the increased ultimate production resulting from the gas-lift process. Since gas is recognized as one of the essential factors in bringing the oil from the sand interstices to the well, it follows that any decrease in the ratio of formation gas produced per barrel of oil will result in a corresponding increase in the ultimate recovery from the well. The application of the gas-lift process usually results in a lower gas-oil ratio, the extent of which depends on the efficiency of the former production method. For an average of the results so far obtained, it seems that the gas-oil ratio can be reduced at least 25 per cent. An additional factor tending to increase the

Fig. 6 Typical Distributing Header Handling 25 Gas-Lift Wells

ultimate recovery from a well is the elimination of all moving equipment from the hole. This reduces the liability of parted tubing and the resulting fishing jobs which more than once have meant complete abandonment of the hole. The increased daily rate of production tends toward an increase in ultimate recovery

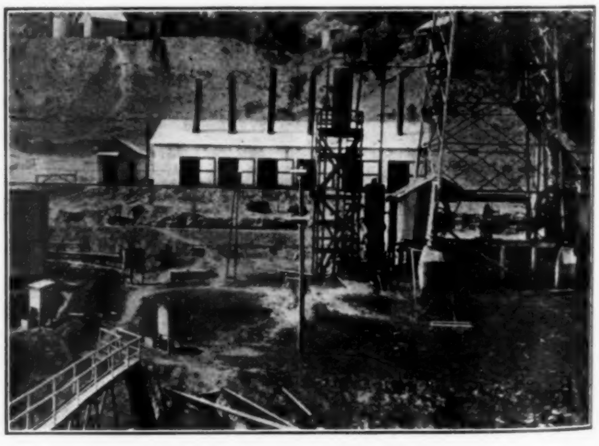

Fig. 7 Typical Connections and Relative Locations of Well, Trap, and Tanks for Gas-Lift Hook-Up

as a more rapid delivery of oil is effected, with an equal or less hazard of collapsed or deteriorated casing.

Under proper application of the gas-lift process, a greater net return is possible. This is due not only to production increases but also to other conditions resulting from the process. The central power system results in lower operating costs, particularly from a labor-saving standpoint. The elimination of individual power plants and the power centralization permits better care of machinery, with subsequent decreases in repair and maintenance costs. With no pumping equipment in the hole, the necessity

for well-pulling labor is almost eliminated. In addition to these factors, the increased rate of production means a more rapid return on the investment in a property. As a result of the application of the gas-lift process, the net income from a property should be appreciably increased and should be realized in a shorter period of time.

### Factors in Operation

The control of the process lies in the tubing diameter and depth, the gas volume circulated, and the pressure held back on the producing sand, which latter varies with these factors and also with the tubing-head pressure. Oil and gas exist under pressure in the interstices of the producing horizon, and the rate of extraction is inversely proportional to the existing back pressure in the hole opposite the producing horizon. Hence for the maximum daily production the effective back pressure should be a minimum opposite the most productive portion of the producing horizon. The effective back pressure at the bottom of the tubing is equal to the sum of (1) the tubing-head pressure, (2) the pressure drop due to friction of the oil-gas mixture in flowing from the bottom of the tubing to the top, and (3) the pressure due to the difference in elevation of the bottom and top of the tubing with the static head of the oil-gas column. Where there are no appreciable losses of gas due to casing leaks or low-pressure sands, the effective back pressure at the bottom of the tubing is also equal to (4) the casing-head pressure, less (5) the pressure drop due to friction of the gas flowing down the annular space between the casing and tubing from the surface to the bottom of the tubing, and plus (6) the static head of the gas between the casing and tubing. If the tubing extends lower than the top of the producing horizon, items (5) and (6) are influenced by the amount of oil entering the well above the bottom of the tubing and moving down with the gas to the lower end of the tubing. Thus the minimum back pressure occurs at the bottom of the tubing.

The most efficient tubing diameter is dependent on two factors, namely, friction and slippage. Friction is inversely proportional to the tubing diameter, while slippage is directly proportional to the tubing diameter. For maximum results, that diameter should be used which will give the minimum friction with the minimum slippage, consideration being given to the relative volumes of oil and gas to be handled and their respective physical properties.

With respect to the tubing-head pressure, all connections, the trap setting, the tank location, and the trap pressure should be such that the minimum tubing-head pressure is obtained. Pressure drop due to friction should be reduced to a minimum. Trap and tank locations should be so arranged that gravity flow is possible. Trap pressures should be reduced to as near atmospheric pressure as possible. The relation between a low tubing-head pressure and the minimum back pressure is evident, and proper attention to these details will result in more efficient gas-lift operation.

The volume of gas circulated should be controlled so that the minimum steady pressure is obtained. Lack of gas causes heading or surging with the average back pressure higher than necessary. Too much gas, although the pressures are steady, crowds the system with gas and results in a higher back pressure than necessary with a corresponding decrease in production.

Thus tubing-head pressure, tubing diameter and depth, and the gas volume circulated are the factors permitting adjustment and upon which the efficiency and results of the gas-lift process are dependent.

### Limitations of the Gas-Lift Process

While exceptional results are possible from a proper application of the gas-lift process in certain instances, still it is not without definite limitations. Where water in sufficient quantities is produced with oil of such physical characteristics that tight emulsions tend to be formed, gas lift may not be economical, due to the high cost of treating the emulsion. This limitation is dependent on the physical properties of the oil and relative quantities of oil and water produced. Under some conditions, the advantages resulting from gas lift may be more important than the disadvantages resulting from the formation of emulsions. This is an economic problem peculiar to local conditions.

In areas of low rock pressure the continuous gas-lift system may not be economical. If the minimum pressure for continuous gas-lift operation causes a back pressure on the producing formations in excess of that which exists by reason of the fluid head in the hole during pumping operations, the production by gas lift will be less than that produced by pumping. Intermittent gas lift, where the fluid is blown out of the hole at periodic intervals, may be applied and some of the advantages of the continuous gas-lift system obtained. Experimental work is now being carried on for the development of a stage gas lift which will reduce emulsion difficulties and prove more efficient than the intermittent gas-lift system, particularly in application to production from low-pressure horizons.

# The Degree-Day Method of Fuel-Consumption Analysis

## Its Application to Fuel Deliveries for Domestic Oil Burners

By W. R. Abbott,[1] Louisville, Ky.

The circumstances leading up to this particular application of the degree-day method of fuel consumption analysis are as follows:

The company with which the author is associated is engaged in the refining and marketing of various petroleum products and one of its problems is the creation of a local fuel-oil market and the subsequent permanent retention of the business so developed.

The first step was to engage in the sale, installation, and servicing of oil burners with particular attention to fully automatic domestic equipment.

After a survey has been made of the existing or proposed heating equipment we recommend (in the event conversion to oil is justified) such tankage, oil burners, control equipment, etc., as the company has found from its experience to be most suitable. This recommendation is made in the form of a definite proposal covering a completed job at a lump-sum price. The company guarantees complete satisfaction as to capacity of equipment installed, automatic operation, and dependability. Night-and-day service is available, and in the event the customer chooses to purchase his fuel oil from the company, this service is without charge. The company obtains customers' permission to deliver fuel when and as needed, and assumes full responsibility for the prevention of "empty tankage" service calls.

The result, from the customer's point of view, is that he is actually purchasing automatic heat as free from care on his part as is his electric light, telephone, gas, or water service. The result, from the company's point of view, is that it develops a tank-wagon fuel-oil business which is of a more permanent nature than that of the average petroleum product marketed, and does so with a minimum of direct sales effort.

The company first applied the degree-day method of fuel consumption analysis to the invesigation of complaints as to excessive fuel costs. Later it was used in checking up the results obtained from various changes made to original installations for the purpose of lowering fuel costs. Then it was applied to checking efficiencies of oil-fired heating plants, and lastly to the subject under discussion, fuel-oil deliveries.

The ideal in tank-truck delivery is:

1 Full tank-truck dumps
2 Complete freedom from idle or stand-by time
3 Continuous operation of rolling equipment.

It is necessary to know, therefore, exactly when a tank is down to the point that it will permit a full tank-truck dump, and it is necessary to know when it will be empty if the delivery is not made. The interval between these two is the company's delivery margin as to time.

The company's procedure to obtain this information without periodically gaging each and every tank is as follows:

The daily mean temperature is obtained from the United States Weather Bureau and what is termed a "Degree-Day Log," Fig. 1, is compiled from this information.

Column 1 is the date.

Column 2 is the mean temperature in degrees fahrenheit.

Column 3 is difference between this mean temperature and 70 deg., and represents in degree-days the heating load for this particular day. The term "degree-day" is, as its name implies, the product of two quantities, temperature and time—one degree fahrenheit and one twenty-four-hour day. We assume 70 deg. as

| DATE | MEAN TEMP | DEG-DAYS | TOTAL TO DATE | DATE | MEAN TEMP | DEG-DAYS | TOTAL TO DATE | DATE | MEAN TEMP | DEG-DAYS | TOTAL TO DATE | DATE | MEAN TEMP | DEG-DAYS | TOTAL TO DATE | DATE | MEAN TEMP | DEG-DAYS | TOTAL TO DATE |

Fig. 1 Degree-Day Log

the average temperature maintained inside of the building heated.

Column 4 is the total to date of degree-days which have elapsed since the beginning of the heating season.

The entries in the log shown in Fig. 1 submitted herewith are for the heating season of 1927–1928.

It has been found that *within the limits of the Company's requirements* the fuel consumption for a given heating plant is in direct proportion to the elapsed degree-days. A job constant $K$ is therefore obtained by dividing the fuel consumed in gallons on any particular job by the degree-days which have elapsed during the period in question, and this has been found to be a convenient expression of the fuel-consuming characteristics of this installa-

Fig. 3 Computation Sheet

tion. This constant $K$ is worked out for every job each time a fuel delivery is made. On the Customers' Card, Fig. 2 (one for each installation), is entered the necessary information and calculations to obtain this job constant. Fig. 2 is a continuous period-by-period record of the fuel consumed on this particular job. An explanation of the entries follows.

Column 1: Starting date of period under consideration.

Column 2: Degree-days corresponding to above date (from Fig. 1, col. 4).

Column 3: Completion date of period under consideration.

Column 4: Degree-days corresponding to above date (from Fig. 1, col. 4).

Column 5: Difference between degree-days written in columns 2 and 4. This entry represents the degree-days which have elapsed during the period.

Column 6: Gallons in storage at beginning of period. (A gage-stick reading obtained from drivers' delivery ticket.)

Column 7: Deliveries during period.

Column 8: Total of columns 6 and 7.

Column 9: Gallons in storage at end of period. (A gage-stick reading obtained from drivers' delivery ticket.)

Column 10: Consumption in gallons during the period. (Entry in column 8 less entry in column 9.)

Column 11: Job constant $K$ obtained by dividing gallons consumed (column 10) by elapsed degree-days (column 5). This is in terms of gallons per degree-day.

Column 12: Job constant $K$, which is in terms of gallons per degree-day per unit load. The unit load assumed is 1000 sq. ft. of steam radiation or its equivalent. In the upper right-hand corner of each card is entered the load on the boiler together with this equivalent unit load, designated as $C$. The entry $K'$ is obtained by dividing job constant $K$ by equivalent unit load $C$.

The constant $K'$ is unnecessary as far as fuel deliveries are concerned, but is important as an index of the overall efficiency of the plant and for comparing fuel consumption of plants which vary in size and manner of heat distribution. A study of the constant $K'$ is of interest in evaluating the various types of building construction, insulation, weather strips, etc.

A comparison of the job constant $K$ with preceding ones is an index of the efficiency of this particular installation during the period as compared with previous periods. Normally these job constants will vary only a few per cent from the seasonal constant, and abnormal variations are immediately reported to our service department. In this manner inefficient operation due to burner equipment's getting out of adjustment is subject to correction before it has become serious from a fuel-consumption point of view, and the results of these corrective measures is immediately known in terms of gallons consumed per degree-day. Fig. 2 gives duplicates of two cards picked at random from our files.

The Computation Sheet shown in Fig. 3 is a tabulation of the daily computations. Actual entries are shown with numbers inserted for names and addresses.

Column 1 is date of fuel delivery. This is the same as column 3 in Fig. 2 for the installation in question.

Column 2 is name of installation.

Column 3 is the job constant $K$ and is taken from Fig. 2, column 11.

Column 4 is gallons in storage after delivery has been made. This entry is the same as in column 9 of Fig. 2.

Column 5 is the degree-days in storage, and is the stock of fuel oil on hand expressed in degree-days rather than gallons. The entry is obtained by dividing the gallons in storage (col. 4) by the job constant $K$ (col. 3).

Column 6 is the elapsed degree-days from beginning of season

to date, and is obtained from degree-day log, Fig. 1, column 4.

Column 7 is the sum of the entries in column 5 and column 6, and represents the "empty tank" point in terms of elapsed degree-days (column 4, Fig. 1). In other words, there would be a run-out of oil on the day in which the total elapsed degree-days from October 1 equals the entry in column 7.

Column 10 is this "fill point" in terms of elapsed degree-days from the beginning of the season. It is found by subtracting entry in column 9 from entry in column 7. A 700-gal. delivery could be made then on the day in which the elapsed degree-days from October 1 (Fig. 1, col. 4) equals this entry (col. 10).

It is now known when any tank will be empty and when it may

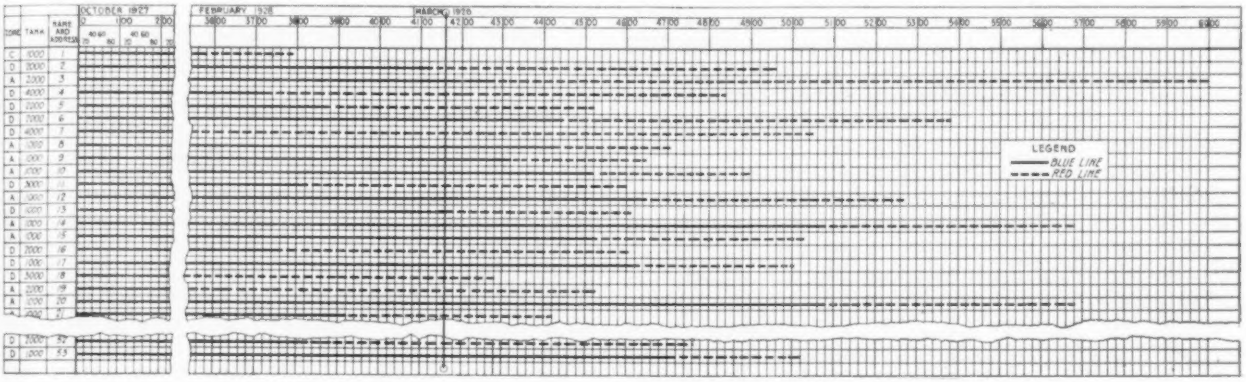

Fig. 4 Wall Chart

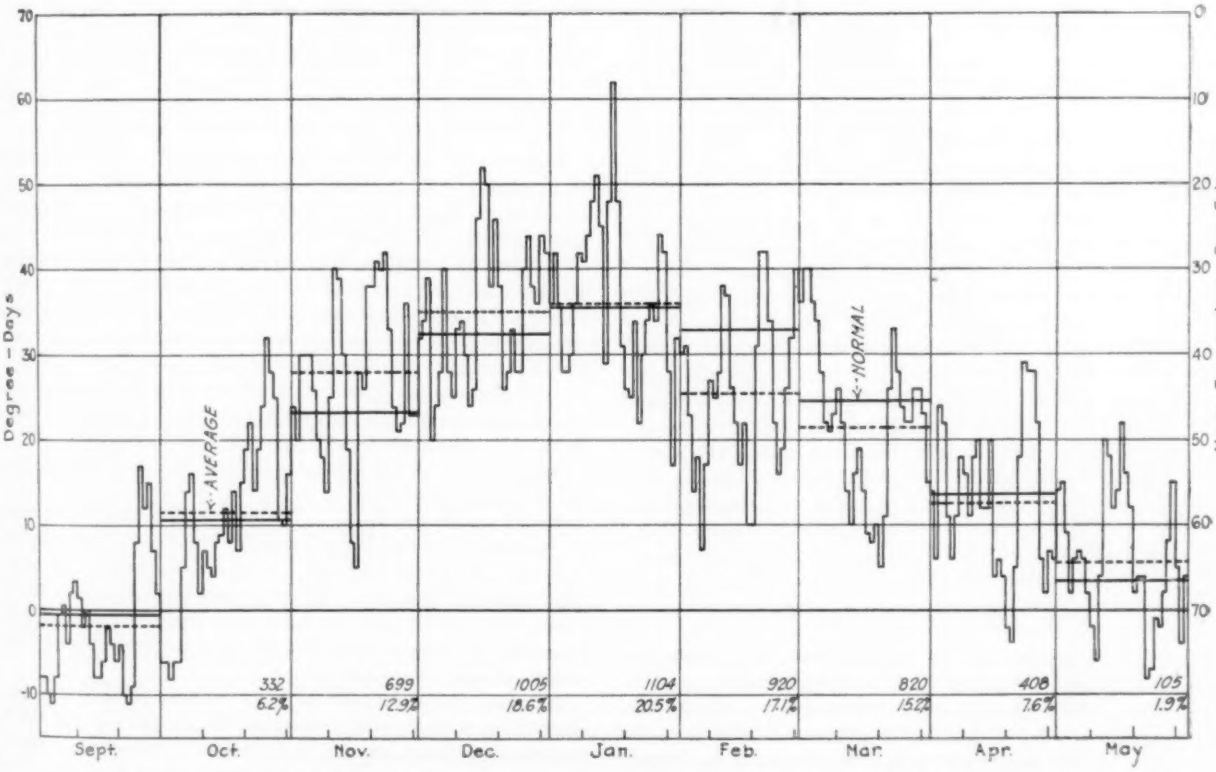

Fig. 5 Chart Showing Relation Between Mean-Temperature Daily Fluctuations and Monthly Averages and Corresponding Degree-Days

Column 8 is the period expressed in gallons which exists between the possible full tank-truck dump point and the empty point. Seven-hundred-gallon deliveries are assumed as standard and the entry in this column, "fill point," is the capacity of customers' tank less 700 gal.

Column 9 is the same period expressed in degree-days and is obtained by dividing gallons in column 8 by the job constant of column 3. It is the degree-day interval which exists between a possible "fill point" and the "empty point."

be filled. The wall chart shown in Fig. 4 is the graphic representation of the fuel-delivery situation. It is posted daily and is the sole source of information for the routing of truck deliveries.

Fig. 4 is ruled vertically and horizontally. The horizontal lines represent installations, and the customer's name and address is inserted alphabetically at each end of the line, together with tankage and delivery zone. The vertical lines are elapsed degree-days from the beginning of the heating season and in the full-size chart are to the scale of 100 degree-days per inch, with the

zero at the left and 6000 degree-days at the right. The average season in our territory contains 5390 degree-days. A vertical guide is moved in a horizontal direction progressively from left to right each day a distance equal to the degree-days corresponding to that day and obtained from column 3 of the degree-day log shown in Fig. 1.

Its position at any day during the heating season coincides exactly with the total elapsed degree-days as entered in column 4, Fig. 1. Its position in Fig. 4 is for March 2 and represents 4162 elapsed degree-days.

The deliveries and tank gagings are posted daily on customers'

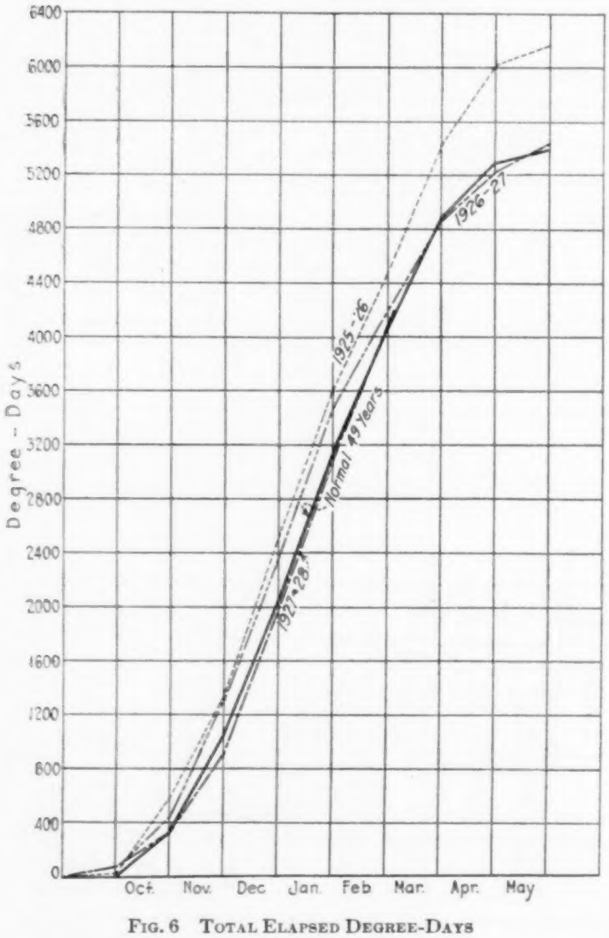

FIG. 6 TOTAL ELAPSED DEGREE-DAYS

cards, Fig. 2, computed on Fig. 3, and the results obtained are marked on the chart Fig. 4 in the following manner:

Centered in the horizontal space corresponding to the installation in question a red-pencil line is projected to the right and terminated at the degree-day point corresponding to "empty tank" conditions, column 7, Fig. 3. A blue-pencil line is drawn in a similar manner terminating at the degree-day point indicated in column 10, Fig. 3, as the "fill point." This blue line covers and obliterates the red line underneath so that the result is a blue line extending to the "fill point" and a red line the remainder of the space to the "empty point." When the traveling guide leaves a blue line and is traversing its extension in red, that particular installation may be supplied with oil in a full tank-truck delivery, and the length of the red line is indicative of the margin which exists between "fill point" and "empty point."

With red and blue lines properly drawn opposite each installation, it is possible to determine by inspection every possible delivery. Knowing the round-trip time for each installation, a schedule is worked out in advance for each tank truck and maximum economy in truck operation is facilitated.

Fig. 5 is a graph showing:

1 Daily fluctuation of mean temperatures and corresponding degree-days for the 1926–27 heating season. (Light full line)
2 Monthly average mean temperatures and corresponding degree-days for the 1926–27 heating season. (Heavy broken line)
3 Monthly average mean temperatures and corresponding degree-days for normal season which is the average of 49 years of weather records. (Heavy full line)

The mean temperature vertical scale is indicated on right margin of the chart, and the degree-day vertical scale on the left.

Time in days and months is plotted horizontally, with the beginning of the heating season at the left.

The total monthly degree-days and its percentage of the total for the season 1926–27 is tabulated in the monthly space under the base line.

Fig. 6 is a graph of total elapsed degree-days.

The time is plotted horizontally.
The total elapsed degree-days from Fig. 1, column 4, are plotted vertically.
The normal (49-year average) season is indicated by a heavy full line.
The seasons of 1925–26 and 1926–27 as well as the 1927–28 season to date are plotted in broken lines.

Posted up to date at frequent intervals, this graph is of value in indicating whether the fuel-delivery demands are running ahead of or lagging behind the normal demand. At just this season of the year (March) the company is making every effort to regulate deliveries so that customers will have a minimum gallonage in storage on June 1 to carry over through the summer season. An empty tank on that date is its goal, but it is not the company's practice to encourage broken tank-truck dumps to attain this end.

Arrangements are made with customers to fill their storage tanks at the company's convenience during the summer months so that the season starts with customers' tankage filled.

Briefly outlined, the following are the various applications of the foregoing information:

*Peak Fuel-Delivery Loads.* The sum of all of the job constants $K$ multiplied by the daily degree-day load gives the daily fuel consumption. Deliveries must of course be geared up to the peak loads of December, January, and February, and the information which is now available simplifies the problem of determining at frequent intervals the relation between total consumption and total deliveries.

Knowing the summation of job constants $K$ on installations already in service, and estimating the summation for the installations sold but not yet in operation, the total gallonage for the season can be predicted very closely, and from Fig. 5 the distribution of this gallonage by months can be estimated. Tank-truck equipment necessary to handle this business may be arranged for and the necessary advance storage of fuel oil anticipated. In estimating the job constants $K$ for installations not yet in service, the installed radiation, estimated equivalent unit load (Fig. 3), and an assumed $K'$ are used as a basis.

*Bulk-Station Location.* The company has considerable suburban territory which is beyond the limits served by the local gas company. A large percentage of the homes located in this territory may be listed as Class A prospects for domestic oil heating equipment. At the present time there is located in the

area a considerable portion of the company's domestic fuel-oil business, and it so happens that in order to make these deliveries the trucks have to traverse downtown streets subject to serious traffic congestion during business hours.

It is proposed to install bulk storage as nearly as possible to the "center of gallonage" of the area referred to. From this storage delivery trucks of 700 gal. capacity will be operated. (The 700-gal. limitation is due to limit loadings on private drives.) To this storage maximum-capacity tank trucks will be operated during the hours which are free from city-traffic delays. On the company's installation map is located accurately every job. The area in question is outlined and each job constant $K$ inserted in the circle representing its location geographically. The sum of the job constants multiplied by the yearly average degree-days, 5390, is the gallonage to be arranged for. Its fluctuation during the year can be obtained from Fig. 5 and the "center of gallonage" or theoretically perfect location of bulk storage computed as a "moment" problem, the factors involved being $K$ (gallons per degree-day) and distance (in miles). The estimated amount of future business must of course be taken into consideration in this survey.

*House Heating and Domestic Water Heating.* In installations beyond the gas-service areas, the company automatically heats the domestic water as well as the residence, and generally with the same oil-burner equipment. This domestic water-heating load is fairly constant and does not fluctuate materially with the outside temperature. The job constant $K$ then must be separated into two parts, one, a domestic-hot-water factor, which is constant, and the other, a heating factor, which fluctuates with the outside mean temperature. The former is determined during the summertime when there is no heating load and is in terms of gallons per day. This quantity multiplied by the days in the period in question gives a quantity which must be subtracted from the gallons consumed, column 10, Fig. 2. The job constant $K$ then found by dividing the entry in column 10 by the entry in column 5 is for the heating load only. In other words, it is possible at all times to make a separation in the fuel consumed with an accuracy within the limits of the company's requirements.

*Sales.* The whole scheme of operation is capitalized in sales work in the following manner:

1 The prospect is offered an opportunity to purchase automatic heat and not just an oil burner.
2 There is an undivided responsibility resulting from a single organization's installing the equipment, servicing it, and supplying the fuel which it is found meets with favor in the mind of the prospect.
3 The prospect is well protected from the hazard of purchasing what might later on become "orphan" equipment.
4 The service organization is financed through the saving effected in direct fuel-oil sales effort. In other words, the service department must be operated for what it would cost to sell the fuel oil by means of salesmen and advertising. In self-protection it is necessary to keep this service cost as low as possible, and in so doing the customer is certain to receive a quality installation as to both material and workmanship. For the same reason it is necessary to be very particular as regards the uniformity and specifications of the fuel supplied.

This degree-day method of fuel-consumption analysis has its limitations, and what has been outlined in this paper may be subject to criticism from a purely engineering standpoint; within the limits of the company's requirements, however, it gives entirely satisfactory results and is easily understood by the layman and the operating personnel.

# Discussion

A. B. Morgan.[2] The application of the degree-day method of estimating fuel consumption to fuel-oil deliveries, as covered in the paper, is most interesting, and there is no reason why it should not be most practical. The degree-day is a comparatively new unit which has come into national prominence within the last ten years. It was originally used in connection with the estimating of total fuel consumption, and served as a very reliable basis for comparing similar installations located in different parts of the country. When used in this manner the mean monthly temperatures were usually sufficiently accurate to yield comparable results. The possibilities of the new unit were further developed by P. E. Fansler of the *Heating and Ventilating Magazine*, who originated an "iso-degree-day" chart which was based on daily mean temperatures. This iso-degree-day chart divided the United States into sections, with comparable total degree-days. Another very important development in this line was the survey made by the American Gas Association which resulted in the establishment of a mean outside temperature of 65 deg. as the temperature at which the average person would operate some form of heating device if automatic heat were not provided.

The relation of the amount of fuel, either oil, coal, gas, or electricity, to the number of degree-days has been repeatedly established and checked for domestic installations. It has even been carried to such a point that it is now indicated that the amount of electricity required to run the motor which operates an oil burner is also proportional to the number of degree-days in domestic establishments.

Even after considering the marked expansion in the use of the degree-day during the past ten years, it is apparent that only the surface has been scratched. This method should be given consideration by all who have problems to solve which involve space heating by any known method.

In the oral discussion which followed the reading of the paper, the use of the degree-day in connection with domestic establishments was not questioned to any great extent, as it was practically obvious that once the particular constants had been established the amount of fuel which would be required by any installation would, under ordinary conditions be practically proportional to the number of degree-days. The practice of using the current daily temperature reports will of course give results which are much more accurate than those based on the normal mean monthly temperatures. A further refinement which might be made where the utmost accuracy is desired would be the use of the temperature or temperatures at which the installation is actually maintained instead of an average temperature such as the 65 deg. determined by the A.G.A. However, it was interesting to note how closely the curves of the total number of degree-days followed each other for a normal year and the years 1925–26, 1926–27, and 1927–28 for the city of Louisville. The practice followed by the author's company of checking the constants at each delivery of oil is an extremely good one, inasmuch as it gives a definite indication of the condition of the particular burner.

Theoretically the degree-day method should be applicable to all types of installations. However, in the case of the hotels, office buildings, and apartment houses there are certain features which must be considered in addition to those of the domestic establishments. For example: in a hotel which is heated by steam at a given pressure, there is a certain amount of fuel required to bring the steam up to that pressure and also to supply process steam for hot water, cooking, etc. Whatever fuel is

[2] Assistant Engineer, National Electric Light Association, New York, N. Y.

necessary to take care of the steam required for process work and losses which are due to the maintenance of fire and pressure so that immediate heat may be supplied, should be considered aside from the fuel which is actually used in heating the rooms. It is therefore obvious that a certain amount of fuel will be required before any heat is furnished to the building. In other words, the total amount of fuel is not directly proportional to the number of degree-days. However, the amount of fuel in excess of that required for the various processes and losses would be proportional to the number of degree-days; this would give a curve which would be in the form of $y = a + (f)\,x$ instead of, as in the case of domestic establishments, $y = (f)\,x$, where $y$ = amount of fuel, $x$ = degree-days, $a$ = constant—dependent on losses and processes, and $(f)$ = function—relation of degree-days to fuel used for space heating.

The preceding paragraph was based on theoretical premises, but recent tests which have been made by a company which supplies steam to hotels, apartments, and office buildings has demonstrated that this method checks fully as close as the simple method in the case of domestic establishments. In conclusion, it is clearly evident that the degree-day method of estimating fuel consumption is applicable to practically all types of service with a fair degree of accuracy. The only question is whether or not the desired information would warrant the necessary labor involved in applying this method to the more complex installations.

# List of A.S.M.E. Transactions Papers Published Since January 1, 1928

*BELOW is published a complete list of the papers which have appeared in the various sections of Transactions since January 1, 1928, together with references to the issues of "Mechanical Engineering" in which abstracts of them may be found.*

# Distillation and Fractionation in the Petroleum Industry

By H. R. Swanson,[1] New York, N. Y.

*In the author's opinion, with the efforts of refinery engineers in the direction of simplification of the distillation operation and equipment, the single-tower unit would seem to be the solution of a previously complex problem. Contingent matters which must be carefully considered are: (1) the selection of a simple, accessible, and practicable heat-recovery system, and (2) the simplest possible sealed piping arrangement.*

Realizing that increasing competition demanded a reduction of manufacturing costs, the refining industry has been one of the outstanding fields of engineering development during the past few years. This development has of course been apparent in every phase of refining, and we now find a rather general application of improved distillation methods, vapor-phase treating, and contact clay treatment of lubricating oils, in addition to remarkable strides in the field of cracking.

Until quite recently only a few tube stills of the old conventional type were in operation as preheaters, and the general refinery distillation was conducted in shell stills with only primitive tower equipment. The condition of this phase of the refining operation can be taken as indicative of the general condition of the industry when competition was not keen and the margin between raw materials and marketable products was relatively large.

In a paper published in the engineering issue of *National Petroleum News*, David E. Day has stated that, to improve profits from its operation, the refinery must either increase its returns as far as products are concerned, or decrease its costs, or both without sacrifice of quality. Further analysis develops the extreme importance of yields in addition to fuel, labor, maintenance, and chemicals for treating distillates.

It is readily apparent that the solution of this problem, as regards the important items determining the cost of refined products, rests upon the distillation operation. Yield, the most important factor, is controlled largely in the primary distillation unit. The use of a minimum of steam and the elimination of rerunning immediately reduce to a minimum both the direct and the auxiliary fuel. The selection of a simple, compact, soundly engineered, and properly constructed unit insures a minimum labor cost and low maintenance. The improved quality of products from the primary distillation unit cannot but decrease the chemicals and treating costs.

The primary distillation unit, which is obviously the most important phase of the refinery operation, is dependent upon the success of three steps: the heat-recovery system, the main heating unit, and the fractionating system. These three sets of equipment are quite inseparable in the study of a distillation unit and will be discussed somewhat individually but primarily as a complete unit from the standpoint of realization of yield, simplicity and practicability of arrangement, fuel efficiency, and investment. Inasmuch as the yield of products is of paramount importance, any arrangement which could be proposed must necessarily satisfy this requirement. It then becomes a problem of selection of the practicable arrangement.

Originally the tube still was considered a desirable adjunct to the usual shell-still battery, but not a necessity or an independent unit. This condition has entirely changed, and as a result the tube still is now generally recognized as the economical heating unit, not only for crude-oil distillation but for any refinery distillation operation. The increased experience gained by the tube-still manufacturer has contributed to the development of the tube still to a point where units of proper design are now operating with low excess air and resultant overall efficiencies approaching boiler practice.

With the application of fractionating equipment to the refining industry, there developed the logical discussion of the advantages and disadvantages of the various types of recognized countercurrent scrubbing devices. This trial period for the various types found application to shell stills particularly, and along with the widespread application of tube stills, the bubble tower has been quite generally accepted as being more economical as a result of the lower fixed charges and operating costs.

## The Bubble Tower

In consideration of the internal construction of a bubble tower, some important points might be mentioned. Many of the general principles of design, such as the influence of tray spacing, vapor velocity, etc., are generally recognized. However, present developments indicate perhaps too much emphasis has been placed upon submergence as governing contact, apparent velocity through the nozzles, or percentage of nozzle area as governing capacity, etc. The major contact between liquid and vapor for latent-heat interchange is unquestionably in the vapor space above the tray. Perhaps ample provision has not been made for the proper utilization of this ideal contact zone. The proper distribution of liquid and vapor and the elimination of entrainment are interdependent and demand careful consideration.

Several types of tray arrangement have been resorted to in an effort to insure distribution and contact. The true bubble-cap tray arrangements, however, resolve themselves into two general types:

1 The long rectangular nozzle with the long rectangular cap
2 The round nozzle with individual round, square, rectangular, hexagonal, or, in some cases, a long rectangular cap covering several nozzles.

The obvious difficulty encountered with the conventional round nozzle and individual bell cap, as usually arranged on the tray, is the short-circuiting of liquid across the tray, since no path of flow is defined. Such short-circuiting of the liquid inevitably results in unbalancing of the vapor flow, the major portion of the vapor going to the side of the tray where the liquid remains quite stagnant. A tray of this construction may be perfectly balanced if tested by air and water when no water or less than the operating liquid load is being delivered to the tray, but absolutely unbalanced with liquid flowing. In an effort to eliminate the possibility of the unbalancing difficulty, the long rectangular construction has been resorted to as shown in Fig. 1. These nozzles, with caps arranged for individual leveling, ex-

[1] Chief Engineer, Refinery Division, Foster Wheeler Corporation. Jun. A.S.M.E.

Presented at a meeting of the Metropolitan Section of the A.S.M.E., sponsored by the Petroleum Division, New York, March 6, 1928.

tend the full width of the tray from a distributing weir on one side to a retaining weir on the opposite side. The liquid delivered at one end of the nozzle follows a definite, unobstructed path across the tray. We have obtained the best results in practice with this type of tray construction. This problem of distribution is relatively simple in small towers and accounts for the apparent success of the conventional construction in the past,

FIG. 1 BUBBLE TRAY

but with the present demand for large units, the inherent advantage of the rectangular cap and provision for definite flow will be more pronounced.

The early application of bubble towers to the industry was on batteries of continuous shell stills which called for a relatively simple tower as a part of a complex unit, as viewed from the standpoint of multiplicity of control. The development of continuous tube-still distillation with all its advantages derived from the very short time the oil is under high temperature, in addition to the economies of operation and maintenance, made imperative the development of satisfactory fractionating equipment for large capacities. The natural tendency was in the direction of a step-up type of unit, which included a tube still and tower for each cut desired. Most of the early units were equipped with partial condensers, which only add to the difficulties of operation and control as compared with pumping back condensate. Fortunately the operation was applied to the production of light distillates only, with a fuel-oil residuum for market or for reduction to coke in the case of paraffin crudes to produce lubricating distillates. It is difficult to conceive of a more complicated set-up than would be necessary if the charge were reduced to an 8 to 10 per cent bottom for the production of the heavier distillates in this type of unit. Obviously, such a complex system with its numerous necessary points of control and duplication of equipment was difficult to synchronize, and particularly difficult to design and balance, except for one particular crude oil, without overdesigning every part for the maximum load condition dictated by various charging stocks. This method is also uneconomical because of the successive overvaporization required to effect fractionation. With this type of unit two salient advantages of modern tube-still installation, simplicity and flexibility, were not realized.

### Multiple-Tower Unit

Sometime ago the many advantages of single-flash over successive-flash vaporization were realized, and the trend was immediately in the direction of the single-flash operation. A paper by Leslie and Goode in the April issue of the *Journal of Industrial and Engineering Chemistry* summarizes very clearly the comparative results of a carefully conducted investigation of vaporization, which checks the results obtained in commercial installations during the past three years. Concurrent with existing practice the multiple tower unit, as shown diagrammatically in Fig. 2, without the heat-exchange flash tower, was the immediate result. The principle of partial condensation for the removal of latent heat at several points is illustrated. This method of heat removal might well be replaced by a plan incorporating a single point of latent-heat removal and arrangement for pumping back from the bottom of each tower to the top of the preceding, but has not been resorted to because of the complicated pumping operation. The outstanding disadvantages of the step-up unit, limited flexibility and complexity of control whether the partial condensation or condensate pump back principle was utilized, were inherited by this type of unit. Progressive steps have been made in the direction of combining some of these towers and arranging for side streams. The complete reduction to a low-bottoms product might be conducted in two steps only with a flash tower for each tube still and one side stream from each tower, but here we have a duplication of con-

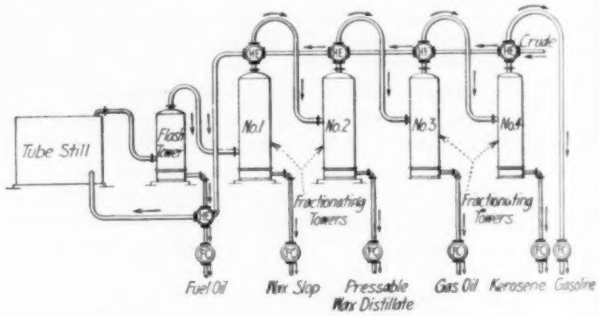

FIG. 2 SINGLE-FLASH MULTIPLE-TOWER UNIT

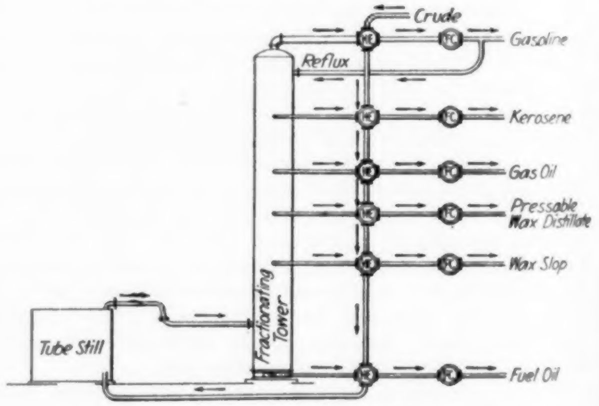

FIG. 3 SINGLE-FLASH SINGLE-TOWER UNIT

trol and lose the inherent advantage of single-flash vaporization in attempting to obtain a minimum of residuum or encounter the necessarily higher temperature for a given type of bottoms cylinder stock.

### The Single-Tower Unit

The next logical step is apparent—the development of a single-tower unit as shown on Fig. 3, which can be considered as derived by placing the series of towers one on top of the other. We can then utilize the condensate pump-back principle for each stream and take advantage of the gravity flow of reflux, eliminating the pumping difficulty except for the pump back to the top tray where the entire reflux liquid is originated. Such a

unit includes only the one source of latent-heat removal, and therefore a single opportunity for a vapor heat exchanger, all other exchanger units being for sensible heat only. The argument commonly voiced against this arrangement is the fact that the main source of heat exchange is at a relatively low heat head, requiring more surface, and because of the low entering vapor temperature the ultimate heat recovery is limited. To meet this argument we might consider the installation of heat exchangers for the condensation of the several streams at points intermediate to the top and bottom, as shown diagrammatically in Fig. 4. When distilling normal Mid-Continent crude oil at a temperature of 800 to 825 deg. fahr. with Navy gasoline from the top of the tower it is possible to recover by the first method about 35 per cent of the heat input of the tube still, and by the second method possibly 45 per cent. The complexity of the second arrangement indicates its impracticability; whereas the first is entirely practicable, simple of control, and flexible. To make the second arrangement capable of handling several crudes with varying yields of the several products would necessitate the overdesign of each intermediate partial condenser to care for the maximum possible cooling requirement, which immediately indicates that the argument of economy of heat-exchange surface is subject to question. Also, it might be noted that of course the whole 10 per cent extra heat recovery would not be realized because of the added stack losses, which would reduce this by about one-half.

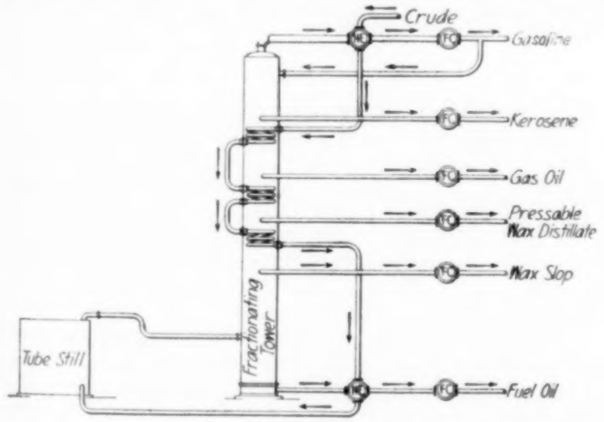

FIG. 4 SINGLE-FLASH SINGLE TOWER WITH INTERMEDIATE PARTIAL CONDENSERS

Obviously, the unit incorporating the single point of latent-heat removal possesses many advantages as compared to others. With a proper type of side-stream control, there remain only two important points of control for the production of any set of products, the tube-still outlet temperature and the top-of-tower vapor temperature. The first is easily controlled by hand regulation of firing with oil, gas, or pulverized fuel, provided the charging rate is maintained reasonably constant. Both are susceptible to the application of standard automatic control equipment.

Inasmuch as the size of the tower is dictated by the top heat load, this type of unit is extremely flexible. The ratio of the various streams may vary widely without affecting the operation or overloading any part of the unit while bringing the unit up to its top heat capacity, which with one set of products or a certain total vaporization may correspond to twice the throughput with another vaporization. It should be noted also that with the single set of heat exchangers, condensers, and coolers for the top vapor stream designed for the lowest anticipated outlet temperature at capacity, the same equipment will be in balance for any higher outlet vapor temperature.

As an example, a unit designed for, and operated with, a throughput of 5000–6000 bbl. of Oklahoma crude with the vaporization of 95 per cent, has also been operated as satisfactorily and efficiently with a throughput of 9000–10,000 bbl. of the same crude with the vaporization of 50–60 per cent. Obviously, the

Charge, 1900 bbl. per day; operating temperature, 725 deg. fahr.; process steam, 15 lb. per bbl. of charge.

Products: Top of tower, gasoline; side stream, kerosene and gas oil; side stream, wax distillate; side stream, slop wax; bottoms, cylinder stock.

| | Sp. Gr., A.P.I. | Viscosity at 100 | Flash, deg. fahr. | Fire, deg. fahr. | Pour |
|---|---|---|---|---|---|
| Slop wax.......... | 29.1 | 235 | 400 | 490 | 90 |
| Cylinder stock..... | 24.5 | 205 | 570 | 660 | 30 |

charge in each case contained the same percentage of gasoline. This variation would not have been possible with a set of multiple towers with partial condensers, such as Fig. 3, with the last tower designed for gasoline from the top since this tower would have been loaded with a throughput of 6000 bbl., even though gasoline only were removed.

Side streams, as commonly removed directly from the tray, possess the characteristic "tail" or small percentage overlap of the next lighter fraction, due among other things to vapor contamination as a result of condensation in the flow line. This can be re-

moved by the introduction of very small amounts of steam into a satisfactory stripping chamber located either inside or just outside the tower, but more satisfactorily and economically within the tower. The same purpose cannot be accomplished as easily or with the same fuel input by a conventional reboiler. Such a stripping arrangement is absolutely essential in producing lubricating distillates to flash specification.

### Typical Distillation Curves

Typical distillation curves of the products from Pennsylvania crude, processed in a single tube still-single tower unit, are shown in Figs. 5 and 6. The unit was originally designed for an operation producing long residuum and Fig. 5 indicates the type of products which were obtained. The two side streams, kerosene and gas oil, were removed from interior stripping chambers and indicate the absence of the "tail" referred to previously, as well as the close boiling range streams possible by close fractionation. Incidentally, the ability to remove a 60–70 deg. boiling-range naphtha with an end point of 430–440 deg. fahr. demonstrated on another unit of this type, proves a decided advantage when a maximum yield of export gasoline is desired.

The same unit is now being operated to produce cylinder stock, and Fig. 6 shows a typical set of distillation curves for the several products. It should be noted that with the limited number of trays in the tower, it has proved advisable to remove the kerosene with the gas oil from the normal kerosene stripping chamber. The pressing stock is being removed directly from a tray, and the wax slop from the normal-gas-oil stripping chamber. Steam is introduced into the bottom of the tower to bring the cylinder stock to flash. No steam was used in either stripping chamber from which the gas oil-kerosene and wax-slop streams were removed. In spite of this, the absence of the "tail" or overlap on the lighter stream will be noted. Unfortunately, no distillation on the slop stream was available. With steam in the stripping chamber, the initial of the gas oil-kerosene stream is normally about twenty degrees above the gasoline end point. The total quantity of steam used in the tower, approximately three-tenths of a pound per gallon of crude or about twelve pounds per barrel, is superheated in a separate convection coil in the tube still.

The production of pressable wax distillate is no longer subject to question. This operation is being successfully carried out on both Pennsylvania and Mid-Continent crudes. The yields straight from the crude, due to absence of cracking, are at least as great as by the old method of operation, including the rerunning. We realize that the pressability is not dictated by gravity or viscosity essentially, or by the so-called "cracking" operation, but by the boiling range. It is obvious that viscosity and gravity could be the same for a long-boiling-range or a short-boiling-range distillate with the same average as cut from the crude, but the one might contain wax which would interfere with the sweating. It becomes of primary importance to take a distillate with the highest possible end point and necessarily of constant specification to insure maximum yield. In operating the single-tower unit, as stated before, two temperatures must be maintained constant to insure the constancy of these streams—the tube-still outlet and the top-tower vapor outlet. With this type of tower unit, as with every other, the specification of any one stream cannot be changed without affecting one or the other, or both, adjacent streams unless an intermediate cut is removed. This fact is not peculiar to this type of unit but this type of unit with the proper tower construction is peculiarly well adapted to the removal of such an intermediate stream with a minimum of difficulty and delay.

As a matter for consideration from the efficiency point of view, the fact that steam is introduced only in the tower and not in the tubes of the tube still, permits the utilization of the exhaust steam from the pumping equipment as a source of supply for the superheater.

### Summary

In summarizing, it might be stated that with the efforts of refinery engineers in the direction of simplification of the distillation operation and equipment, the single-tower unit looms as the solution of a previously complex problem. The contingent problems which must receive careful attention are:

1 The selection of a simple, accessible, practicable heat-recovery system, perhaps at a sacrifice of a few B.t.u., but eliminating the duplication of controls and possible variation of inlet temperature to the tube still.

2 The simplest, but properly sealed, piping arrangement.

Throughout the entire design the engineer must carry foremost in mind a point of paramount importance to the modern refinery, particularly the smaller ones, and that is flexibility.

# The Construction and Protection of Oil and Natural-Gas Pipe Lines

By W. H. T. Thornhill,[1] Tulsa, Okla.

*After calling attention to the magnitude of the underground systems required for the transportation of oil and natural gas, the author considers in detail the methods employed in field construction, dealing successively with surveying the route, purchasing and preparing the right of way, "stringing" the pipe along the route, welding pipe joints, excavating the ditches, lowering of line into the ditch, laying all-coupled lines, etc. He then takes up the subject of river crossings, following which he discusses at length methods of protecting pipe lines from soil corrosion, and the principal requirements which a good protective coating should meet. Such a coating, the author states, provides reasonable insurance against the destruction of large investments in permanent underground pipe lines.*

THE building of oil and natural gas-pipe lines is one of the most interesting and fascinating forms of construction work in existence. Probably this is on account of the constantly shifting nature of the work as it progresses, the fact that speed is always the primary object, and furthermore that it usually involves a more strenuous battle with nature than is customary in other types of construction.

A preliminary map of a projected pipe line is a straight line between two points. Deviations are made with great reluctance and only because of some major topographical condition, such as the elimination of hazardous river or creek crossings, avoidance of cities, towns, or densely populated areas, as well as mountains or canyons, or on account of difficulties of obtaining the necessary right of way. It is surprising how often a completed pipe line is practically a straight line between its terminals.

It is certainly true that the average citizen, when buying a gallon of gasoline or lighting the gas stove, has no knowledge of what has been accomplished in order to make these necessities of modern life so readily available. Most engineers, unless they happen to be in contact with work of this kind, also have very little knowledge of the subject, and therefore it may prove interesting if a brief description of the building of such lines is given.

Oil pipe lines are built to transport oil from producing areas to refineries, ship terminals, or loading racks along railroads. Natural-gas pipe lines of the type under consideration are built from producing areas to large cities to transport the gas for domestic and industrial use as fuel.

Very few persons have any idea of the magnitude of these operations, and a few figures may be of interest.

## Magnitude of Pipe-Line Transportation Systems

There are approximately 90,000 miles of main and gathering oil lines, about 75,000 miles of main natural-gas lines, and 81,000 miles of manufactured-gas lines, the total approximating the railroad mileage of our country. These lines constitute an underground railroad system that is one of the largest and least-known transportation organizations in the world. The various lines are similar to a railroad system in that they comprise trunk lines, gathering or feeder lines, terminals, parallel lines on the same right of way, storage yards, switching systems, stations, dispatchers, and telegraph and telephone lines. Unlike railroads, however, only a single commodity is handled.

Oklahoma and Texas oil is pumped to refining centers either on the Gulf Coast or on the Atlantic Coast, about half-way across the continent. If all the crude oil moved in a year by the various pipe lines were loaded in tank cars, it would require a train 40,000 miles long, or one and two-thirds times the circumference of the earth.

Over $800,000,000 is invested in oil pipe lines alone, without considering the approximately quarter billion of dollars required each year to maintain and extend them.

In projecting the construction of a new oil line such factors are involved as the production in sight, gravity of the crude, length and size of the line necessary, daily production of the well or field to which the line is to be constructed, the probability of the production's being maintained over a long period, the possibility of the producing area's being extended, etc. The factors entering into the construction of a new natural-gas line are also varied, but in general they require a study of the possibility of an adequate gas supply over a long period of years, the feasibility and cost of construction and operation of the pipe line, the necessity of a dependable market diversified in character, the cost of the gas, and other similar items. Furthermore, the cost of the project over the shortest route must be balanced against any possible markets along other longer and more expensive routes.

Fig. 1 Pipe Line Extending Up 45-Deg. Canyon Wall 500 Ft. High

The various elements of the design of the pipe line and its auxiliary features will not be touched upon here, but a description will be given of the methods used in the actual field construction.

## Methods Used in Field Construction

The first necessity, after the preliminary map of the project has been made, is to run a survey in order to determine the best route for the line. Frequently several surveys are made and a final choice of one is determined after a study of the various conditions involved.

Next comes the purchase of the necessary right of way, which

[1] Mid-Continent District Manager for the Wailes, Dove-Hermiston Corp.

Presented at a meeting of the Kansas City Section of the A.S.M.E., May 22, 1928.

often follows closely behind the making of the survey. Pipe-line companies always endeavor to come to a reasonable agreement with land owners, and very seldom exercise their right of condemnation.

The actual construction work is now ready to proceed, and the first or right-of-way gang goes ahead along the course of the proposed pipe line, removing trees, stumps, undergrowth, and grading wherever necessary.

*"Stringing" the Pipe.* Arrangements have previously been made with the pipe companies to ship a certain designated number of carloads of pipe to certain railroad stations most nearly accessible to the proposed pipe line. Distribution of this

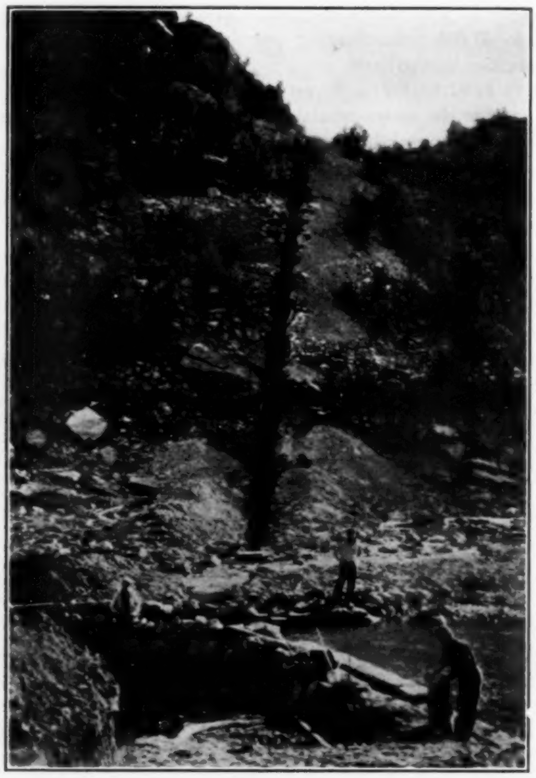

Fig. 2 Pipe-Line Ditch in Solid Rock Across Small Stream and Up Canyon Wall

pipe from these railroad stations is called "stringing." It is necessary that the pipe be handled so that it will not be damaged, and also that it be accurately "strung" along the right of way so that the construction crew will not be obliged to do any extra work in hauling joints forward or backward. Sufficient pipe is stored at each road crossing to span the gap.

"Stringing" pipe is one of the most interesting jobs in pipe-line laying, and usually it is let out to a firm making a specialty of this kind of work. The transporting of the pipe, as well as the other materials required, is a very real problem. Quite frequently the pipe line passes through scarcely populated sections where there are few or no roads, and in many cases roads have to be built.

Wherever possible, motor trucks and trailers are utilized. When these are not practicable, mules and heavy wagons are substituted. Sometimes these cannot get through, as in the case of swamps, and oxen are used. There are cases where pipe and other material have been hauled 80 miles or more over very difficult country.

*Welding Joints in Pipe Lines.* Oil pipe lines have either screwed or welded joints, with a tendency toward all-welded lines today. Most of the main lines are 8 or 10 in. in diameter, with some 12 in. Natural-gas lines are usually coupled or employ a combination of coupling and welding. A few all-welded gas lines have been built. Screw-jointed lines are never used for gas because of the extensive leakage. A welded gas line has been found to have less leakage than one of any other type, but in most instances the engineers fear breaks due to contraction. Main lines for large natural-gas systems usually vary from 16 to 24 in. in outside diameter.

The sequence of the remaining operations varies according to the type of construction. For an all-welded oil line, the next operation is welding. This is done by oxyacetylene flame, although several small lines have been electric-arc welded. An acetylene generator is mounted on a four-wheel truck and moved along the right of way as the welding proceeds. Each generator will supply enough gas for about six welders. Oxygen cylinders are also "strung" along the line.

The usual practice is to have several different gangs of welders for each construction camp, among whom the welding is divided. For instance, one arrangement is to have one gang, known as the "firing line," to weld from 2 to 4 joints. This is followed by a "swing gang" who weld these sections into 400- to 500-ft. lengths. Then follow the "bell hole welders" and bending gang, who tie the whole line into a completely welded unit, make all bends necessary for curves in the line and to follow the grade, and put in railroad, creek, and highway crossings.

Each joint of pipe is cleared out with a swab, in order to be sure there are no obstructions in the completed line, and at night the open end of the completed pipe is closed with a plug in order to prevent animals from entering the line.

*Ditching.* The trench in which the line is to be placed is excavated by means of a ditching machine, of which there are various types. Ditches are dug to a depth that will leave about 16 to 24 in. of soil on top of the pipe. This depth is sufficient to

Fig. 3 Welding of 20-In. Gas Line

keep the pipe line below the usual plowing depth on farms and also below the frost line, so that the temperature changes throughout the year will be very slight. Ditching machines are usually run night and day in order to keep ahead of the construction crews. In case rock is found, the usual practice is to blast it. Occasionally topographical conditions will not permit a ditching machine to operate, in which case hand ditching must be resorted to.

The line is then placed above the ditch on wooden skids, ready for painting and lowering. In some cases where cold paint is used to protect the line against soil corrosion, the application is made before the line is entirely welded together. The best practice, however, is to paint the line after it is over the ditch and just prior to lowering, in order to reduce the possibility of damage

to the paint coating to a minimum. When a skid is encountered the line is temporarily lifted in order to paint the pipe.

*Lowering of Line into Ditch.* This must be carefully done in order not to put any undue strain on the pipe which will cause it to break. The practice is to remove some of the skids, supporting the line in the meantime on a pipe windlass, and then slowly lower this portion into the ditch. By repeating this operation the line is successively lowered in short stretches without damage.

Pipe lines are naturally subject to expansion and contraction underground, due to the temperature changes of the soil in contact with them. Expansion causes no particular trouble, but contraction, on the other hand, will result in breaks. As no expansion joints are used on an all-welded oil line, provision for this contingency is made by lowering the line in the cool, early morning hours, and allowing as much "slack" as the conditions seem to require. Frequently the line is also swung from side to side in the ditch in order to allow it to contract without danger

Fig. 4 Open Ditch 24 In. Wide and 46 In. Deep, With Pipe and Couplings "Strung" Beside It

of breaking. This is an added precaution when a line is laid in flat country.

After the line is lowered, the backfilling gang fill the ditch so it is heaped up with the dirt previously removed by the ditcher. This work is done mechanically in several different ways.

There is now work for the "right-of-way damage man." All during construction, fences have been removed for short sections on farms or gates opened by each gang, in turn, to facilitate the passage of men and equipment. Sometimes these are not closed after a particular gang has passed, allowing stock to escape and damage crops. Ditches at road crossings may not be properly lighted at night, resulting in accidents to persons or livestock. Equipment strays from the right of way occasionally, causing damage to crops. Tile on tiled farms is broken by ditching machines. These are only a few illustrations of occurrences that make life interesting for the damage man. It is surprising, for instance, what an extraordinary value a tree acquires in the eyes of an owner if a few branches are injured during construction work.

*Laying All-Coupled Lines.* An all-coupled or a coupled-and-welded gas line is built with a slightly different sequence of

Fig. 5 Applying Hot Coal-Tar-Pitch Enamel to Oil Line to Protect It Against Soil Corrosion

operations. After the pipe is "strung," the welders come along and usually weld together two or three joints of pipe. If an all-coupled line is being built, this operation is of course not required. Then the ditcher comes along, followed by the painters. Painting is done alongside the ditch. The single or welded joints, as the case may be, are then coupled together over the ditch and made gastight, the couplings and pipe surface immediately adjacent to them are painted, and the line is ready for lowering.

On gas lines of this type, the lowering closely follows the coupling. If long stretches were coupled before lowering, some of the movement of the joints in the couplings, due to lowering, would likely be increased above normal, with the result that the line would pull out of the coupling. If this did not occur, there would certainly be more strain on some couplings than on others, and a leaky joint would result. As each coupling is an expansion joint, no slack is required, but the lowering must be very gradual and very carefully done so that the coupled joints will not be distorted enough to leak when the gas is later turned into the line. Usually on a large-diameter line five or six frames, called "horses," are spaced along the line successively at each joint. Ropes from these "horses" to the pipe support the latter as the skids are removed. These ropes are gradually slacked off their supports to lower the line. The "horses" are continually being moved from the back end of the lowering operation to the front as the lowering progresses. Before lowering, men go along in the ditch to remove any dirt, stones, rocks, etc., that may have fallen into it after the ditcher passed. An all-welded line, such as an oil line closely follows the contour of the country over which it passes, but much more care is required in laying a coupled gas line to secure a more even grade with only gradual and easy changes in the profile.

### River Crossings

River crossings for pipe lines usually present the worst and most difficult construction problems. Special gangs are assigned to this work and are independent of the other construction forces.

River crossings provide the greatest hazard to the continuous operation of the completed line. It is therefore customary practice, especially in the case of gas lines, to install multiple lines. Sometimes as many as six multiple lines are placed across an important river as an insurance of uninterrupted service in case breaks occur in flood times.

Manifolds or headers, with valves, are placed on each side of the river at positions which records indicate will be above the highest water likely to exist during floods. The multiple lines across the stream are then connected to these headers. For some of the shallow sand rivers of the Southwest, these manifolds may be one and one-half miles apart.

It is essential to prevent the river lines from moving after they are laid in position, as otherwise a break will likely occur. The usual practice is to attach a casting weighing from 800 to 1600 lb. and known as a river clamp to the pipe at each welded joint. This strengthens the joint and provides sufficient weight to cause the line to settle to the river bottom and embed itself. Sometimes as an added precautionary measure a collar leak clamp is also placed over the weld and the river clamp placed over it.

Extra heavy pipe is used for these river crossings. Double-length pipe is employed, and all lines, whether gas or oil, are usually welded. River-crossing lines for large-diameter gas pipe are smaller in size than the main line; generally 12-in. is used, but the total capacity of these smaller multiple lines is somewhat in excess of the main line.

If a navigable stream is to be crossed, the Federal Regulations provide that the lines must be buried a certain depth below the river bed. This requires dredging of trenches for the various multiple lines and subsequent backfilling after the line is laid.

For crossing wide navigable rivers, the best practice is to lay the line from a barge. As the barge is pulled by a boat along the course of the pipe line, successive joints are added, river clamps are attached, and the line is painted and then carefully lowered into the river trench. Several sets of lowering pontoons or another barge, following the first one, are used so that the lowering of the line does not put it under too much of a strain. A diver inspects the line after the work is completed to make certain that it has been properly done.

On short navigable rivers, creeks, or sand rivers, the crossing lines are prepared on the shore in as long sections as can be handled and then pulled across into the desired position for each one.

All river-crossing lines are bowed upstream to reduce the possibility of breakage in service. The height of the arc of the bow may be as much as 1000 ft. for a wide river crossing.

In some cases crossings are carried over rivers by special bridges constructed solely for this purpose. This method has seemed necessary in the case of some of the Southwestern sand rivers on account of the shifting nature of their bottoms, quicksands, and similar conditions difficult to combat otherwise.

### Gangs Required and Their Size

In constructing a pipe line, several complete gangs, each with a full set of equipment, are placed in the field at different points in addition to the river-crossing gangs, and the construction work proceeds simultaneously along the different sections. The number of gangs will depend largely on the time available for completing the work, size of line and type of construction, construction difficulties expected, etc. Sometimes six to fifteen or more gangs are in the field at one time, all working on the same project.

The number of men required varies with the conditions. Usually the number of men in each gang for a welded oil line will be from 50 to 100, and for a gas line of large diameter, up to as high as 300.

Because of the shifting nature of the work and the wild country usually encountered, tented camps are utilized and moved frequently. The men are conveyed back and forth to the work each day in trucks. Unless state laws prohibit, work is carried on seven days a week. The camps are carefully supervised to keep them sanitary. An abundance of good food is served, with plenty of variety. This is always an important point as the work uses up a great deal of energy and men quickly become discontented if the living accommodations are poor.

During the construction of the pipe line, pumping or compressor stations, depending on whether the line is intended for oil or gas, are built by a separate organization. An effort is made to have these completed by the time the line is finished so that the entire project can be placed in service immediately. The design, number, and location of these stations are given very careful study so that the most economical operating conditions will be realized. In general, pumping stations are located every 40 miles or more on an oil line, and compressor stations about every 100 miles on a gas line. It is also the usual practice to build a natural-gasoline plant in connection with a gas line.

An oil line pumps from tanks at one station into the tanks at the next one. The movement of the oil is really a succession of individual movements, although all are occurring simultaneously. In effect, therefore, the movement is continuous.

A gas line is different as no holders are used. The pipe line itself acts in the capacity of a holder. The gas never leaves the line, and each compressor station acts as a booster to push it along.

Oil lines operate at pressures around 700 to 900 lb. per sq. in., and gas lines around 300 to 500 lb. per sq. in. The maximum pressure is at the discharge side of the station, and drops off to the minimum at the intake to the next one. It is general practice to use heavier pipe for some distance on the discharge side of a station than is used for the main line. Some oil lines are also constructed of smaller-sized pipe for this part of the line.

### Protection of Lines Against Soil Corrosion

After a line is built the problem which is giving executives of pipe-line companies the most concern is its proper protection against deterioration from soil corrosion. It should be borne in mind that the line is completely buried and out of sight, so that its condition cannot be readily observed. Any structure above ground can be easily watched, and the problem of maintenance against corrosion is a simple one. Usually the failure of a pipe line from corrosion is not known until a break or leak occurs.

C. R. Weidner, chief engineer of the Prairie Pipe Line Company, recently estimated that the loss to the pipe-line owners from soil corrosion amounted to at least $100,000,000 annually. Some engineers believe that this figure is conservative and that the loss is really greater; however, it will convey some idea of the importance of the problem of preventing losses to pipe lines from this cause.

The problem is complicated by the fact that soil corrosion is a most complex natural phenomenon. Instances of differences in rates of corrosion under apparently identical conditions are frequently encountered and baffle any attempt at explanation. It is nothing unusual to discover severe corrosion in a portion of a joint of pipe, while the rest of it, located apparently in the same soil and subjected to the same weather conditions, is still in good condition. Frequently the same thing is true of parallel lines lying within a few feet of one another. In one case a line laid hurriedly with no thought given to any feature of its construction except getting it into service as quickly as possible, was in far better shape after eight years than a parallel one laid with great care four years later. These illustrations could be multiplied many times and are simply mentioned to indicate to some extent the puzzling nature of the problem.

In many cases unprotected underground steel pipe shows no appreciable signs of corrosion for some time, when suddenly a decided increase in the rate of corrosion results in a rapid deterioration. There are cases known where a line was apparently in

good condition four or five years after installation, but three years later was in such bad shape from soil corrosion that replacement was necessary. It is therefore realized that in many cases even a periodical examination of a buried unprotected line is no positive assurance that early failure will not occur.

Of the various methods that have either been proposed or put in practice to combat this condition, the one that seems to be the most practical and is now in the widest use is the application of a protective coating to the outside of the pipe.

There are differences of opinion regarding the various theories of soil corrosion. Every one is agreed, however, that if moisture or other electrolyte can be insulated from the pipe surface, there will be no resulting corrosion. The real corrosive agents are the solutions of the soil surrounding the pipe and not the soil itself. The problem, then, is to provide a satisfactory material which will prevent any of the soil solutions from coming in contact with the steel and continue to prevent it, not only for a short time after the application, but for years to come.

### Requirements of a Good Protective Coating

The main requirements of a good protective coating for permanent installations will now be considered. These requirements are not merely theoretical but are based on a long-time experience with this type of work. They are:

1 It must be waterproof.

2 It must be unaffected by soil acids and alkalis.

3 It must have good adhesion to the pipe surface and maintain its adhesion.

4 It must not disintegrate with age due to internal changes of a chemical nature.

5 It must be incapable of absorption by the soil in contact with it.

6 It must not be affected by underground temperature changes.

7 It must be a dielectric, in order to offer protection against electrolysis.

8 It must be capable of practical application in the field, and at a speed that will not retard the progress of the pipe laying.

9 It must be unaffected by ordinary handling in the field after application and not damaged by lowering into the ditch.

10 It must have a substantial thickness on all surfaces.

11 It must have been in actual use long enough to show actual long-time records of satisfactory performance on steel pipe underground.

12 The cost of using it must be such as to more than justify its use.

The requirement that the protective composition must be waterproof is obvious. Many protective compositions are waterproof when first applied, but subsequently this characteristic is destroyed and the material loses its protective value. A good many bituminous paints contain water, not from design but because no effort has been made to eliminate it. Other materials are manufactured with water acting as a vehicle. It would seem doubtful practice to place a material containing water on a steel pipe line if one of the primary objects in making such an application is to exclude water.

If soil acids and alkalis should have an effect on the coating, or it should lose its adhesion and come off the pipe surface or disintegrate from internal chemical changes, there would naturally be no advantage in using it for protective purposes of a permanent nature. The use of such a coating would be not only of no advantage, but a positive disadvantage, because it would lose its protective value in spots, at which corrosion would be concentrated, and extensive pitting would result. Such a line would probably last longer if no protective coating was used in the first place, because the corrosion would be distributed and not concentrated.

Pipe lines move underground due to temperature changes. Good adhesion of the coating to the steel surface is therefore absolutely essential and must be more than sufficient to meet this condition; otherwise the coating will be torn loose from the pipe, with resulting failure of the pipe from corrosion.

It is also obvious that the coating must not be susceptible to absorption by the soil in contact with it. Some coatings are affected to a considerable extent in this respect by certain types of soil. In general, a soft coating is much more susceptible to this trouble than a hard one.

There is always a variation in ground temperature from winter to summer. This variation naturally depends on the extremes

Fig. 6 Laying 20-In. Gas Line From Pampa, Tex., to Wichita, Kan.

Fig. 7 Laying 22-In. Gas Line From Amarillo, Tex., to Denver, Colo.

of atmospheric temperature as well as on the depth at which the line is buried. In addition the velocity, composition, and temperature of the oil flowing in the pipe line are factors. Accordingly a protective coating must possess a temperature range greater than the underground-temperature variation to be expected in the pipe on which it is to be applied; otherwise the coating will either crack at the low temperature of the variation or become soft enough at the high temperature to sag and flow off the pipe surface. Usually the underground-temperature variation from the low to the high point in the Mid-Continent field is about 40 to 45 deg. fahr. Some protective compositions desirable in other respects have a temperature range of only about 45 deg., but it is possible to obtain a material of a similar base with a temperature range of approximately 80 deg. A desirable factor of safety is provided in choosing the latter composition.

Oil and natural-gas pipe lines are seldom troubled with stray-current electrolysis in view of the fact that they avoid cities and other congested areas. However, for gas or water distributing systems in the cities this is a live problem; consequently it is necessary that a coating be a dielectric to combat this condition satisfactorily.

Invariably in laying a pipe line, speed is the most important consideration. Therefore a satisfactory coating must be capable of application as fast as the other work progresses. Weather or field conditions over which no one has any control enter into the problem of application of any protective composition. This feature will be discussed later.

Pipe-line construction is rather rough work owing to topographical conditions and transportation difficulties, and its shifting location prevents the same carefulness usually exercised in other construction work at a fixed location. The pipe coating after application must therefore be capable of withstanding rough handling without serious injury, otherwise it is hardly practical. In recent years better tools and more careful methods for handling the pipe have been developed, but with the best of care there will likely be some damage to the coating. Therefore it must also be capable of being easily and quickly repaired. The harder coatings without brittleness, but with the best adhesion, fulfil the handling requirements better than the softer ones. Atmospheric temperatures during the time the line lies above the ground must also be taken into consideration. Practically all protective compositions are black, which color has been proved to absorb heat. A coated pipe at an atmospheric temperature of around 100 to 110 deg. will more than likely have a temperature of around 140 or 150 deg. Consequently the coating must not be affected by this temperature to such an extent that it will sag or run off. If this condition should exist, it is common practice to apply a coating of whitewash over the protective composition. If, on the other hand, the work is done in cold weather, the coating must not crack either before or during the time the pipe is lowered into the ditch.

Fig. 8 12-In. River-Crossing Lines Showing River Clamps in Position

A coating may possess all the desirable requirements previously mentioned, but if it cannot be readily applied so that a thickness of at least $^1/_{16}$ in. or more will be obtained, the protection will not be permanent. It is practically an axiom that physical thickness is absolutely essential for permanence. For this reason paints applied cold, which usually have a film thickness of from 0.005 to 0.01 in. per coat, cannot be considered as a permanent protection. Such paints dry by evaporation or oxidation, the result in either case being pinholes and hairline cracks in the film. These openings allow the corrosive agents to reach the metal, with the result that corrosion spreads under the coating and eventually pushes it off. Corrosion is consequently concentrated at these points of weakness and more pitting probably results than if no coating had been applied. Field tests of such materials usually show poor results and indicate their unsuitability for permanent work. If soil conditions are extremely favorable, some measure of protection will be secured from cold applications, but it is being generally recognized that for permanent work underground it will be necessary to adopt some material applied hot.

## Application of Protective Coatings

The hot coatings available are manufactured with either an asphalt or a coal-tar-pitch base. Some of the available coatings require a wrapping of asbestos or wool felt, while others are applied without any wrapping.

In building up a substantial coating it is obvious that a better result will be obtained if a satisfactory thickness is secured from one application of hot material than if several applications alternating with a wrapping are employed. In the first case a thick, homogeneous coating of one material results, and only one application besides the priming coat is required. Wrapped coatings, on the other hand, require from three to five applications in addition to the priming coat, and as a result the possibilities of errors, mistakes, carelessness, etc., in making the application are increased in a corresponding degree. Very careful field work and rigid inspection are necessary to prevent wrinkles, folds, and sags in the coating. Various methods of cutting the wrapping material and applying it have been developed, and it is true that better work is being done now than formerly. However, as it is possible to make a single application of a satisfactory hot coating with a thickness of approximately $^1/_{16}$ in., it is doubtful whether wrapping is necessary to fulfill the requirement of thickness.

It is not practical to wrap the couplings on a gas line, but this drawback has been overcome in some cases by placing a paper or fabric form around the coupling and filling it completely with the protective composition. This method is expensive and not very satisfactory, because leaks are hard to repair.

Wrapped coatings are more expensive than unwrapped ones, especially if more than one ply is used.

There are a great number of different compositions offered today for protective purposes. Experience has indicated, however, that bituminous compounds, which include asphalt and coal-tar materials as a base, are the important ones. Each of these basic materials has its advocates, and therefore a discussion of their advantages and disadvantages may prove of value. The asphalt compounds used in the past for the underground coatings have not given consistent and reliable results. In some cases results seem to be satisfactory, while in others the material seems to have disintegrated and lost its protective value. Sometimes these contradictory results have taken place under conditions that seemed to be identical. Apparently leaching occurred,

leaving a hard, brittle material. This eventually becomes cracked, usually with only fine hairline cracks, but sufficient to allow moisture to reach the pipe. With wrapped coatings the same thing has occurred with the outer coating of asphalt. Moisture then reaches the wrapping, eventually softens it, and causes it to sag away from the bottom of the pipe. This results in a pocket containing water and causes extensive pitting. Hundreds of miles of pipe line coated in this way, which from a superficial examination were considered to be in good condition, were later found to be badly pitted along the bottom of the pipe. A coal-tar-pitch-base compound is being recognized today as a superior material for underground protection against corrosion. It meets all of the requirements mentioned above for the ideal pipe coating, provided the choice of the raw materials entering into its manufacture is based on sufficient experience and knowledge of the physical characteristics of the various pitches and their reaction in combination with the other materials involved in the manufacture of the coating. Most coal-tar pitches, however, have a very narrow plastic temperature range and are unsuitable in many cases for use underground if the variation in ground temperature exceeds the temperature limitations of the material. It is possible, though, to compound a protective composition of an all-coal-tar-pitch base that is not subject to this narrow temperature range, and therefore, in choosing a coating of this type the question needs careful consideration.

It should be borne in mind that there are literally hundreds of coal tars and coal-tar pitches with widely different physical as well as chemical characteristics. Some are absolutely of no value, while others only fulfil some of the requirements of a good coating. The same is true of asphalts. Most of these compositions are simply by-products, and are worthless for the purpose of permanent underground protection. Therefore the fact that a material is designated as having a coal-tar base, with nothing available in the nature of performance records, does not mean anything. An enthusiastic coal-tar advocate will find many good asphalt products far superior to some poor coal-tar compositions, and vice versa.

Many bituminous compositions suffer chemical changes with age, which is one reason why laboratory or accelerated tests are not conclusive. Such tests have a value in that they will eliminate materials of little merit, but there is no test known which will predict the condition of the material in, say, ten or fifteen years. Compositions that pass a test may later prove unsatisfactory on account of subsequent deterioration.

The only satisfactory test is a real service test on a pipe line in the field, preferably in the worst soil conditions. Some companies maintain a "graveyard" for testing. Cinders, salt, sulphur, manure, and similar well-known corrosive agents are mixed with the soil, and then coated pipe is buried in the mixture, which is kept wet. It has been found that the life of coatings in actual service will follow very closely the results predicted by such a test, and consequently it has real merit.

Fortunately, there is a growing tendency on the part of pipe-line men to recognize that a satisfactory job consists of two main factors: proper material for the purpose, and also proper application. Money spent for the best pipe coating in the world might just as well be thrown in the ditch if the application is not carefully and properly made.

The principal requirements in the application of a coating are that the pipe surface must be absolutely clean and dry. All dirt, dust, loose mill scale, rust, grease, oil, or moisture must be removed before any protective composition is applied. This is imperative and applies not only to the main pipe surface but, in the case of a coupled gas line, to all surfaces of the couplings. The best way to clean a pipe line, new or old, is by means of a portable pipe-cleaning machine. It is just as important that the pipe be dry as that it be clean. It is therefore evident that weather and field conditions have considerable bearing on the application. Some officials positively prohibit the application of any protective coating if the pipe is dirty, wet, or frosted, realizing that no coating can be expected to adhere under these conditions.

Field cleaning has been considerably reduced recently and the chances of a more satisfactory pipe coating job secured by specifying that the pipe be given a preliminary coat of the priming solution before shipment from the pipe mills. The extra cost of this preliminary coating is slight and either wholly or to a large extent offset by the reduction of field costs in cleaning. This preliminary field application will not be of much value as a priming coat for the hot material, and should be followed in the field by the customary first coat of priming solution before the hot coating is applied.

The cost of any protective coating must be such that the expected protection or increased life of the pipe will more than justify its use. For permanent lines it is justifiable to spend more money than for temporary ones. Conversely, it is not economic to purchase a high-priced material intended for permanent work if the line is only to be in service for a short time.

In general, costs will be about as follows: For paint applied cold, 1 to 3 per cent of the total cost of the line; for thick unwrapped coatings applied hot, 5 to 9 per cent of the total cost of the line; and for wrapped coatings, 10 to 15 per cent of the total cost of the line. Pumping stations or compressor stations are not included in the total cost of the line. The variation in cost is due principally to dissimilarity in location, topography, field and weather conditions, and also to whether the owner, general contractor, or coating manufacturer makes the application. As a rule it will cost more if the coating manufacturer does the work, for the reason that he supplies a separate organization which necessitates a duplication of trucks, camps, and commissaries. He must also regulate the speed of application to conform with both the laying and ditching. This often necessitates delays or disorganization in his schedule of operations, with a resulting increase in cost. The owner or general contractor can maintain a much better schedule by shifting labor from one operation to another.

When it is realized that the cost of reconditioning a line is usually about three times that of applying a satisfactory protective coating, it seems desirable to adopt the policy of coating all new lines, whether or not the soil conditions are known to be corrosive. Eventually all lines not properly protected may be expected to fail from corrosion and from nothing else. Since there is a lack of complete knowledge regarding the complex problem of soil corrosion, and it is impossible even approximately to predict the life of an unprotected line, a good protective coating provides reasonable insurance against the destruction of large investments in permanent underground pipe lines.

# One Example of Centrifugal Pumps for Petroleum Transportation

By FLOYD E. WARTERFIELD, JR.,[1] MUSKOGEE, OKLA.

*This paper deals with the problems involved in one specific installation of motor-driven centrifugal pumps for pipe-line work. The author describes conditions prior to the installation, and gives the reasons for the selection of centrifugal pumping units, as well as actual construction and operating costs so far as possible. He also discusses the effect that the experience gained from the installation described may have on the future use of centrifugal pumps in petroleum transportation.*

Recently there has been much agitation as to the relative merits of pumping equipment. A great many comparisons have been made upon purely assumed conditions. It is unfortunate that there are so few actual data available, upon which to base a direct comparison between different classes of equipment, or between different equipments of the same class. The elements entering into pipe-line "cost analysis" are, for the most part, hard to determine; and when once determined, hard to evaluate correctly. Because of this difficulty, some one or more of the component parts are only roughly approximated or else omitted entirely. Every pipe line or station presents its own particular set of problems, and it is wholly unfair to assume that whatever may serve in one case would work equally well in any other. Before a true comparison can be made between any two stations, the whole story should be told, and the existing conditions in each made absolutely plain.

In view of the foregoing statements, this paper will confine itself largely to the problems involved in one specific installation of motor-driven centrifugal pumps for pipe-line work. It has for its purpose, first, the presenting of the conditions prior to the installation; the reasons for the selection of the centrifugal units; and so far as possible, actual construction and operating costs; and second, the effect that the experience gained from this one installation may have upon the future use of centrifugal pumps in petroleum transportation.

The data and information have been furnished through the courtesy of the Oklahoma Pipe Line Company, and the installation referred to is the one known as their Henryetta Station (Fig. 1).

Initially, a 10-in. line had been built between their Cromwell and Council Hill Stations, to provide an outlet for a portion of the oil produced in the Seminole Area. The line was designed to handle 32,000 bbl. of oil per day at 480 lb. pressure. The gravity varied from 35 to 40 deg. A.P.I. and had an average viscosity of about 48 sec. Saybolt Universal at 60 deg. fahr. Some concern was felt as to whether there would ever be sufficient production for the line to operate at its maximum capacity. But, as frequently happens in pipe-line work, the line was hardly completed before it was found necessary to effect an immediate increase in the delivery to Council Hill.

The guide chart shown in Fig. 2 is introduced for the purpose of showing one method that may be employed for the rational selection of pumping equipment but will be discussed only so far as it applies to the equipment selected at Henryetta Station.

Production from a new field is almost invariably well in advance of all storage and pipe-line facilities. Seminole was certainly no exception. As is always the case in caring for a sudden increase in output, the element of time becomes the one item of paramount importance.

To attempt to determine, even approximately, the maximum production of a field, the time required for it to reach a settled figure, or even what this amount would be, is most certainly a hazardous undertaking for any one. However, it was generally believed that the added capacity, so far as this case was concerned, represented a peak load that would only be handled for a maximum of six months. At the end of this time the load would have fallen to the original value of from 30,000 to 32,000 bbl. a day.

It is customary to compare equipment, and in some instances (where ample time will permit) to select it on the basis of the "unit cost per barrel of oil pumped." Even under ordinary conditions "time of operation" is hard to determine. "Time of operation" refers to the length of time the equipment shall operate, and is a very important item in the unit cost figure. Under the stress of "do it now" it seldom, if ever, receives the consideration that it should. It is generally the case that comparative analyses, and more especially where the time for the increase is short, are forced to neglect "fixed charges" and the equipment is selected on the basis of the "time required for delivery." Unit-cost comparisons are investigated at some future date.

There was adequate pump capacity at Cromwell Station for the proposed increase and the problem was to find the quickest way in which the delivery could be made to Council Hill. It was a case of either looping the line or constructing an intermediate booster station. No line pipe was available, and even if there had been, with an adequate amount of time in which to lay it, the expenditure of $528,000 would not have been justified, for the short time it would be used. In order to effect the ultimate increase that has been realized, approximately 37.6 miles of 10-in. pipe, laid from Council Hill and parallel to the old line, would have been required. Computations for a booster station placed it at a point quite close to an existing high line, and electric power could be obtained quickly and easily.

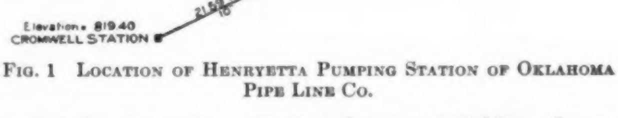

Fig. 1 Location of Henryetta Pumping Station of Oklahoma Pipe Line Co.

Immediate delivery could be made on motor-driven centrifugal units, and as a whole conditions seemed to be ideal for their use. It was realized that the operating cost would be high, but with due consideration for the time saved and the low fixed charges, it was thought that the high rate could be profitably paid for the short time the units would be in service.

Accordingly there were installed two automatic compensator-controlled 300-hp. 440-volt General Electric induction motors, driving two Byron-Jackson 6 × $17^1/_2$ four-stage centrifugal pumps arranged in series and running at a full-load speed of 1750

[1] Oklahoma Pipe Line Company.

Presented at a meeting of the Mid-Continent Section of the A.S.M.E., Tulsa, Okla., December 1, 1927.

r.p.m. Following is a summary of the installed cost of the present completed station. As will be explained later, certain changes were made in the motors. The cost given does not include the expense of making these changes but is given as though the present equipment had been initially installed.

| | |
|---|---|
| 1 Pump-house building and incidental construction, i.e., small storehouse, roads, walks, grading, fencing, etc. . . | $ 3,500 |
| 2 Pumping equipment to include pumps, motors, switchboards, foundations, wire, and miscellaneous. . . . . . . . . | 16,000 |
| 3 Other station equipment, to include 5000-bbl. surge tank, gages, pipe, gates, and miscellaneous fitting and connection work. . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . | 9,000 |
| Total. . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . | $28,500 |

and keeping the station in an operating condition. When it was found that the pumps would deliver this quantity of oil, and that the line capacity was adequate, it was thought advisable to correct for the overload on the 600 hp. of motors by installing two of 400 hp. each and operating at 2300 volts.

The increased delivery is explained by the fact that the weather was warm and the oil run fresh from the field at a temperature of 75 deg. fahr. On test the oil showed an average gravity of 38 deg. and a S.U. time of 46 sec. In addition there was actually 155 ft. of fall between Henryetta and Cromwell that was only approximated in the original calculations. In order to protect the motors as much as possible the station was run with a wide-open header gate during the cooler hours of the day, and under

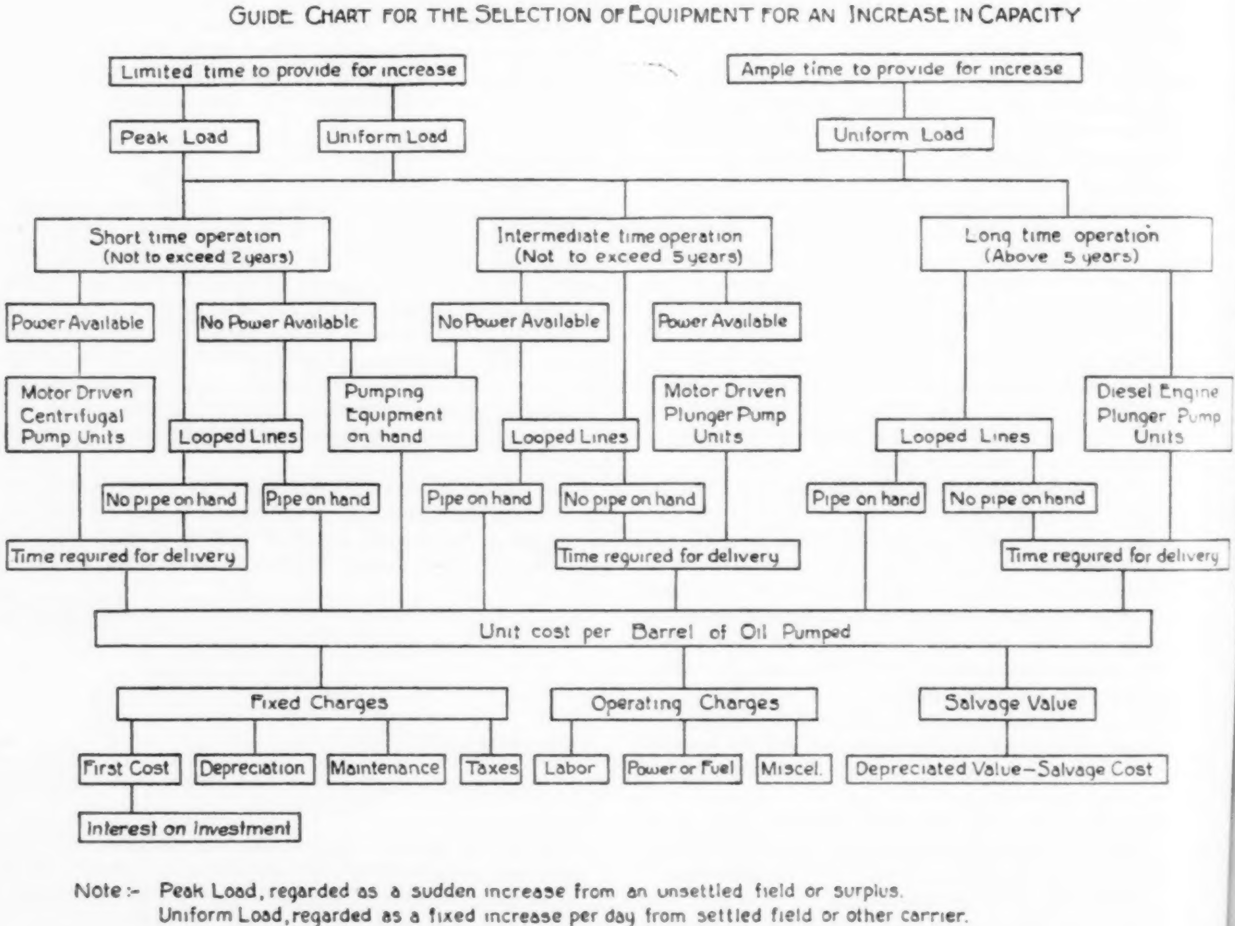

FIG. 2 GUIDE CHART FOR USE IN SELECTION OF PUMPING EQUIPMENT FOR AN INCREASE IN CAPACITY

Local construction conditions for this station were far above the average. If an estimate should be required for a similar installation remotely located and built under adverse conditions a figure of $30,000 would be approximately correct.

The installation was designed for the adverse operation usually experienced in winter pumping and was to deliver 44,000 bbl. of 38-deg. A.P.I., 75 sec. Saybolt Universal oil, at a pressure of 580 lb. Much satisfaction was experienced when the station was started the latter part of April, and it was found that the capacity exceeded that calculated for the assumed conditions. The increased delivery was very much needed, yet it could only be realized at the expense of a very severe overload on the motors. This caused no small amount of trouble in maintaining

this condition delivered around 50,000 bbl. per day at a line pressure of 535 lb. For the remainder of the time the gate was pinched down in order to raise the head and decrease the load on the motors, with a consequent reduction in delivery.

At the present time the oil has a line temperature of about 60 deg. fahr., with a S.U. viscosity of 52 sec. When the header gate is wide open, the delivery is around 51,500 bbl. per day at 580 lb., and no troublesome temperature overloads have developed such as were experienced with the 300-hp. motors.

The following is the result of a brief test made by representatives of the Oklahoma Pipe Line Company and the Oklahoma Gas and Electric Company to determine the approximate mechanical efficiency of the pumps:

TEST OF OKLAHOMA LINE COMPANY'S HENRYETTA STATION, MAY 31, 1927

*Equipment*

Two 300-hp. motors, 1750 r.p.m., 3-phase, 6-cycle, 440-volt
Two 6 × 17½ 4-stage Byron-Jackson pumps arranged in series

| Low-duty pump.... | 405 | 448 | 89.5 | 280 | 375 | 345 |
| | | | | 570 | 763 | 702 |

*Oil-Pipe-Line Data*

| Line pressure Suction | Discharge | Bbl. per hr. 12 M. to 1 P.M | Viscosity S. U. deg. | Temp. oil, deg. fahr. | Hydraulic hp. |
|---|---|---|---|---|---|
| 12 | 555 | 2057 | 46 | 75 | 466 |

*Efficiency of pump* $\frac{466}{702} \times 100 = 66.2$ per cent

NOTE: A 5000-lb. working tank was installed and the suction pressure of 12 lb. was due to the height of the oil above the level of the pumps at this period. The header gate was pinched down and the pressure given is between the discharge of the high-duty pump and the header gate.

The actual money expended for operation during the months of May, June, July, and August is as follows:

| | | |
|---|---|---|
| 1 Maintenance: | | |
| *a* Material for repairs............ | $ 99.34 | |
| *b* Labor for repairs............... | 613.49 | $ 712.83 |
| 2 Transportation Operation: | | |
| *a* Station, labor, regular.......... | 3,307.42 | |
| *b* Casual labor and misc. (i.e. waste, lamps, brooms, etc.)........... | 470.12 | |
| *c* Lubricating oil................. | 50.53 | |
| *d* Power (1.03 cent per kw-hr.).... | 14,984.44 | 18,812.51 |
| Total........................ | | $19,525.34 |

Total barrels of oil pumped during period.............5,464,002.2
Total energy used, kw-hr...............................1,454,800
Average number of barrels pumped per kilowatt-hour.........3.75
Operation and maintenance cost alone, per bbl., cents.......0.3575

With the foregoing figures as a basis, maintenance is 3.65 per cent of the total transportation cost and is at the rate of 7.8 per cent per year on the present investment of $27,500. This rate of 7.8 per cent is not a true figure; it should be slightly higher due to the fact that the present investment is greater than it was at the time the maintenance figures were taken. It must be remembered that the maintenance cost of $712.83 applies to a time when the station was being placed in operation and that many things were done that would be avoided in the future. Considering the heavy overload that was placed on the motors, it is not unreasonable to assume that the operation was abnormal in every particular. The present 400-hp. motors have not been in operation long enough for a true figure to be determined, but indications are that it will not exceed 3 per cent of the total cost as a yearly maintenance cost.

In order to arrive at an exact cost per barrel of oil pumped it is necessary to take into account the item of fixed charges. For this purpose, the useful life of the station is assumed to be 20 years and the functional depreciation to be taken care of by setting up a 4 per cent sinking fund to provide for replacement. Interest on the total investment is at the rate of 6 per cent, and taxes 3 per cent.

PUMPING COST

(Four months operation)

| | | |
|---|---|---|
| *Fixed Charges* | | |
| Interest on investment.................. | $550.00 | |
| Depreciation............................ | 307.80 | |
| Maintenance............................. | 712.83 | |
| Taxes................................... | 275.00 | |
| | | $ 1,845.63 |
| *Operating Charges* | | |
| Labor, power, and miscellaneous.................. | | $18,812.51 |
| Total.......................................... | | $20,658.14 |
| Unit cost per barrel of oil pumped, cents................. | | 0.3780 |

A comparison between the actual cost at Henryetta and an estimated cost for a motor-driven plunger-pump station of about the same capacity may not be entirely correct, but if all the items are considered some idea of the respective operating costs can be obtained.

50,000-BBL. TWO-UNIT BOOSTER STATION WITH MOTOR-DRIVEN PLUNGER-PUMP UNITS

| | |
|---|---|
| 1 Pump-house building and incidental construction....... | $12,000 |
| 2 Pumping equipment, to include two 300-hp. motors direct connected to two 25,000-bbl. triplex plunger pumps, and miscellaneous........................... | 50,000 |
| 3 Other station equipment, to include working tank and all incidentals........................................ | 13,000 |
| Total.......................................... | $75,000 |

The station is assumed to deliver an average hourly amount of 2085 bbl. of 37-deg. A.P.I., 52 sec. S.U. oil through 25 miles of single 10-in. line at a pressure of 580 lb. Efficiency of the pumps, 85 per cent, and of the motors, 93 per cent. The useful life is assumed to be 20 years, with depreciation taken care of by a 4 per cent sinking fund to provide for replacement; maintenance and taxes taken at 3 per cent and interest on the total investment at 6 per cent. Computations based on 730 hours' operation at a flat rate for power of 1.03 cent per kw-hr.

| | | |
|---|---|---|
| *Fixed Charges* | | |
| Interest on investment.................. | $ 375.00 | |
| Depreciation............................ | 209.87 | |
| Maintenance............................. | 187.50 | |
| Taxes................................... | 187.50 | |
| | | $ 959.87 |
| *Operating Charges* | | |
| Regular station labor.................... | $ 525.00 | |
| Incidental labor, lubricating oil and miscellaneous material for operation....... | 300.00 | |
| Power................................... | 3,500.09 | |
| | | $4,325.09 |
| Total.......................................... | | $5,284.96 |
| Total barrels of oil pumped in 730 hours............... | | $1,522,050 |
| Unit cost per barrel of oil pumped, cents.................. | | 0.3471 |

This would indicate that the plunger-pump station would operate 0.0309 cent, or 8 per cent per barrel cheaper than the centrifugal units. However, for short-time operation, if the centrifugal units could be delivered and installed quicker, this difference can be disregarded.

That a working tank is unnecessary is a point frequently advanced in favor of the centrifugal pump. There are instances wherein this is true, but the unqualified statement will not hold for all cases. For example, the pumps at Cromwell Station were all of the plunger type, and in case of an enforced and unforeseen shutdown at Henryetta, immediate and very destructive

pressures would be built along the line. To safeguard against this emergency, relief valves had to be placed on the discharge lines from the pumps at Cromwell. There is no question that relief valves do afford some measure of protection, but by no means should they be regarded as positive insurance against accident. Further difficulty was experienced at Henryetta due to the low-duty pump pulling a vacuum and hence working at a decided disadvantage. A surge tank was the only logical solution to the troubles, and in addition to providing adequate safety, insured a well-filled pump. Positive local control has everything in its favor, and present experience indicates that a working tank will merit the added expense and should most certainly be installed.

If conditions in the future should be similar to those described for Henryetta Station, there is no doubt that a centrifugal installation would be made. In addition to some of its other advantages, the series arrangement of pumps is very desirable. When their main-line service is terminated they may be used as individual units on local-station work where only a temporary installation is required. Not only are the units compact and comparatively light, and hence can be transported easily, but they require a minimum foundation and housing space and can be installed more quickly than any other unit of even greater capacity.

A serious drawback to the centrifugal pump, and especially with small quantities at high heads, is its low mechanical efficiency. When coupled with an electric motor as a prime mover, the rate that can be paid for power must necessarily be as low as possible. Because of this low efficiency, the power companies should not be expected to compensate for it by furnishing power at a loss. Neither should the power companies penalize the pipe lines because they use the electric motor—in itself a remarkably efficient piece of equipment. It is almost time for the rate makers to adjust their demand and standby charges to fit true conditions. Apparently sufficient consideration has not been given to the fact that pipe-line work is the exact opposite of an industry. The pipe line in general begins with a peak and grades downward; the industry usually starts with a minimum and works toward the peak. It is doubtful if one rate can ever be conceived that can apply equally to both classes of loading. Centrifugal- as well as plunger-pump manufacturers naturally desire the best possible efficiencies for their products, and competition will keep them striving for improvement. Whether they succeed or fail, before the electric motor can retain its rightful place in oil-field work some change must be made in power rates. It is realized that the whole method is relatively new and that present rates may be the nature of an experiment; yet unless there is some revision, power companies are in danger of finding themselves with ample equipment on their hands for service—and no customers.

Pipe lines have been constructed wherein all stations used motor-driven centrifugal pumps entirely, but it is unlikely that this practice will meet with much favor in the Mid-Continent Field when the rates that must be paid for power are seriously considered.

The data that have been presented for this one installation should not be used as a criterion for the acceptance or rejection of the centrifugal unit. Although not entirely defined, the centrifugal pump does have a real place in petroleum transportation, and its use under certain conditions will not only be continued but increased. However, it must be remembered that each installation is to stand on its own feet, and that the selection of any pumping equipment must be made on the basis of existing circumstances.

# Pumping Problems in Paper Mills

## Trash Pump of Recent Design That Does Not Clog When Handling High-Density Paper Stock nor Pull the Water Away From the Pulp

By HELMER N. ANDERSON,[1] ST. PAUL, MINN.

ONE of the most difficult pumping problems in paper mills is that of handling paper stock, particularly where the consistency is 3 per cent or higher. The handling of 5, 6, and $6^1/_2$ per cent paper stock is one that has caused paper-mill engineers considerable concern. For many years vertical triplex single-acting stuff pumps were used, then centrifugal pumps, and finally the non-clogging Wood trash pump came into service.

The vertical triplex stuff pumps are of the outside-packed plunger pattern. The water passages are extremely large and so designed as to give continuous flow. They are usually equipped with large bronze ball valves, which give an easy flow of the paper stock. Triplex stuff pumps have the advantage of being positive-acting machines. The result is that any paper stock that flows into the pump is practically certain of being pumped out. The pump will not clog easily, and being of the positive-displacement type, it will naturally free itself and clear the discharge line in the event that either tends to clog. The efficiency is quite high, resulting in low power consumption.

This type of pump has several disadvantages, however. In the first place, the capacities are low, so that, for example, if a total capacity of 2500 gal. per min. is desired, it would be necessary to install a battery of four or five stuff pumps. This makes the initial investment quite high, and the floor space required is sometimes enormous. In the second place, mechanical difficulties are experienced owing to wearing of gears, replacement of crossheads, pinion-shaft bearings, crankshaft bearings, and crank-pins. In the third place, some difficulty is encountered in pumping the liquid. Occasionally, exceedingly large particles or stringy, fibrous substances accompany the paper stock, and these clog the suction line or the suction-valve passages. Particles which remain on the valve seats are pounded into hard chunks, which results in poor paper. It is thought that the small transparent spots in high-finish papers, known as "shiners," are possibly the results of such masses of pulp.

### Use of Open-Impeller Centrifugal Pumps

Centrifugal pumps with enclosed impellers are used in some paper mills in place of the stuff pumps. The openings are small, with the result that the impellers clog. These pumps are not satisfactory for paper-mill pumping. Centrifugal pumps with open impellers were then designed and furnished for paper-mill work.

The theory of the open-impeller pump (Fig. 1) is that side plates are built into the casing, the pump being furnished with a double suction or single side-suction open impeller, and then any fibrous materials tending to clog would be caught between the impeller and the side plates, thus being cut up into fine enough particles to pass through the pump. The open-impeller centrifugal pump gives fairly good satisfaction, particularly if the percentage of paper stock is 3 per cent or less. This type of pump has the advantage of low initial cost and in addition will handle large capacities with fair efficiency, low power consumption, and a minimum of floor space. Furthermore, the speeds of the pumps adapt themselves for ready direct connection to electric motors.

The disadvantages of this type of pump are that the impeller vanes in the eye of the impeller are sharp, causing paper stock to lodge in the throat. More paper stock will pile up behind this, and finally the pump will become clogged. Any multivane centrifugal pump of the conventional type has a low shut-off head, and therefore the pump will not clear itself once it starts to become clogged. When paper stock is handled heavier than 5 per cent, the water tends to separate from the stock when it is being pumped. Therefore, care must be used to keep the passages straight, uniform, and with the least number of separate channels. The conventional open-impeller pump usually has

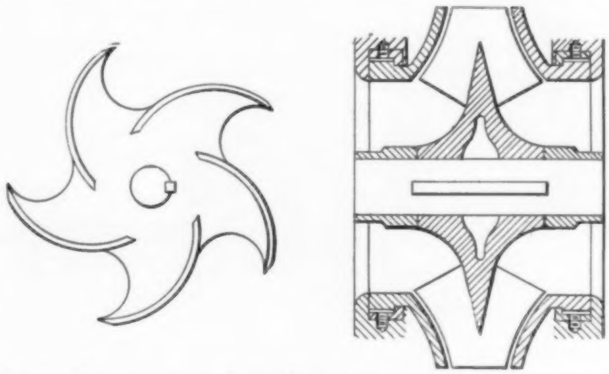

Fig. 1 Conventional Sharp-Blade Open Impeller, Double Suction, With Side Plates

(At the left is shown the side view, and at the right is a sectional view.)

five, six, or seven vanes. This tends to split the fluid into so many separate passages that the water separates from the paper stock, causing the pump to discharge water and some stock, but leaving a portion of the paper stock to pile up in the suction openings.

One of the recent developments in pumps for handling paper stock is the Fairbanks-Morse Wood stock pump. This machine, known as the Wood trash pump, was designed by Mr. A. B. Wood, of the New Orleans Sewerage and Water Board. Mr. Wood has had considerable experience in the very unusual sewage-pumping problems of the City of New Orleans, La. These convinced him that the standard open-impeller centrifugal pump was not satisfactory for the pumping of sewage and other large particles owing to the fact that it clogged continually. Mr. Wood set out to develop a pump that would pass solids practically as large as the discharge and suction openings of the pump and that would handle large solids, twigs, rags, roots, string, and other fibrous material without clogging. He desired a pump with a very steep head-capacity characteristic and with a strong coughing action. This would tend to build up sufficient pressure before the flow would stop so as to clear the discharge line and pump any particles through that might tend to clog. He also desired a unit that would be readily cleanable in the event that extremely large, irregular particles became stuck in the pump and one that would develop a reasonable efficiency over a wide range of capacities.

[1] Manager Pump and Electrical Dept., Fairbanks, Morse & Co.

Contributed by the Printing Industries Division for presentation at the Summer Meeting, St. Paul-Minneapolis, Minn., August 27 to 30, 1928, of The American Society of Mechanical Engineers.

### First Wood Trash Pump

Mr. Wood's first trash pump was a 14-in. unit installed for dredging a sawmill logging pond at Laurel, Mass. This pump gave unusual satisfaction, and the only difficulty encountered

Fig. 2 Wood Pump Impellers

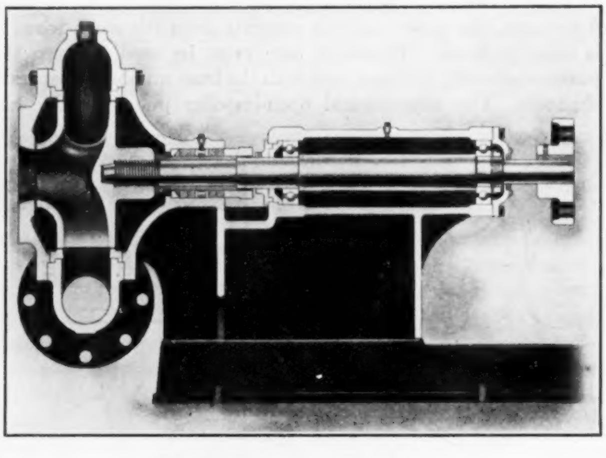

Fig. 3 Section of Wood Pump

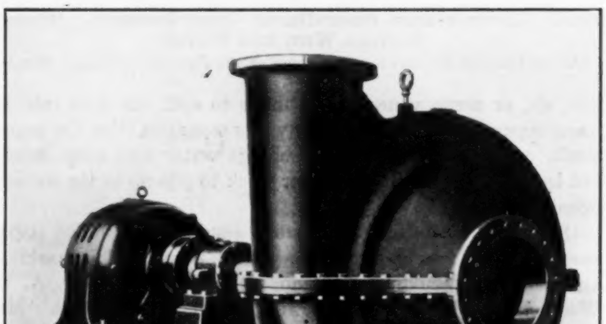

Fig. 4 Horizontal Trash Pump Direct-Connected to Motor

was that the pump endeavored to pick up particles larger than the suction pipe would handle. Such trouble could have been eliminated had a cutter-head or agitator been used to break up the trash. Mr. Wood then designed a 22-in. trash pump and installed it on the dredge *Texas*, the property of the Atlantic, Gulf & Pacific Company, and leased to the Board of Port Commissioners of New Orleans. The pump was driven by a 750-hp. engine, and the complete outfit was placed in operation excavating a canal through a cypress swamp.

Mr. Wood, after these two experimental efforts, then designed and built Wood trash pumps in sizes from 3 in. to 30 in. A large number of these pumps were installed in the City of New Orleans, in the Sanitary District of Chicago, and in other large lift stations and sewage disposal plants throughout the country. However, there is little to indicate that any of these pumps were originally used for handling paper stock.

Fairbanks, Morse & Co., a little over three years ago, secured

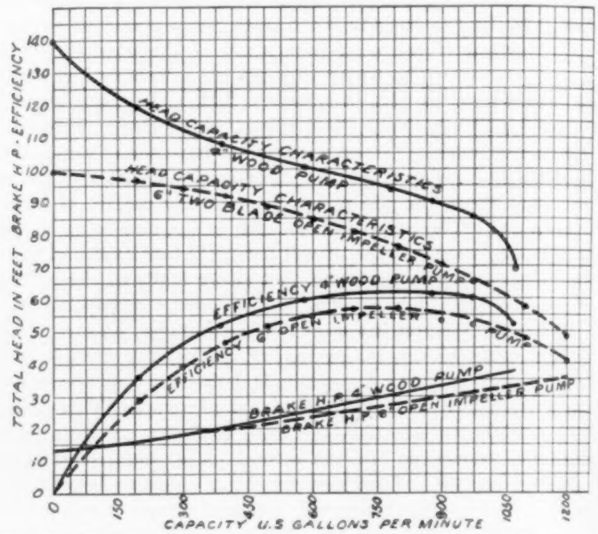

Fig. 5 Comparative Performance of a 4-In. Wood Pump and a 6-In. Pump Having Two-Blade Open Impeller

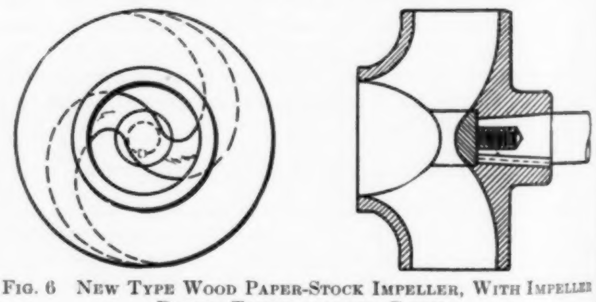

Fig. 6 New Type Wood Paper-Stock Impeller, With Impeller Blades Tapered to the Center

the manufacturing and selling rights under the Wood patents and also obtained the consulting engineering services of Mr. Wood. Thereupon its sales organizations presented many new and interesting industrial problems for the application of Wood pumps, among the most important of which was the pumping of paper stock.

To all outward appearances, the Wood trash pumps resemble the standard side-suction centrifugal pump intended for heavy duty, but the impeller is radically different. It has two vanes so designed as to give absolute mechanical and hydraulic balance. At the entrance, the blades are rounded and the sides or shrouds are filleted, so that throughout the impeller water ways there are no sharp edges, corners, or projections on which materials may catch or clog. The blade gradually tapers to a narrow edge at the outer periphery of the impeller, and the blade and periphery are very smooth (Fig. 2).

The tapering action of the impeller blade, with its low discharge angle, exerts a powerful action on fluids and materials that are being discharged. This crowds out any substance which might tend to clog in the pump; even large solids of irregular shapes are easily expelled. A given particle of material is in contact with the impeller a relatively long period of time. This gives the Wood pump an extremely sharp characteristic curve. The shut-off head is usually double the head at the point of maximum efficiency.

Since the impeller is of the enclosed type, foreign matter does not come in contact with stationary side plates such as are necessary on the older style of open-impeller centrifugal pump. The liquid is promptly discharged through one of the large ports directly into the volute. A saving in power with increased efficiency is thus effected on this type of pump (Figs. 3 and 4). An easy way of visualizing the action of the Wood trash pump is to consider an ordinary pipe tee whirling, drawing the liquid into the center and discharging it from both ends of the tee.

Fig. 5 shows the comparative performance of a 4-in. Wood pump and a 6-in. open-impeller pump of the older design. Both pumps are equipped with impellers 11 in. in diameter and both were tested at a speed of 1750 r.p.m. by the same Sprague dynamometer. The solid lines indicate the characteristic of the 4-in. Wood pump and the broken lines indicate the characteristic of the 6-in. open-impeller pump.

It is interesting to note that the 4-in. Wood pump has a shut-off head of 140 ft. as compared with a 99-ft. shut-off head as made by the open-impeller pump. The wedging action owing to the long tapered vanes of the Wood pumps is the cause of this larger shut-off head. The efficiency of the 4-in. Wood pump is better than that of the 6-in. open-impeller pump, the capacity of the 4-in. pump being practically the same as the 6-in.

### Tendency of Water to Separate

After several Wood pumps had been applied to the pumping of paper stock, it was found this type eliminated many of the difficulties, except that when handling 6 or $6^1/_2$ per cent paper stock the water tended to separate from the stock. When coarse materials such as bagasse are being pumped, this tendency to pull the water away from the stock is very pronounced. This was given serious study by Mr. M. B. MacNeille, manager of the pump division, Fairbanks, Morse & Co., Chicago, and by Mr. Wood, and they came to the conclusion that the heavier stocks, such as high-density kraft, could be handled more effectively if the impeller blades were brought back into the impeller eye and tapered to the center of the hub. The blades could then take hold of this heavy material in the very center of the shaft and immediately begin forcing it outward toward the periphery (Fig. 6). This new type of impeller has been found very effective.

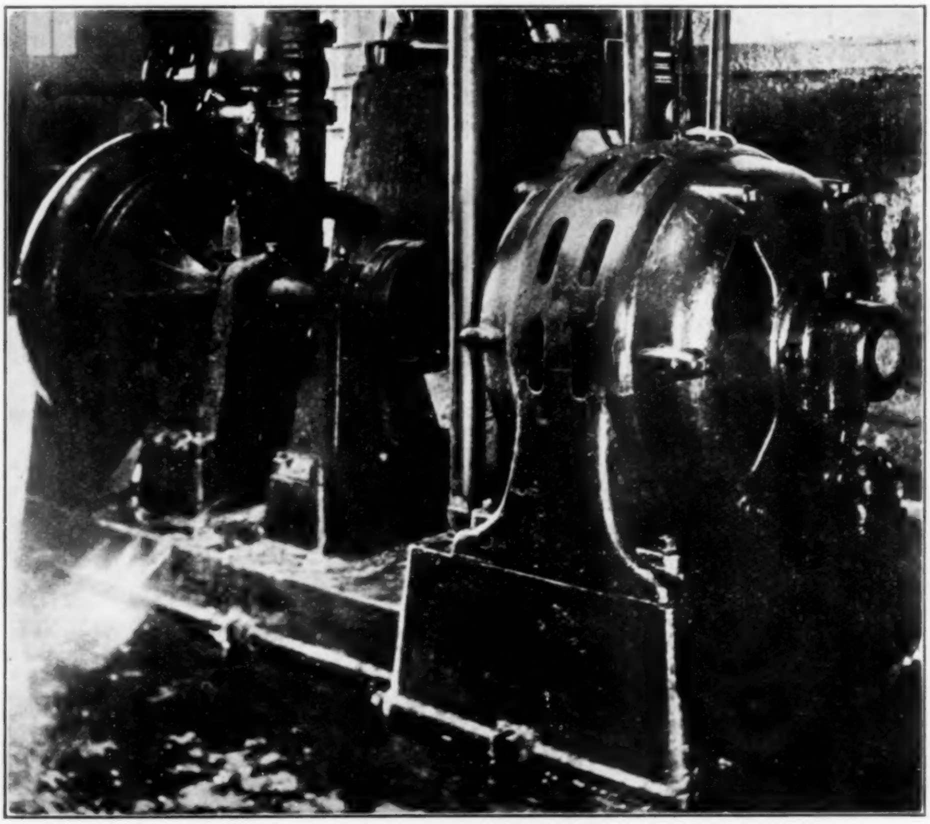

Fig. 7. An 8-In. Wood Pump With 75-Hp. Motor at Eddy Paper Company, Three Rivers, Mich.

A large number of the new Wood pumps with the special stock impeller have been placed in operation. One interesting installation is an 8-in. pump direct-connected to a 75-hp. 720-r.p.m. motor installed in the Eddy Paper Mill at Three Rivers, Mich., for pumping stock from a stock chest to a battery of beaters (Fig. 7). This unit is in daily use and has never had a shutdown caused by clogging, although the stock is not particularly clean. The material handled is of various grades; frequently, the consistency has been over 6 per cent. The total head pumped against, including friction, is 65 ft., and tests have shown discharges considerably in excess of 2500 gal. per min. at this head.

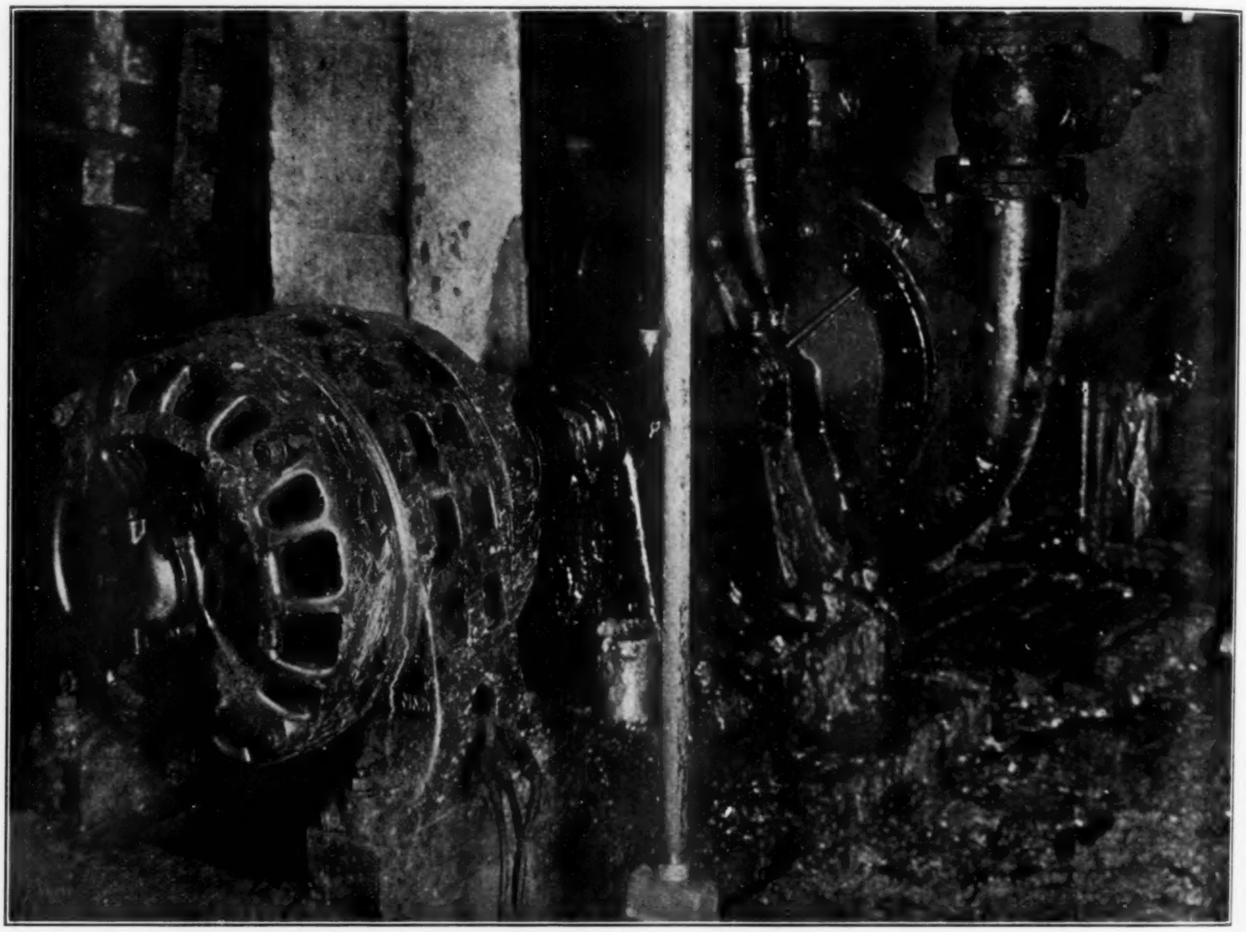

Fig. 9 A 6-In. Wood Pump at Bogalusa Paper Company, Bogalusa, La.

Fig. 10 A 4-In. Wood Stock Pump in Use at Brown Paper Company Plant, Monroe, La.

The Flambeau Paper Company, Park Falls, Wis., has installed a 6-in. horizontal Wood paper-stock pump, direct-connected to a 25-hp. 900-r.p.m. motor. This pump operates against a 70-ft. head and handles 6 per cent stock very satisfactorily. The Waldorf Paper Products Company, St. Paul, Minn., recently installed a 6-in. Wood trash pump arranged for belt drive to a lineshaft. This pump handles 5 per cent paper stock effectively. It delivers 750 gal. per min. against 110-ft. total head which includes pipe friction losses.

Another problem encountered in paper stock pumping is the determination of the correct size of motor required to drive a pump when handling stock of a certain density under a given set of conditions. The power requirements depend upon many factors, some of which are uncertain at present. The capacity desired and static head, or vertical lift, are easy to ascertain. However, the friction losses in the pipe lines are unusually difficult to estimate. Friction tables are available on stocks 4 per cent lighter, but friction losses of heavier stocks must be estimated. For that reason, pumps with steep characteristics will usually prevent the disappointment of obtaining a pump which delivers less capacity than desired. If a pump with a flat characteristic is installed, a few feet more or less may cause the capacity to be seriously reduced, or else to be considerably greater than required.

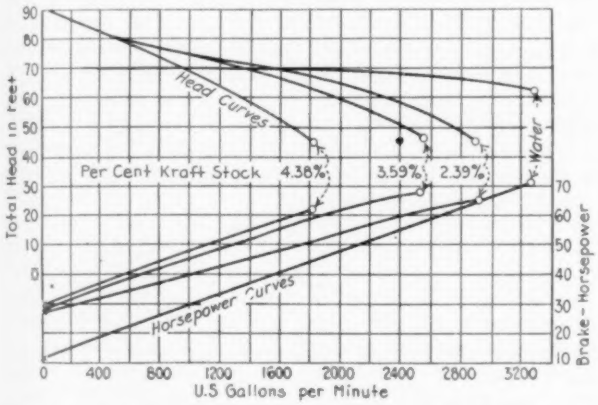

Fig. 8 Comparative Performance of an 8-In. Wood Pump Handling Stock of Various Densities and Handling Water

### Recent Tests Show Horsepower Requirements

Recently a series of tests were run at the Thilmany Pulp & Paper Company at Kaukauna, Wis., on an 8-in. Wood paper-stock pump. A chart has been prepared showing the comparative performance of this pump handling stock of various consistencies as compared with the pumping of water (Fig.8 ). This chart is an interesting study, and undoubtedly the relation will hold more or less for other sizes of pumps. The maximum horsepower required for pumping water exceeds that required for pumping any consistency of paper stock. This may seem unreasonable, but it must be remembered that the capacity of the pump is limited directly in ratio with the heaviness of the stock. The obvious conclusion is that if the size of motor is determined from the maximum horsepower required when pumping water, then no danger from overloads can result, regardless of the consistency of the stock pumped. As more experiments are carried out, more accurate means of determining friction losses and horsepower requirements will result.

The Bogalusa Paper Company, Bogalusa, La., recently installed a 3-in. Wood stock pump direct-connected to an enclosed ventilated motor. This pump delivers 400 gal. per min. of lime-soda solution against a total head of 40 ft. This same company has a 6-in. Wood stock pump direct-connected to a 25-hp. ball-bearing squirrel-cage motor, which handles 300 gal. per min., of 6 per cent sulphite kraft stock against a 72-ft. head (Fig. 9). The Brown Paper Company, Monroe, La., has a 4-in. Wood stock pump working under unusually severe conditions. This pump is direct-connected to a 10-hp. ball-bearing squirrel-cage motor. It handles lime sludge and caustic liquor. Fig. 10 shows the installation of this unit.

The experience encountered in paper stock pumping, together with suggestions and reports given by various paper-mill engineers, have resulted in some additional refinements. The casing on new stock pumps is being split on an angle of 45 degrees so as to facilitate quick inspection. The impeller may be constructed with three vanes where required. Finally, a pulp seal is now being furnished on all wood stock pumps, so as to prevent pulp from working into the stuffing box.

Considerable information on paper-stock pumping is still necessary, particularly knowledge of power requirements. The most economical sizes and kinds of piping, together with friction losses encountered in the pumping of heavy paper stock, have yet to be determined. The most important is the friction of the material itself and it is hoped that additional data and research work will be available in the near future.

### Resume of Advantages

The Wood trash pump has the advantages of the triplex stuff pump in that the efficiencies are good and the power consumption is low. It has eliminated the mechanical troubles such as replacement of gears, valves, pinion-shaft and crankshaft bearings, and plungers, also the difficulties owing to clogging in the passages and to valves pounding portions of the paper stock into lumps.

The Wood trash pump also has the advantages of the centrifugal pump in that the capacities handled are large, the floor space required is small, and the investment is not excessive. The Wood paper-stock pump will not clog when pumping high-density paper stock, string, and other foreign particles such as hats, rags, and sticks, which are encountered in certain classes of paper-stock pumping. With the new type of tapering vanes, no further difficulty owing to the separation of water from the stock is encountered.

## Discussion

M. M. Klosson.[2] This paper was heard with pleasure, first because of the writer's interest in all pumping problems, and second because of his connections with one of the oldest centrifugal-pump manufacturers making extensive investigations of various perplexing pumping problems, one of which has been the pumping of high-density stock. This company manufactures the non-clogging and also the standard open and enclosed impeller, single and double suction, solid and split-shell types of paper-stock pumps, and from experience the writer finds that this paper may give some wrong conceptions of the actual results obtained with different types of paper-stock pumps.

This company manufactures all the various types of pumps, and therefore makes no effort to urge any one particular type, but instead recommends the type of pump best suited for the particular conditions of each installation. Each type of pump has certain advantages which must be considered in order to obtain the most satisfactory and economical pumping unit.

The non-clogging pump, such as the Wood design mentioned by the author, has no special advantages, in a majority of the cases, over a properly designed open- or enclosed-type, single- or double-suction paper-stock pump. The non-clogging type

[2] Chief Centrifugal Pump Engineer, Buffalo Steam Pump Co., North Tonawanda, N. Y. Mem. A.S.M.E.

of pump, however, is the only type of pump that should be used under conditions of operation where long fiber or rags, string, etc., are to be handled; such, for instance, as are encountered in paper-board mills. There is no advantage in the use of non-clogging pumps in ordinary service where refined or even raw sulphite or paper stock is to be handled. The conventional type of a single- or double-suction pump, properly designed, usually will prove more efficient, equally reliable, and in general more economical.

In order to make this clear the writer made some comparisons of actual tests made by one of the largest paper mills in this

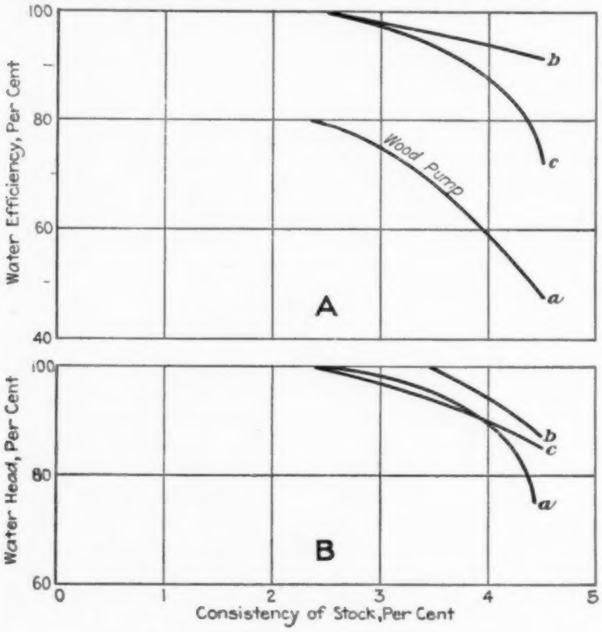

Fig. 11 Curves of Stock Losses

(Curve *a*, 8 in. Wood pump; *b*, 8-in. single-suction Buffalo pump; *c*, 8-in. double-suction Buffalo pump—based on constant capacity and wastehead.)

country. These tests were made on both single- and double-suction, open and enclosed types of impellers. The results are plotted in Fig. 11 against the performance on an 8-in. Wood pump as given by the author.

It will be seen from the curves that the loss of head, in spite of the liberal area claimed for the non-clogging Wood pump, is greater than that for the conventional type of pump. It will also be seen that the loss of efficiency is greater; consequently, less useful work is done for the power consumed than that for either a single- or a double-suction pump, both of which have considerably smaller yet liberal and correct areas.

These curves also indicate that beyond certain liberal water ways there is a disadvantage with a loss of efficiency if the size of water ways is made too large for the given conditions.

The author makes a statement to the effect that the non-clogging pump is better adapted for handling stock of high consistency than is a conventional type of pump. A study of the curves (Fig. 11, *A* and *B*) reveals the fact that the stock losses are greater in a non-clogging pump than they are in a properly designed conventional type of pump.

It will be seen that this particular Wood pump, based on Fig. 8, is capable of delivering 3200 g.p.m. of water against about 64 ft. total head and cannot deliver more than 1200 g.p.m. of 4.38 per cent stock against about the same head. In other words, the pump capacity decreased about 62.5 per cent for 4.38 per cent stock. It is clearly seen that if still higher consistency of stock was to be handled by this pump the capacity would decrease still further. In view of this, it is not clear why the author thinks the Wood pump is better suited for handling stock of higher consistency.

Attention is now called to Fig. 5, showing comparative results of a 4-in. Wood pump and a 6-in. conventional type of pump. The fact that the impellers are of the same diameter and operating at the same speed does not indicate anything nor make a true comparison. In order to make a direct comparison between pumps, it is absolutely necessary to have the shells designed for the same impeller diameter and the discharge volutes in each case perfectly alike. The impeller does not influence the pump efficiency as much as does the casing; consequently, the comparison as shown in Fig. 5 cannot be considered of much significance, and without complete information it may be very misleading. Had there been less variation in the design of the two pumps there would have been less test difference between them, and probably the efficiency would have been higher in the 6-in. pump. High water efficiency does not necessarily mean high stock efficiency, for with proper understanding and selection it is possible to have a pump showing a low water efficiency, but which will, however, have a higher stock efficiency than that of a high water efficiency pump.

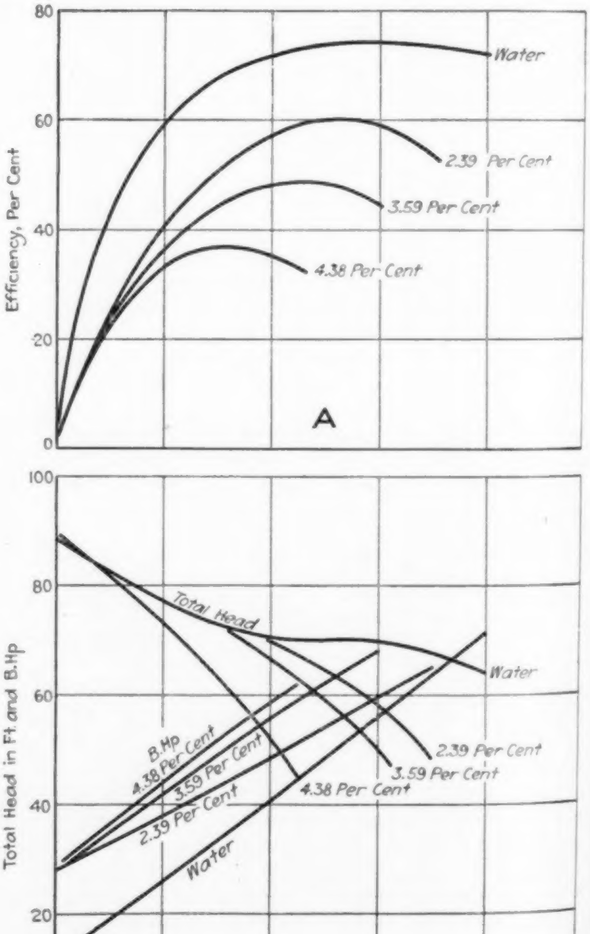

Fig. 12 Comparative Performance of an 8-In. Wood Pump, Based on Fig. 8

It is seen from Fig. 5 that the maximum efficiency corresponds to about 93 ft. head and the shut-off 140 ft., or only about 50 per cent higher, and from Fig. 8 the point of maximum efficiency corresponds to about 70 ft. head and shut-off 90 ft. A statement is made that the shut-off head in the Wood pump is usually double the head at the point of maximum efficiency. The variation between the actual results and the statement requires some explanation.

In reference to the types of head and capacity curves, the writer wishes to add that a steep characteristic curve can be produced with almost any type of pump. In the writer's opinion, pumps with a compromise characteristic—that is, not too steep nor too flat—are best adapted for average operating conditions. A pump with extremely steep characteristic, such as claimed as a standard for a Wood pump, but not shown by the curves, will not usually prevent clogging, as stated by the author. The clogging usually takes place in the direction of flow, and a higher shut-off head, depending on the pipe line, may tend to pack the substance in the pipe and cause a more serious clogging trouble. When the pipe line is clogged on the discharge side of the pump, it is best to clear the pipe by pressure, in the direction opposite to the normal flow.

Another point that must not be overlooked is that a pump with an extremely high shut-off head, with everything else being equal, will consume more power at partial loads than a pump with a flatter characteristic, and consequently with more waste of power.

The description and cut of the special type impeller shown in Fig. 6 and the results obtained with it are all interesting as they confirm the writer's experience of several years ago when a special impeller was designed with the vanes extending into the inlet eye of the runner, and thus the similar troubles were overcome, as has recently been experienced with the original Wood-type impeller.

The writer has made up from Fig. 8 another curve, Fig. 12, which includes efficiencies so that the readers can obtain the necessary information directly. The curves indicate clearly the loss of head and efficiency and the increase of power when pumping paper stock over that required for a corresponding water point. The curve also indicates what the pump user may expect if the pump is selected on the basis of water without considering losses that will take place when pumping stock.

This Fig. 12 clearly indicates that a pump should not be selected on a water but rather on a stock performance, as water performance and especially water efficiency is a very misleading basis; and in proof of this statement it will be noted that the pump delivers 1800 g.p.m. of water against about 70 ft. total head, and when handling 1800 g.p.m. of 4.38 per cent stock it develops only 45 ft. stock head. In other words, there is a 25-ft. loss of head and about 55 per cent loss of water efficiency. Actually the pump efficiency is only about $32^1/_2$ per cent when handling 4.38 per cent stock and about 73 per cent when handling water.

In comparing the results shown in Fig. 5 of a 4-in. Wood pump against a 6-in. open-impeller pump, it will be noted that theauthor credits the higher shut-off head to long tapering vanes of the non-clogging impeller. This statement would lead one to believe that there is a "special new" hydraulic law governing the head developed in a non-clogging Wood pump. This is not the case, however, as the basic laws of hydraulics are the same for all centrifugal pumps, whether of the Wood or other types.

The author says that the maximum horsepower required for pumping water exceeds that required for pumping any consistency of stock; but one must not overlook the fact that such a selection will not meet the conditions of installations, nor will a steep characteristic in such a case prevent disappointment, because a definite capacity corresponds to every pressure developed by a centrifugal pump, as is clearly indicated in Fig. 8. If the stock pump selected on a water basis is to deliver 1800 g.p.m. of stock against a 70-ft. head, it would fail to deliver more than about 1000 g.p.m.

A further study of Fig. 8 will reveal another point that must be charged against the non-clogging Wood pump and especially against the construction. It will be noted that the pump requires 41 b.h.p. to deliver 1600 g.p.m. of water, but the power required is increased to 58 hp., or about 41 per cent, when 1600 g.p.m. of 4.38 per cent stock is delivered against a much lower head. The writer has checked many tests on paper-stock pumps of various types and has never found one that showed such a high increase of power as tests indicate for the Wood pump.

The author says that information regarding pump losses is meager, and this is probably true, but by a consistent study of these problems one is able to separate the various stock losses that take place in a pump and so to solve without much guesswork the problems as they present themselves. The writer trusts that his discussion of the author's paper may be of some value to those interested in the pumping of paper stock and other similar substances.

### Author's Closure

The paper endeavored to point out some of the advantages of the Fairbanks-Morse Wood's patent paper-stock pump when applied to the pumping of high-density paper stock. Mr. Klosson in his discussion mentions that his concern manufactures a non-clogging pump as well as the standard open- and enclosed-impeller pumps. In the first place, to the author's knowledge, the Buffalo non-clogging pump cannot accurately be so named as compared to the Wood pump. Their 6-in. pump has only a 2-in. width of impeller, whereas the same size Wood pump will pass a 5-in. sphere. Furthermore, the Wood pump has the impeller vanes rounded at the entrance so as to prevent clogging of rags, string, and other fibrous material.

Mr. Klosson states that the non-clogging pump is the only type to be used when handling heavy stocks and those containing rags, string, etc. As a matter of fact, the main purpose of the paper was to present the fact that the Wood trash pump would not clog when handling high-density stock nor pull the water away from the stock.

It is true that an open-impeller pump, with close clearances, will sometimes have a greater efficiency when handling light stocks than will the two-vane Wood pump. This is not so true, however, when compared with recent results obtained with the new three-vane Wood pump.

Of far more importance than efficiency are reliability and continuity of operation, low maintenance cost, and prevention of shut-downs. An open-impeller pump, because of the rubbing action of the material between the impeller and side plates, will have greater repairs than will the enclosed-impeller Wood pump with large openings and no close clearances.

The Wood pump is primarily designed for the pumping of fluids containing large amounts of foreign substances. The author made the statement that usually (of course not always) the shut-off head is twice the head at maximum efficiency point. Referring to Fig. 5, we note that the shut-off head is 60 per cent greater, but in Fig. 8 we note that the head at maximum efficiency when handling stock is 45 ft. with a shut-off head of 90 ft., or exactly double.

With the introduction of the three-vane Wood paper-stock pump and with the vanes tapered toward the center of the hub, there is much less drop in capacity and head than in former two-vane units, resulting in considerably greater efficiencies than those shown in Fig. 8.

The author made the statement that pipe-friction losses

(not pump losses) are as yet difficult to determine owing to lack of actual experimental data, to which Mr. Klosson concurs. Considerable study is required with reference to pipe-friction losses when handling 5 or 6 per cent stock. Without this the pump builder is handicapped in ascertaining the correct pumping head. The author therefore repeats that for the present, without accurate knowledge of the total dynamic head, a Wood pump with its steep characteristic curve will often prevent disappointment to paper-mill engineers who desire to move a given amount of heavy stock from one elevation to another.

# Pulp-Grinder Control Reduces Paper Costs

By ADOLPH F. MEYER,[1] MINNEAPOLIS, MINN.

*Large amounts of power are used in grinding wood pulp for use in paper, and unregulated pulp-grinder loads vary greatly and rapidly. This paper describes a governor for controlling waterwheel-driven and motor-driven pulp grinders and points out the economies effected through such regulation. Governors operating on the waterwheel gate are impracticable and undesirable for the purpose of controlling the speed of waterwheels driving pulp grinders. The Meyer governor maintains uniform friction load, and thereby uniform speed, by varying the pressure with which the wood is pushed against the grindstones. As a speed regulator for waterwheel-driven grinders it is actuated by turbine speed. As a load regulator for motor-driven grinders it is actuated by the load on the grinder motors, which it maintains constant. This paper also describes a master regulator by means of which the total kilowatt load on a given system is maintained constant. The master regulator functions through the load regulators on the individual grinder motors. It automatically distributes the increases or decreases in total grinder load necessitated by decreases or increases in load elsewhere in the system, equally or in any other desired proportion, among the several motors by automatically changing the load setting of the individual regulators. The rate of action of the master regulator to correct load changes is proportional to the variation of the total load from normal at the given moment. No electrical contacts or relays are used, yet great sensitiveness is secured.*

WASTE serves no man. In the final analysis, the elimination of waste is the primary source of progress. Instead of attacking the problem of living by means of his hands, as primitive man did, civilized man conserves his limited physical powers and puts his mind at work to coax from old Mother Nature the power genii to do the hard physical work for him. The ways and means of putting these power genii to work efficiently and economically constitute one of the largest fields of man's present activities.

In the production of paper as in all other fields much attention has recently been given to the elimination of waste in all its forms: waste of human life and limb, waste of human effort, and waste of nature's forces and materials. The author will deal primarily with means for reducing paper costs through the conservation and the more economical utilization of nature's forces.

For every ton of newsprint produced about 2400 hp-hr. of power is consumed. Power may be conserved in the production of the groundwood constituting about three-fourths of the newsprint, and the cost of power used in all the pulp and paper mill operations may be reduced by lowering peak demands and filling in the valleys.

## Control of Waterwheel-Driven Grinders

When groundwood is produced with waterwheel-driven grinders, it is essential to maintain the most efficient waterwheel speeds. At first, pressure regulating valves were used. Next, attempts were made to govern by means of centrifugal pumps driven from the turbine shaft. When the speed increased, the pump produced higher pressures, and vice versa. With this type of installation a small measure of control was secured. At least, runaway speeds and the complete stopping of the line were prevented.

Were it not for the fact that the water pressure in the grinder cylinders does not represent the effective pressure of the wood against the grindstone and that the number of pockets in use, the size and character of wood ground, the grindstone surface, and the head and gate opening all vary from time to time, pumps driven from the turbine shaft could have performed a better job of speed control. Today over three-quarters of all the groundwood produced with hand-fed pocket grinders is produced with grinders controlled by Meyer governors. These governors not only force the waterwheels to run at the desired speed, but they permit a degree of control over the quality of the pulp produced that can be secured in no other way.

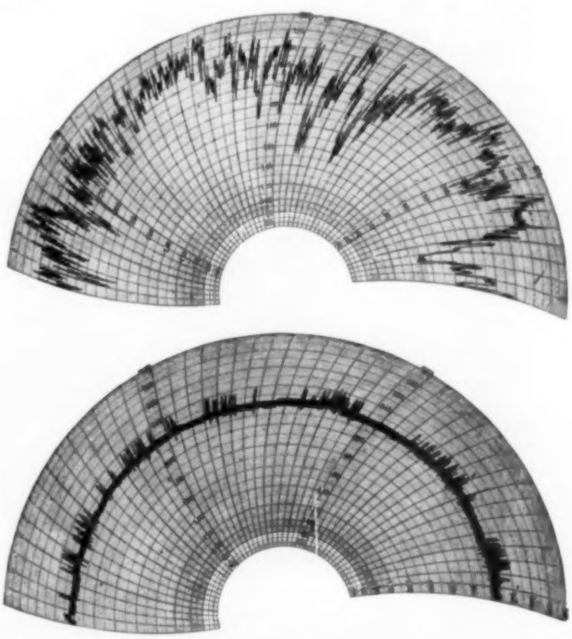

Fig. 1 Typical Tachometer Charts
(Showing speed of waterwheel-driven pulp grinders before and after installation of Meyer governor.)

The final test of whether the groundwood produced is suitable for a given paper is not the blue glass, the freeness tester, the microscope, or the lantern, however useful or necessary these and other pieces of test apparatus may be, but the paper machine; and the final test of the paper made by that machine is the printing press. This, however, does not mean that unfavorable conditions in the printing establishments may not ruin the best paper.

The extent to which Meyer governors have come into use in the mills grinding pulp for news, hanging, catalog, tissue, and book papers in the United States and Canada is in itself proof of the fact that they facilitate the economical production of the desired kind of groundwood.

## Construction of Speed Regulator

The Meyer speed regulator for waterwheel-driven grinders was designed for the severe conditions of the grinder room. Those who are familiar with the slop and the dirt of the average pulp mill realize that it is no engine room or hydro station.

[1] Consulting Engineer, Meyer Governor Co. Formerly Associate Professor of Hydraulic Engineering, University of Minnesota. Mem. A.S.M.E.

Contributed by the Printing Industries Division and presented at the Summer Meeting, St. Paul-Minneapolis, Minn., August 27 to 30, 1928, of the American Society of Mechanical Engineers.

This governor is driven by roller chain because in many mills water is continually dripping or even flowing on the drive, making the use of a belt impracticable. Although essentially the governor is extremely simple, yet the details of the design are of the utmost importance since it is a "functional" rather than a "relay" type of machine. An increase in the speed of the waterwheel driving the pulp grinders increases the speed of a rotor producing fluid pressure in a closed chamber, and vice versa. This pressure acting on a large disk and diaphragm produces a force of about 1200 lb., which takes the place of the ordinary hand wheel in adjusting the pressure regulating valve of the governor for a higher or a lower pressure as the speed increases or decreases. By proper attention to details it has been possible to produce large pressure changes with small speed changes without causing hunting.

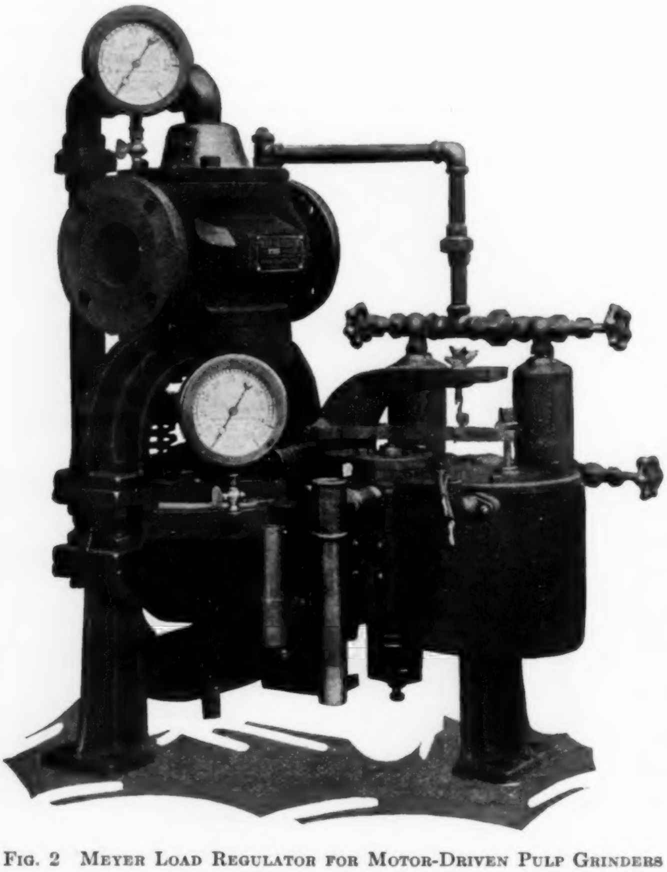

Fig. 2 Meyer Load Regulator for Motor-Driven Pulp Grinders

The valve of this governor is a patented design and is built of Hy-ten-sl bronze. It consists essentially of two sharp-edged, balanced disks closing on flat seats. Dirt will not cause binding. Dynamic effects are practically eliminated. And the valves close remarkably well even after two or three years of wear, when they should have the edges and seats redressed.

Since the governor must operate continuously and since maintenance of small machinery in the grinder room is usually rather lax, ball bearings, gears, and shafts are used that have a rated capacity of about 10 hp., even though the governors require only about half a horsepower to operate them. These parts and their surrounding case, equivalent to the automobile transmission, are designed for an equivalent automobile life of over half a million miles. Each ball bearing is enclosed in a separate casing and supported by a large plain bearing which will come into action if the ball bearing accidentally fails or is not replaced when worn. No gear lubricant can come in contact with the ball bearings. The 600-W used in the gear case is changed after the equivalent of about 25,000 miles of automobile life.

The rotor of the governor produces pressure through centrifugal action, but no space is provided which would permit vortex action as in the centrifugal pump casing. The result is practically instantaneous action without inertia effects. It is sensitive to speed changes occurring several times a second.

Fig. 1 shows typical tachometer charts of the speed of water-wheel-driven pulp grinders before and after the installation of Meyer governors. Besides forcing the waterwheels to run at their most efficient speeds, and thereby increasing the pump output on an average by 10 per cent at no cost but the price of the wood ground, and with consequent reduction in paper cost, these governors also practically eliminate grindstone breakage with the accompanying danger to the men and damage to the grinders.

In most of the pulp mills now being built the grinders are driven by electric motors. Old waterwheel installations cannot economically be electrified except in those mills where the pulp cannot economically be pumped to the paper mill and freight charges are very high. Waterwheels controlled by Meyer governors can deliver to the pulp grinders more power than the same wheels could deliver to electric generators because, by means of this governor, the waterwheel can be run at its most efficient speed for all heads and gate openings, instead of at constant speed at all times. In addition the losses in the generator, motor, and transmission line, and the fixed charges on the additional investment are eliminated. On the other hand, if the pulp cannot be pumped, the cost of lapping, shipping, and beating up again must be charged against the direct-driven installation. Moreover, slush pulp possesses certain advantages.

### Types of Grinders

The ordinary pocket grinder requires 500 to 600 hp. to drive it. Usually one motor drives several grindstones. Most of the old grinders are fed by hand. The large ones, requiring about 1000 hp. each, are fed automatically. Either two pockets fed intermittently by hydraulic cylinders or one large pocket fed continuously by means of chains are used in these grinders. The latest development is the Read grinder, a mammoth machine with chain feed propelled by hydraulic cylinders controlled by a Meyer load regulator. A special chain construction is used on the side of the pockets to eliminate binding, and the direct hydraulic drive for the feed chains insures rapid follow-up capacity in case of slippage or readjustment in the wood.

### Construction of Load Regulator

The Meyer load regulator is designed for use on all types of pocket and hydraulic-feed grinders driven by motors. It maintains uniform motor load by varying the water pressure in the cylinders that force the wood against the grindstones. It is actuated by a large solenoid which exerts a normal pull of 6 to 8 lb. This pull is opposed by a spring by means of which the motor load is set for any desired value. The solenoid and spring oppose each other in pulling on a lever that operates a balanced pilot valve which controls the pressure-regulating valve of the governor and thereby the pressure of the wood against the grindstones. Since this regulator, like the speed regulator previously described, is of the "functional" as opposed to the "relay" type, the proportioning of the parts is of the utmost importance.

By reducing the travel of the plunger of the alternating-cur-

rent solenoid to a few hundredths of an inch, the variation in pull with position of plunger is negatived. The vibration of the plunger keeps the several parts, that have only a few thousandths of an inch travel, from sticking. No contacts are used. The principal advantage of the "functional" as against the "relay" type of regulator is that the former makes a response proportional to the impulse, and action is practically instantaneous. A minor disadvantage is that there must always remain a small residual, uncorrected impulse, which is proportional to the response demanded. Otherwise there would be hunting.

### Load Control Secured

Fig. 2 shows the Meyer load regulator, and Fig. 3 gives typical charts showing how the load curves from the grinder motors were straightened out through regulation. After uniform loads are maintained on the individual grinder motors, the cost of power, and therefore of the paper produced, can be still further reduced by distributing load changes necessitated by other processes in the pulp and paper mill, or variations in miscellaneous light and power or traction loads elsewhere in the system, among the grinder motors so as to keep the total system load constant

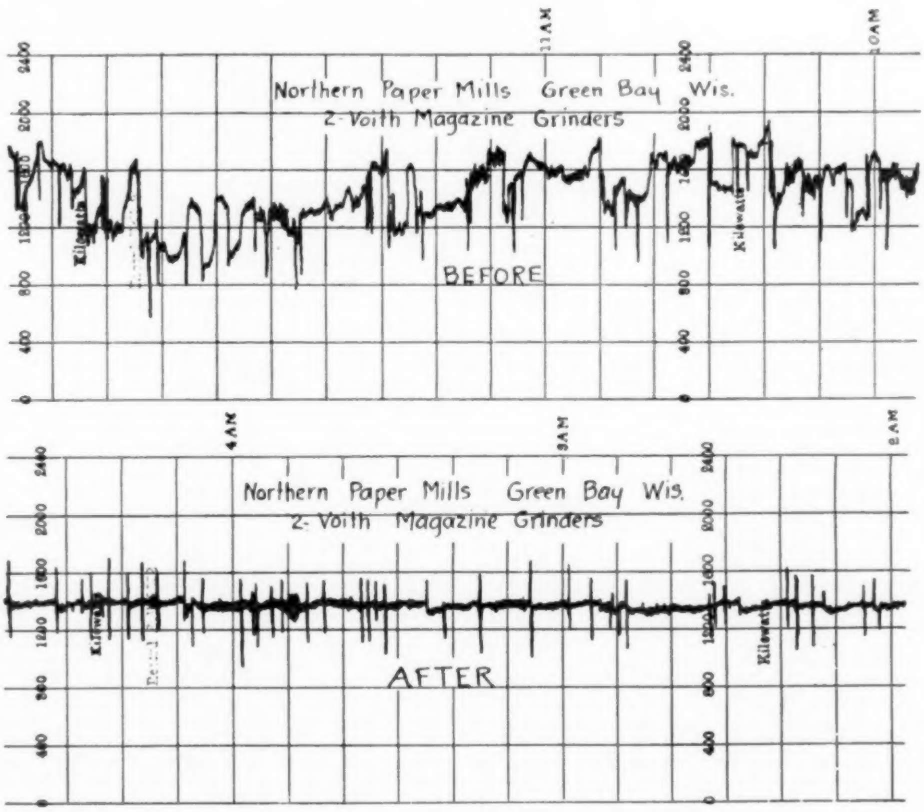

Fig. 3 Typical Wattmeter Charts
(Showing load on grinder motor before and after installation of Meyer load regulator.)

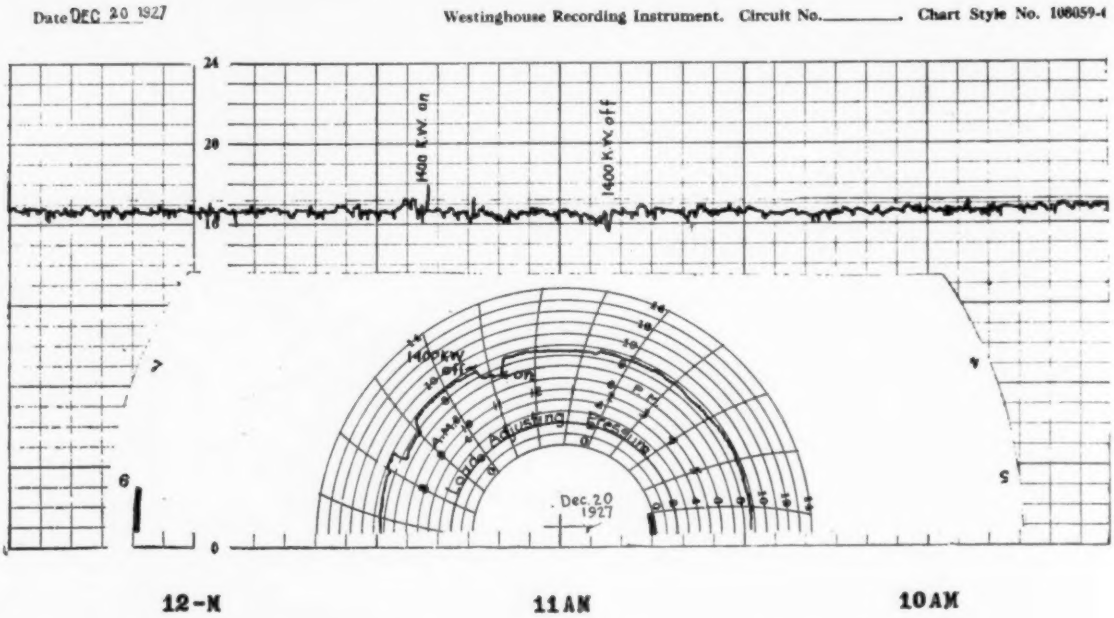

FIG. 5 CHART SHOWING HOW MASTER REGULATOR MAINTAINED CONSTANT TOTAL LOAD
(This was done by changing load-adjusting pressure while 1400-kw. grinder unit was down for temporary repairs.)

from day to day. In one large installation the Meyer system of control increased the daily load factor from below 85 per cent to over 95 per cent. Peak loads were reduced from over 18,000 kw. to about 17,000 kw. Power is purchased on the basis of paying for an entire month at the rate of the highest five-minute demand during that month. The maximum demand is determined from a 4-in.-per-hr. total load chart, and any five-minute period as against successive five-minute periods is used. Such a procedure appears to the author unjustifiable from the viewpoint of any reasonable interpretation of the basic principles underlying peak-load charges. What is the "probability" of random five-minute peaks from a number of plants on one system synchronizing?

Table 1 shows the average load and the five-minute peak load for each working day for a month in the mill referred to. The accuracy of control is attested by the fact that for ten days in succession the peak load was exactly 17,000 kw., as closely as it could be determined from the record made on the large-scale chart.

Fig. 9 shows typical portions of total-load charts from this

The peak-load readings must be corrected for transformer efficiency by dividing by 0.9825. Missing records indicate holidays or other days on which the mill was shut down wholly or in part.

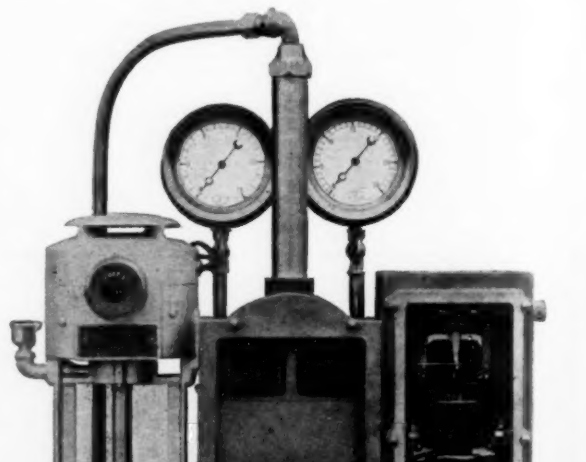

FIG. 6 MEYER MASTER REGULATOR FOR MAINTAINING CONSTANT TOTAL SYSTEM LOAD

mill before and after the installation of the Meyer system of load control, consisting of regulators for the nine grinder motors and a master regulator for the total load.

Fig. 5 shows that the master regulator maintained a uniform total load while a 1400-kw. grinder unit was down for half an hour for repairs. It added one-eighth to the existing load on the other eight motors. The master regulator accomplished this by changing the pressure in the hydraulic load adjusters of the individual load regulators. In this particular instance the load on six banks of transformers, representing different amounts of power, is added up by six similar General Electric Co. watt elements and maintained constant. No electrical contacts or relays are used.

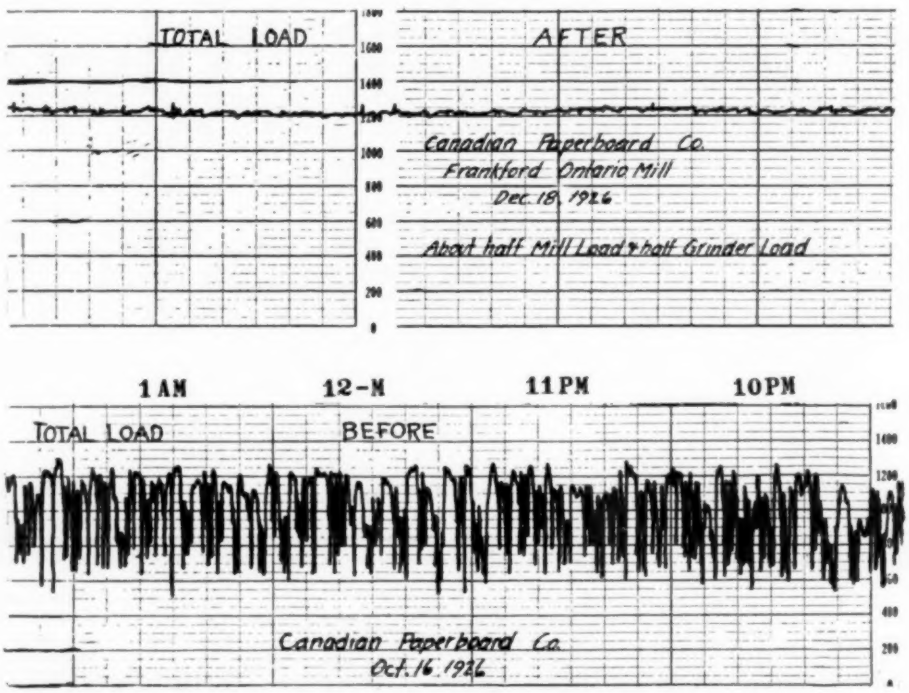

Fig. 7 Total System Load Maintained Constant and Water Power Conserved Through Pulp-Grinder Control

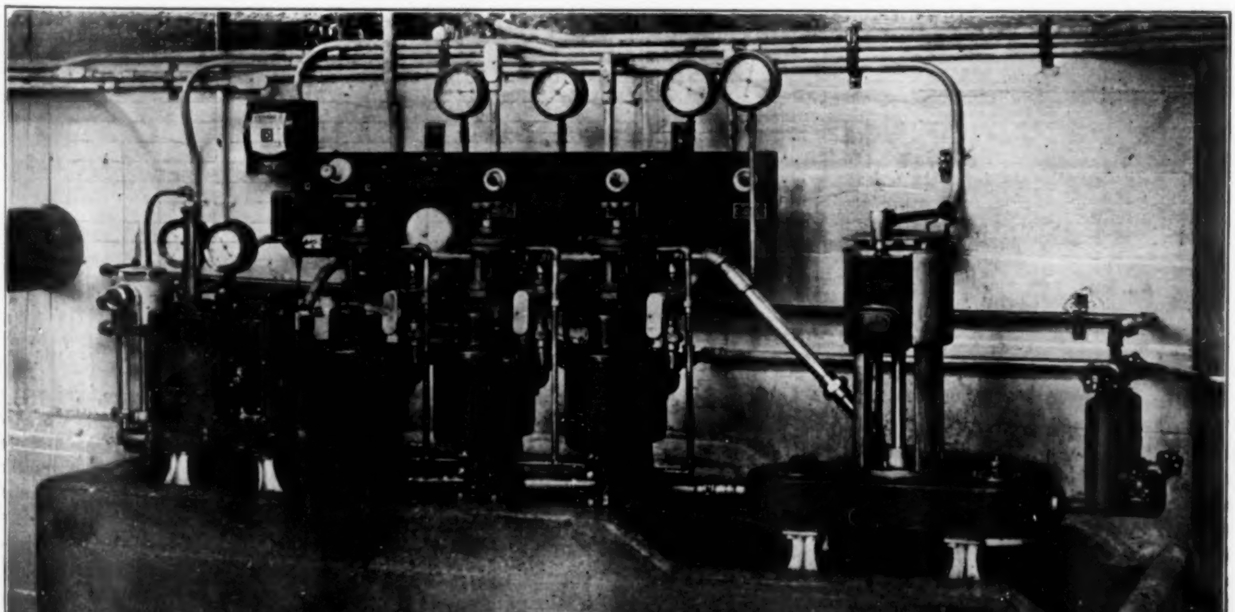

Fig. 8 Typical Installation of Meyer Regulators at Mill of E. B. Eddy Co., Ltd., in Hull, Quebec

(The master regulator is shown at left. The three pilot units with hydraulic load adjusters for the three motors are shown in center. The valve units are installed in grinder room on other side of wall. Pressure-operated switches, signal bell, and switches for load regulators, together with water-pressure gages, are shown in background. At the right is recirculating pump with return tank and make-up water valve by means of which a constant water level is maintained on the suction of the pump.)

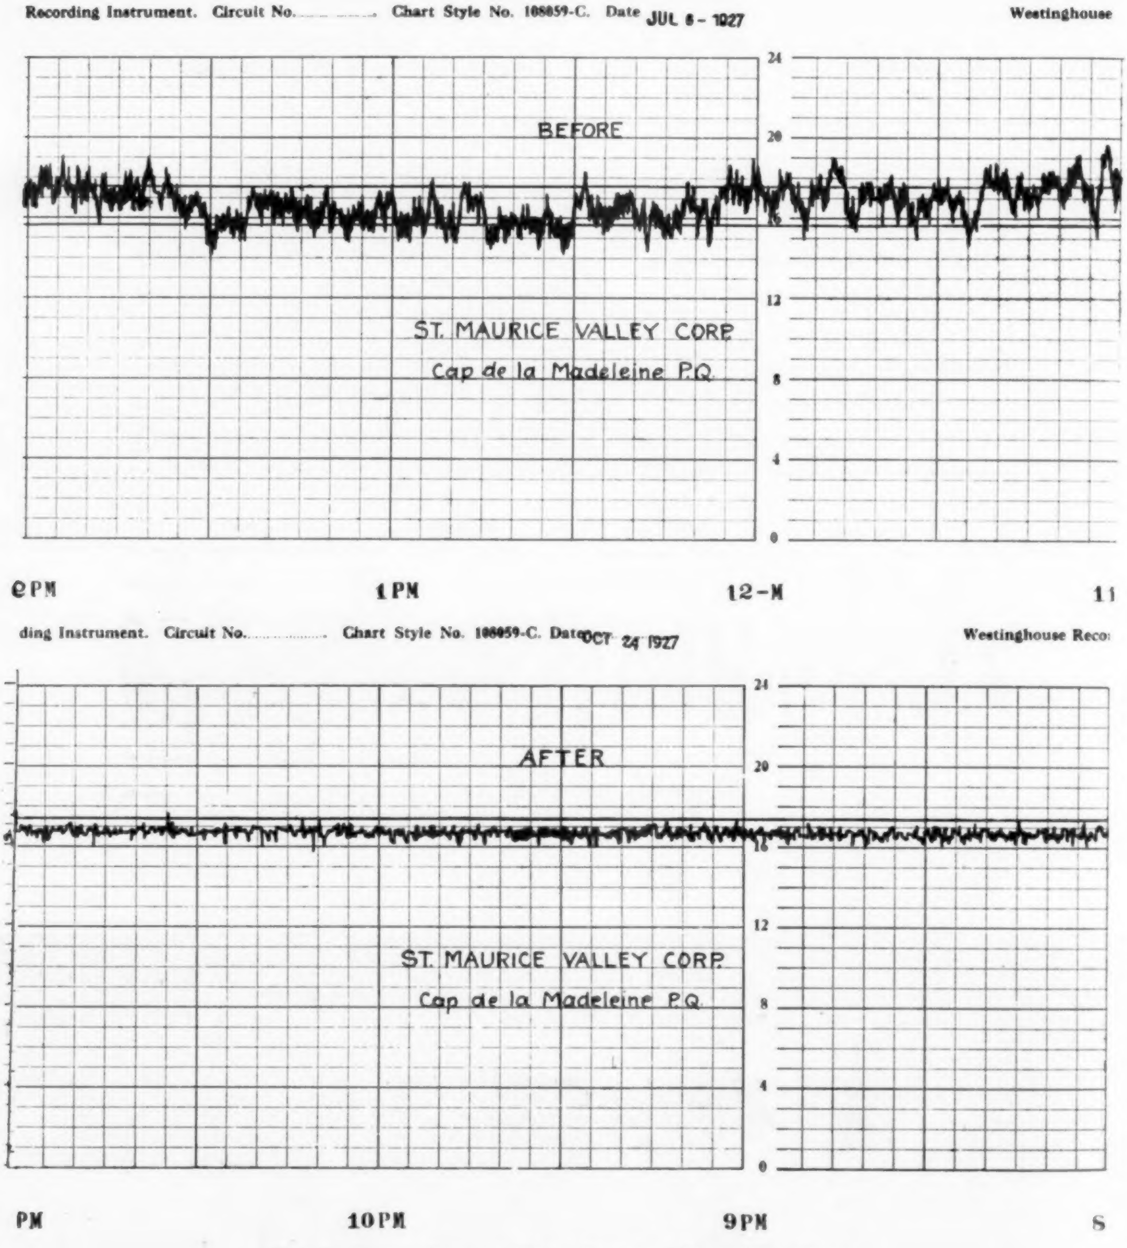

Fig. 9 Charts Showing Total Pulp and Paper Mill Load
(Before and after installation of Meyer system of control.)

### Construction of Master Regulator

The Meyer master regulator, illustrated in Fig. 6, combines all the advantages of the "functional" and "relay" types of mechanism without their disadvantages. The watt element, which measures the total mill load, is opposed by a spring. The tension of the spring is altered to change the total load. An arm on the shaft on the watt element is linked to the lower end of a small pendant tube flexibly connected to a source of water supply furnished by a small centrifugal pump. From the end of the tube issues a flat jet of water. When the load is normal, this jet passes between two knife edges and is led back to the pump. When the load is too high or too low, the tube is pulled to one side or the other by the watt element so that a portion of the jet is intercepted by the corresponding knife edge and deflected down a curved passageway to turn a small waterwheel clockwise or counter-clockwise. The greater the load change, and consequently the greater the portion of the jet which is deflected into the waterwheel, the faster the wheel will turn. It is therefore evident that the response of the mechanism is proportional to the momentary variation of the load from normal. On the other hand, the mechanism makes no response to the numerous severe load kicks of merely a split-second's duration that are characteristic of pulp-grinder loads. Yet there is no dashpot and no damping whatsoever.

By means of a gear train the power of the jet, which is really quite a husky one, is increased and used to adjust a pressure-regulating valve which maintains the required pressure in the hydraulic load adjusters of the individual load regulators, connected to the master regulator by a single line of copper tubing. Each load adjuster has a normal-load, maximum-load, and mini-

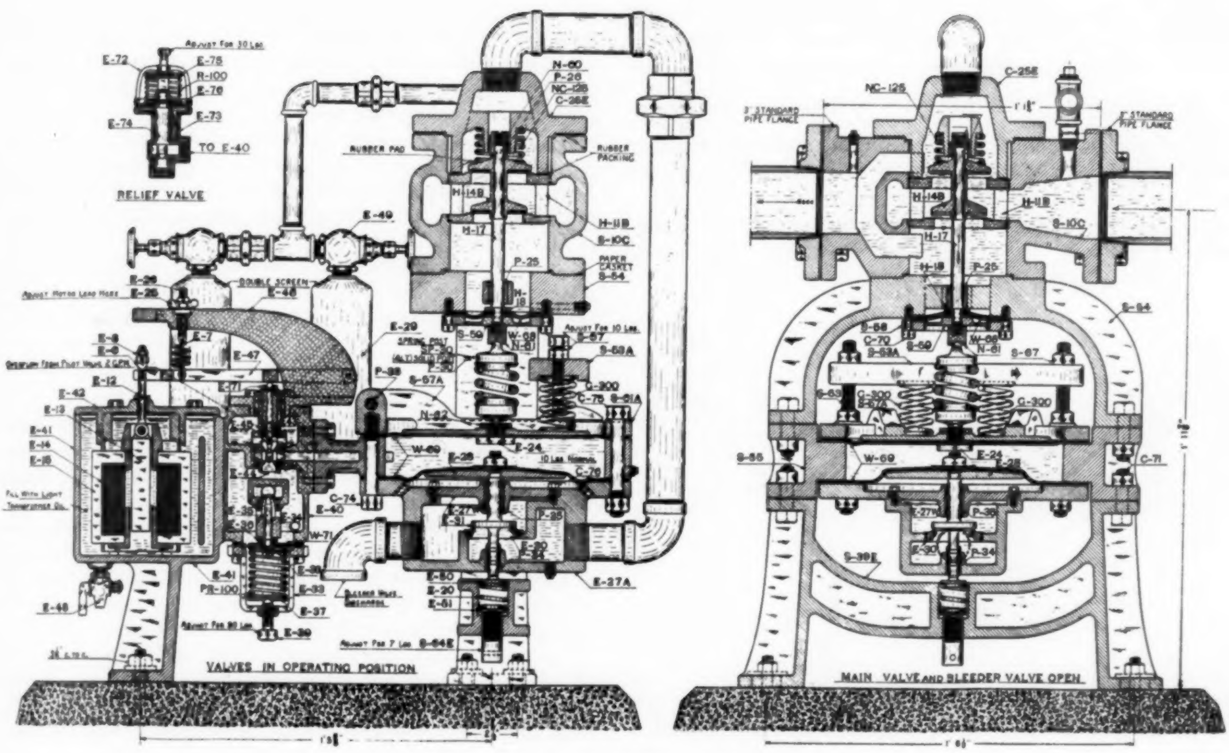

FIG. 10 MEYER LOAD REGULATOR MODEL 25

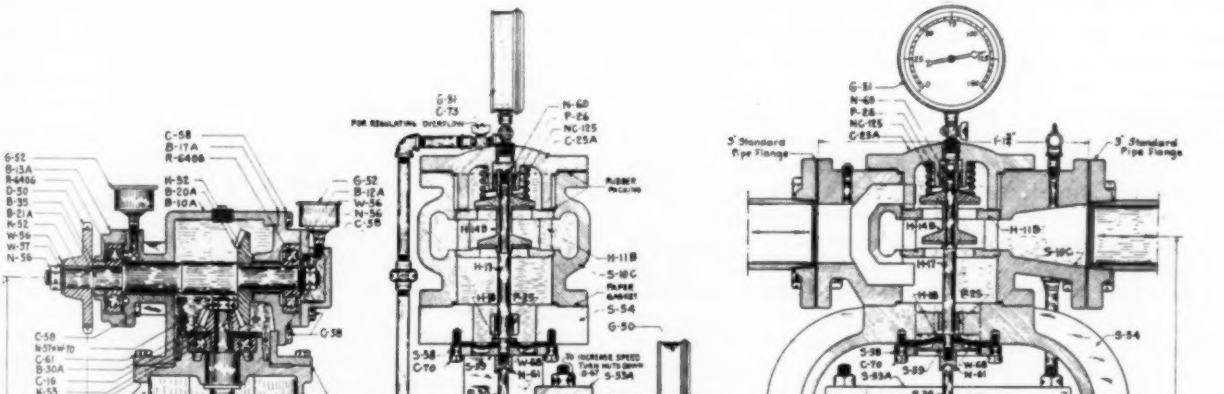

FIG. 11 MEYER PULP-GRINDER GOVERNOR

mum-load setting which can be changed in a moment. In this way different motors may carry different loads and yet share in the load distributions made by the master regulator.

### Conserving Water Power by Pulp-Grinder Control

An interesting application of load control, and one that pays most excellent dividends, is illustrated in Fig. 7. The mill is a

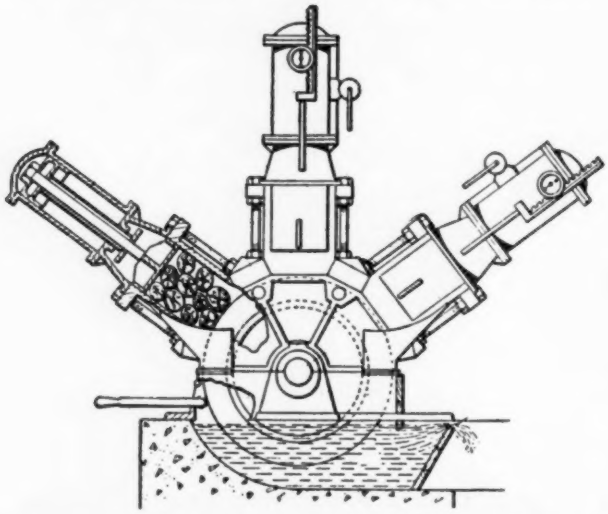

Fig. 12 Typical Three-Pocket, Hand-Fed Pulp Grinder

(The Meyer governor maintains the necessary water pressure in the cylinders back of the pistons to maintain uniform friction load, irrespective of number of pockets in use, binding of wood, or size and character of wood ground. When wood has been practically all ground out of pocket, operator reverses pressure, backing off piston, then refills pocket with wood, turns on water pressure, thus placing pocket under governor control again.)

small one. The power required is supplied by a hydroelectric plant located on a stream where the available water must be utilized or it will waste over the dam. Before regulators were installed, considerable power went to waste, because if an attempt was made to keep the generators fully loaded, and then the mill or grinder load suddenly increased beyond the waterwheel capacity, the frequency would drop and most of the mill operations were handicapped. The chart speaks for itself.

By merely turning a crank on the remote-control apparatus, the power-house operator half a mile from the mill sets the regulator from time to time to maintain more or less total load in accordance with the available water supply. Between such settings the load regulator automatically supplies the mill with all the power required by it and puts the remainder on the grinder motor. The men feeding the grinders change the number of pockets in use from time to time so as to maintain the average grinding pressure desired.

### Improving the Voltage Regulation

The load kicks resulting from the pulling of pockets on grinders, for the purpose of refilling them with wood, are often so severe as to cause undesirable voltage fluctuations. Fig. 4 shows a marked improvement in voltage regulation secured through the installation of Meyer load regulators. The principal reason why such improvement is possible is the unequaled speed of action of these machines. The readjustment required by the pulling of pocket-feeds is usually accomplished in about a second, and the accompanying load kick is absorbed by the inertia of the electric generators.

### Effect of Regulation on the Cost of Paper

By maintaining a higher average load on the grinder motors, a correspondingly larger amount of pulp is produced with the same labor and the same machinery; hence overhead and labor costs are reduced. Experience has also demonstrated that when a uniform friction load is maintained on the pulp grinder a more uniform quality of pulp is produced and the power consumption per ton is reduced about 5 per cent.

By absorbing noon-hour and other reductions in mill load in the grinder room, and by reducing grinder loads at times of heavy demand elsewhere in the system, peaks are avoided, valleys are filled up, and power costs for the entire paper mill are reduced.

The conditions under which paper is made and the principles upon which power charges are based differ so much that it is impossible to predict the average saving which can be effected through pulp-grinder control. Each mill must evaluate its own benefits.

## Discussion

George D. Bearce.[2] It is an old saying that newsprint paper is made in the groundwood mill, and the pulp-grinding equipment and operation are of considerable importance in manufacturing this particular grade of paper.

Wood is a fibrous material of various species and having somewhat dissimilar characteristics. From necessity the mechanical pulp-making process has been carried on largely by rule-of-thumb. The consumption of power was not considered of great importance since each small plant had its own waterpower.

In recent years a closer control of costs as well as an increase in materials, power, and other things has led to a more serious consideration of pulp-grinding methods and control. Many older mills are still using the water-driven pulp grinders, whereas most of the modern plants have adopted the electrical drive with larger units as the most satisfactory method of manufacturing pulp.

In the waterwheel type of grinder the control is especially important. The governor under discussion is widely used and the operating results under regular mill conditions have indicated that this type of equipment is one of the essential controlling factors in the production of groundwood pulp. Since the pulp production of any particular grade is almost in direct proportion to the power required, any increase in the utilization of valuable power means a distinct increase in the production of pulp. Another important feature of this governor is the control of speed and the reduction of danger from revolving the natural sandstones at a dangerous high rate of speed.

In the modern pulp mill where electrical power is used to grind pulp, the development of regulation has been equally important from a cost standpoint. In a majority of cases, the power is purchased on a 5-min. peak-load basis, and any equipment which enables the mill to operate up to but not over its peak load is an important factor in reducing power costs throughout the paper mill. All modern mills watch their load factor very closely, and a number are able to operate at a load factor of 96 to 98 per cent.

The Author. Although most power contracts provide for payments on a peak-load basis, Mr. Bearce's statement that in a majority of cases the power is purchased on a 5-min. peak-load basis may possibly be subject to question. We have furnished equipment to mills paying on the basis of 5-, 15-, 20-, and 30-min. peaks. In one case payment is on the basis of a 20-min. peak, but if that peak is ever exceeded the new peak becomes the basis for payment during the remainder of the life of the contract, which is still over eight years.

The author has tried to present methods of conserving power in the pulp and paper industry through the use of regulating

[2] Engineer, Manufacturing Department, International Paper Company, New York. Mem. A.S.M.E. and Chairman of Paper and Pulp Committee of Printing Industries Division.

equipment on pulp grinders. Large blocks of power are being used directly through waterwheel-driven pulp grinders and indirectly through motor-driven grinders.

For a good many years efforts have been made to build a governor that would control the waterwheel-driven grinder, because, as all know, the waterwheels must run at the right speed in order to produce the amount of power which they are supposed to produce from the water used. For some reason or other these efforts were not successful until the new type of governor was developed which is discussed in this paper. In a general way that governor has made possible, it might be said, an increase in the efficiency of the waterwheels, indirectly through the pulp grinder, of somewhere between 8 and 12 per cent, varying with the conditions under which the power is developed and utilized.

When applied to motor-driven grinders, the new governor has maintained a uniform load on the motors, thereby increasing output and reducing power, labor, and overhead costs, while really improving the quality of pulp produced.

By permitting the master regulator to set the individual governors for more or less grinder load, it has become possible to maintain a substantially uniform total load on the entire pulp and paper mill, thereby reducing the cost of all the power used.

# Engineering in the Printing Industries

By EDWARD T. MILLER,[1] CHICAGO, ILL.

THE introduction of science in the industries and the creation of new industries as the result of scientific investigation form one of the most interesting chapters in the romance of the modern economic world. Since Watt observed the rattling of the tea-kettle lid by the steam generated in the kettle, and even before, we have had ingenious minds seeking to harness to industry in a practical way the laws that have been discovered by scientists. They worked in an atmosphere of prejudice, superstition, and unbelief, but with each accomplishment the human mind was won away from its old habits of thought. Their efforts were "spotty," but today scarcely any untried project is proposed that the people do not believe some day will be accomplished.

The men who hitch these scientific principles and laws to industry and commerce have come to be known as engineers. Their method of approach to any problem is the scientist's approach. They are trained to find the facts by observation, to apply these facts by experimentation, and to establish correct procedure by calculation.

In the printing industry, speaking broadly, we are concerned with three important groups covering rather well-defined and distinct phases of printing: (1) The supply and conversion of raw materials; (2) the manufacture of tools and equipment for use in the conversion of both raw and semi-finished materials; and (3) the distribution, organization, and operation of printing machines and material and the marketing of the final product.

To a greater or lesser degree each of the industries included in the groups mentioned has made use of the scientist and engineer; at first rather indifferently, but later actually building new industries on their investigations.

The supply and conversion of raw materials, the manufacture of tools and equipment, and their distribution are fields so distinctly different from that of the actual production of printing, though closely related to it, that I am passing over them with but a few general observations. In the other addresses scheduled for this occasion we have two splendid examples of what may be accomplished by engineering in the solution of problems in paper manufacture. There are equal opportunities for a number of other addresses covering other problems in the supply and manufacturing groups of the graphic arts industries; so let us hope that others will be inspired to undertake the research necessary to uncover the material and to present their findings through this division of the A.S.M.E. and other recognized agencies.

I think most of us are willing to admit that there was little engineering or scientific consciousness in any of these industries prior to the appearance of the Hoover report on "Waste in Industry." That report began to awaken such a consciousness, and since that time our steps toward the use of science and the scientific approach—in other words, the employment of the engineer—have been more rapid and better directed.

That part of the Hoover report on "Waste in Industry" referring to the printing industry was a direct challenge to every individual and firm, manager, and employee connected with the graphic arts. The United Typothetae of America was definitely named as responsible for "the management of the industry as a whole" and found itself confronted with a situation compelling it to accept the challenge. The association at that time, representing some five thousand commercial printers in the United States and Canada, particularly in the large printing centers, needed programs of activities that would find expression in direct and indirect services to the various individual members and groups; and the Hoover challenge afforded ample reason for undertaking forward movements in personnel training and in better management methods—for the employment of the engineer to direct the application of science. Up to that time the few things which had been done in the direction of better methods in management occupied only small patches here and there in the whole picture of management, and these were only indifferently coordinated.

The first announcement of "Waste in Industry" in 1921 attracted wide attention among the commercial printers group. A liberal portion of the report covering the printing industry was published in *Typothetae Bulletin*, and the Executive Council invited John H. Williams, engineer-author of the report, to address the annual convention. Inspired by all this the general office staff of Typothetae advocated during the fall and winter of 1921 and 1922 the establishment of an engineering department at the general offices, and the executive officers adopted a resolution assuming a sympathetic attitude toward all engineering efforts in connection with the printing industry. In the meanwhile numerous inquiries began pouring in from members for assistance in their production problems, and to the department of research was assigned the duty of rendering such assistance.

To many of the laymen at that time the very word engineering was little understood, and in scores of instances an engineer was thought to be some kind of an exalted janitor who looked after the electric lights, the steam-heating radiators, the repair of windows, or the furnishing of extra keys for the doors. But a series of well-selected articles in the association's journal, referring to the application of scientific principles in printing as really the application of engineering, began to develop no inconsiderable interest in the broad scope of engineering as it might be applied to printing. Of course there was much groping in the dark for the door that would lead the industry out into the light. There were almost as many different conceptions of what engineering in its broadest sense is as there were individuals. Happily we found among managers of printing plants a score or more of men whose early education and training had been along engineering lines, and these men materially assisted in steadying the course along which we were steering and in shaping the growing interest. In the writings of these men at that time it is interesting to note how close together were their definitions and their opinions as to how engineering can be applied to the printing industry.

Matters finally progressed to such a point that our executive council appointed a committee on engineering to study the whole question of engineering as it might be applied to the industry, and Typothetae was reminded that it could not take its real place in "the management of the industry as a whole" until it could bring to bear in a scientific way the experiences of the industry in matters affecting finance, production, marketing, human relations, and matériel.

Gradually there has begun to grow a consciousness among the membership that presiding over each individual member as well

[1] Secretary, United Typothetae of America. Member of Research and Survey Committee of the Printing Industries Division of the A.S.M.E.

Address delivered before the Summer Meeting of the AMERICAN SOCIETY OF MECHANICAL ENGINEERS, Printing Industries Division session, at St. Paul-Minneapolis, Minn., August 27 to 30, 1928.

as the industry as a whole there is one masterful fountain head which we call management, and to it are bound all principles of truth, all scientific knowledge, and all righteous human relations with inflexible sinews, while engineering is the medium through which these laws are interpreted to management.

So closely indeed are management and engineering and industry bound together that there have grown up such expressions as "management engineering," "industrial management," "industrial engineering," all more or less synonymous but all describing the application of the laws governing the engineer and the scientist to management of industry.

When our committee began studying the subject of engineering as applied to printing, in its broad way and under these synonymous terms, a realization came to them that the United Typothetae of America was to some degree attempting to cover the field of management engineering. It was said at the time, "The trade association which so far studies the problems of its individual members as to recognize in them merely problems of engineering and then prescribes proper methods and operations based on scientific knowledge and principles is most certainly engaged in a work that is coming to be known as industrial engineering."

In my report to the executive council in June, 1922, I observed that the United Typothetae of America had progressed rather well in providing service in accounting, cost finding, advertising and sales, but that in the field of production engineering only a limited number of services, such as studies in industrial relationships, production standards, simplification and standardization, and a study of classification of operations, had been set up. I ventured the prophecy that the time was not far distant when we must coordinate all of the phases and elements of production engineering so as to give as complete service in that direction as we were giving in the field of administration and finance, and in the field of advertising, sales, and distribution. I am happy to say that since this forecast was made our management engineering services have not only increased in number, but have been rather well rounded out and are beginning to register real results among our members; but we have done just enough of it to see that we are only at the threshhold of tremendous opportunities and equally tremendous obligations.

It was not until late in 1923 that the whole engineering program was classified and set down in outline form, and it is interesting at this time to note the classification then used. Briefly and in substance it was as follows:

1 Fundamental statistical and experimental research
2 Engineering as it pertains to administration and finance
3 Engineering as it pertains to personnel
4 Engineering as it pertains to matériel
5 Engineering as it pertains to production
6 Engineering as it pertains to marketing.

A development of this outline, it may readily be seen, will provide for each of the four general phases in every commercial printing business; namely, finance and accounting, production, marketing, and personnel training and relationships.

The staff at the general offices began gradually to mold all Typothetae activities and services to this general classification. Standing committees were altered and even consolidated in order to prevent overlapping functions, and all were better coordinated. The departments at the general offices were rearranged and reorganized to parallel this general classification. At present we have a department of finance and accounting, a department of production management, a department of marketing, and a department of education, all backed and supplemented by the bureau of research. In addition to these there are of course the necessary administrative and executive departments and offices. The men in these various departments are specialists trained in their particular lines. The department of production management is the one no doubt of most interest to this division of the A.S.M.E. in that all production-engineering activities are centered in this department. The men themselves are engineers, and the head of the department is a member of this Society. He thinks and acts in terms of engineering, and the department is conducted largely for the purpose of giving engineering counsel and advice not only to the administration of the association but to our members in their daily problems in production.

This department heads up the work of the engineering committee and coordinates that committee's work with the work of the committee on simplification and standardization, the management and research committee, and of a number of minor special committees. Perhaps the most noteworthy achievement of the department of a permanent character has been its accumulation over a period of years and the final publication at a considerable expenditure of the Typothetae Average Production Records—an engineers loose-leaf manual, if you please—averaging the records of production in practically all of the operations of the printing plant. The data on which the records are based were accumulated from original sources and thousands of actual jobs of printing that had gone through plants. It furnishes to the estimator the only known standards of production in the various operations. It furnishes the cost accountant with a reliable measuring stick with which to check costs. It furnishes the sales manager with definite specifications as to the character of printing he proposes to furnish his customer. To the wide-awake printer who takes advantage of all such aids it is a compendium of information equal to any engineer's handbook or manual. It is the basis for job layouts, analyses, and estimates, and it has proved of almost uncanny accuracy in scores and scores of instances. Though only an accumulation of average records the book seems to overawe many to whom it would be most useful. Craftsmen and production executives therefore all have to be trained into the use of it. The younger men in the industry, however, take it up readily—a hopeful aspect of the situation.

More recently the department of production management in cooperation with the committee on engineering has formulated a program covering not only the scope of the productive branch of the printing business but laying out the work of the department for some time ahead. In outlining the scope of the field of production management the fullest consideration has been given to the physical printing plant as a machine for producing printing; to the regular and special printing processes; to the analysis of the functions, methods, and purposes of each job in the producing branch; to the selection, training, handling, compensation, methods of work, and working conditions of the personnel; and to records, forms, and reports used in production management. The work of the department in carrying out this program is outlined under two main divisions; (1) The collection of data on each of the phases of production; (2) the organization of these data into a form usable by the membership and the presentation of the information in regard to it, together with instructions in its purpose and use. It is a significant fact that trade associations in their endeavor to serve their members often expend their energy on tasks that are expedient rather than fundamental, and afterward the fundamental phase of the work becomes so apparent that it is taken up and finally fitted into the picture. Therefore, this program is designed largely to coordinate the work that has been done with the work that is yet to be done so that the tasks that have been accomplished largely on the ground of expediency may be fitted in with those fundamental things that are yet to be accomplished.

Engineering societies such as the A.S.M.E. are needed to cooperate with trade associations and to assist them to bring their activities and services into harmony with the engineering program. The engineering societies can assist very materially in building the engineering program, particularly in production. Engineers will find a new and comparatively little occupied field in serving trade associations in this newer phase of their work. Particularly is this true in the case of engineers who have broadened out in their studies and experiences so as to cover the whole gamut of industrial activities, men whom we are now beginning to call "industrial engineers."

It is gratifying to me to see the activity of the A.S.M.E. in this respect, and I am pleased to serve as a member of your divisional Committee on Research and Survey. Recently I suggested to the chairman of that committee[2] an outline of a program that might well be followed during the next year or so. In my outline I used the engineering approach; that is, I suggested that the first thing to do is to find out what are the actual conditions, what are the facts in regard to research in the graphic arts. When we shall have determined that, then I believe we should gather them together and catalog them, after which we can work out or determine the scope or the phase of research that would prove of the greatest benefit to all industries involved. I suggested briefly the following outline: (1) Compile a complete list of all agencies, domestic and foreign, engaged in printing trades research; (2) classify research work now being done, and ascertain its extent in machinery, systems, and processes; (3) catalog all activities to date showing scope of work already accomplished as a guide to what problems to take up first and which ones already under way to complete; (4) determine the exact scope of the activities of research committees and research departments—whether they are to comprise purely production problems or to include problems of finance, marketing, etc.; (5) work out a functional head of all these research activities to assemble all data, classify these data, disseminate information to the members, and solicit papers and treatises on special subjects.

In the brief time at my disposal it has been possible to refer only to some of Typothetae's efforts toward introducing engineering principles to industry and to outline briefly what may yet be accomplished, not only by it but by the other associations and societies representing other groups in the graphic arts. A great deal of what has already been accomplished is good, but much of it is necessarily indifferent and of little importance, because laymen are apt to undertake such things with a woeful lack of the sense of proportion. Better things are expected of engineers, and if all groups of the printing industries were to cooperate and through such cooperation set up a plan of coordination of our efforts, in comparatively a short time we should have built up a vast fund of practical, technical, and scientific information that will be of immeasurable benefit to all interested. What nobler task can be set up for a society such as the A.S.M.E. and for trade associations such as the United Typothetae of America and the other associations in the graphic arts? Where could there be a program whose objectives are more fundamental and more certain of bringing prosperity to our industries and better services to the public? It seems to me that engineering brings a challenge to the industries, and that the industries will find their greatest advancement by accepting the challenge.

[2] Arthur C. Jewett, Director, College of Industries, Carnegie Institute of Technology, Pittsburgh, Pa. Mem. A.S.M.E.

# The Standardization of Colored Printing Inks and Its Advantages

## Confusion Exists in the Color Field at Present, as Discussions and Instructions Regarding Color Have No Common Basis or Viewpoint

By TAYLOR W. ANSTEAD,[1] CINCINNATI, OHIO

*The author discusses briefly the materials entering into the manufacture of printing ink. Since the pigments used in their manufacture exhibit the widest variations, standardization of colored inks is really the standardization of the pigments involved. Various proposed methods of standardization are considered, and it is hoped that out of their discussion some practical system will result that will do away with the confusion at present enveloping the subject.*

The purpose of this paper is to discuss briefly the confusion existing in the colored-ink field and the need for some sort of standardization so that all discussions regarding color may have a common viewpoint.

Before considering the question of the standardization of colored inks, it might be well to consider the materials that go to make up a printing ink.

### Materials Used in Making Printing Inks

Printing ink consists essentially of two parts, the vehicle or varnish, and the pigment or dry color. While in order to get certain desired working qualities various compounds are often added, yet, as stated, the two essentials are varnish and pigment.

Varnishes for high-grade printing ink are made almost exclusively from linseed oil. This oil adapts itself readily to use as a vehicle for two reasons: first, its viscosity can be increased from that of water to that of molasses taffy; second, linseed oil will absorb oxygen from the air and form a hard film or "dry," as the reaction is called technically.

The "bodying" of linseed oil is carried on by heating it in a copper kettle over an open flame, the resulting body depending on the temperature and time of heating. As the free-acid content of the linseed oil increases with its viscosity, it is necessary to start with an oil of minimum acidity so that the final acidity will be kept as low as possible, otherwise the varnish may react with some of the pigments used in the ink. Color and odor are also two factors entering into the choice of linseed oil.

The drying of linseed-oil varnish by the absorption of, and combination with, oxygen from the air is a true chemical process as opposed to drying by absorption as exemplified by the newspaper where a porous paper absorbs the ink. This chemical action of "drying" may be hastened by the introduction into the ink of very small quantities of substances known as "driers." These driers are resinates, linoleates, or acetates of cobalt, lead, or manganese, and act as catalysts.

Depending on conditions of price, character of pigment, and intended use, mineral oil and rosin oil are often used alone or in conjunction with linseed-oil varnishes, but for the very best type of printing, linseed is to be recommended.

Prior to, say, fifty years ago, coloring matters for printing ink were of mineral or vegetable derivation. Carbon black, bone black, English vermilion (mercuric sulphide), ochers, umbers, siennas, ultramarine blue, iron blues, chrome yellows, and chrome greens were of mineral origin, and indigo blue and madder lake of vegetable origin.

The discovery of the first coal-tar dye by Perkin in 1854, the subsequent discovery of many more and the application of many of these to pigment making, beginning in about the year 1880, led to a new era in printing. While of course most of the old colors are still used to some extent—some of them like carbon black, iron blues, and chrome yellows in enormous quantities—they have been supplanted and the field of color greatly enlarged by the use of pigments from organic dyes.

Three of the main characteristics of the organic pigments have been their good working qualities, their tinctorial power, and their purity of tone, the first allowing for greater speed in the printing press, and the last two for the development of special processes such as the offset process and photolithography.

### How Pigments Are Made From Coal-Tar Dyes

It might be of interest here to consider briefly just how the pigments are made from coal-tar dyes. One class of dye comes on the market in a water-soluble form, usually as the sodium salt of the dye. Naturally, being water-soluble, it is useless as a pigment, especially for lithographic or offset work where water is used. Consequently it must be rendered insoluble, usually by the addition of barium chloride. Expressed by chemical equation this reaction takes place:

$$\underset{\text{(Water-soluble)}}{2\text{Na (Dye radical)}} + \text{BaCl}_2 \longrightarrow \underset{\text{(Water-insoluble)}}{\text{Ba (Dye radical)}_2} + 2\ \text{NaCl}$$

As variants, salts of calcium or lead are sometimes used to obtain different shades of pigments from the same dye.

The precipitated dye if to be used as a "toner" or 100 per cent color is washed and filtered and then dried in a drying oven. It is then ground to a powder. If the color is to be of reduced strength some white such as blanc fixe (barium sulphate) or alumina hydrate is added to the precipitated barium lake and the resulting color washed, filtered, dried, and powdered.

Several important pigment dyes come on the market as insoluble sodium salts, but on being boiled with barium, the latter metal replaces the sodium, producing the same result as if the dye were soluble.

Another type of pigment is produced directly from the dye-forming elements or "intermediates." A familiar example of this type is para red, made by combining the yellow paranitraniline with gray beta naphthol to produce para red.

In making the finished printing ink the powdered dry color and the varnish in a predetermined ratio are given a preliminary mixing in a pony mixer in order to wet the color with the varnish. The mixture is then sent to the mill room and ground on a three-roll mill until the ink is pronounced finished by the tester. The number of passes over a mill necessary to grind an ink varies with the color. Some colors only take two or three runs, while others require seven or eight.

Of all the ingredients going into printing ink the pigments exist in the widest variety, and therefore a discussion of standardization of printing ink is really a discussion of the standardization of colored pigments suitable for inks.

[1] Chief Chemist, Dry Color Division, Ault & Wiborg Co.

Presented at the First National Meeting of the A.S.M.E. Printing Industries Division, Rochester, N. Y., November 8 and 9, 1928.

The term "standardization" is not very definite, and various constructions can be put upon it, namely,

1 Standardization of inks for process work in yellow, red, blue, and black.
2 Adoption of a standard nomenclature for colors.
3 Simplification and standardization of colors, and
4 Standardization by measurement.

### Standardization of Inks for Process Work

Let us consider the first case, that of standardization of inks for process work. Successful selling through printed matter depends upon faithful reproduction of the original idea. An advertiser calls upon one or more artists to submit their ideas for a colored advertisement to run, let us say, in a great national publication. He chooses one that appeals to him, and plates are then made true to color. The publisher now receives the proofs, and the advertiser awaits publication with the joyful feeling that many sales will result from the attractive advertisement.

When the publication comes out the advertiser is sometimes terribly disappointed in that the whole color scheme has been lost. Why? Because while the artist has free rein in his choice of colors, the publisher is held down by the limitations of his inks. He selects what he thinks is a happy medium to do justice to the color scheme, but often the results are anything but satisfactory.

Of course, the only remedy for such a situation is standardization of a series of colors to be used by the artist, the photoengraver, and the printer. The artist would then select from a chart of these standards the color combinations to make his painting. The photoengraver would in turn use the same standard in the form of printing ink in making his proof, and finally the printer would be supplied with progressive proofs by the photoengraver with the particular standard ink used in each case, so that there could be no question as to the color wanted.

It is believed that in this way the results obtained in the original picture by the artist would be carried on through to the final advertisement.

Some printing-ink houses do put out charts showing the color combinations that can be obtained through the use of their standard-process inks, but of course there is no unanimity on the subject, each ink maker having his own ideas. Some central organization such as the National Association of Printing Ink Makers or the Lithographic Research Foundation at the University of Cincinnati, might develop a standard chart that printing-ink makers would follow, and thus assure the printers standard colors no matter from whom he buys his inks.

The opponents of this plan point out that such a standardization would produce stagnation. There would be no incentive to bring forth new color combinations because these would be deviations from the standard. In order, of course, to prevent this the colors used as a basis for the chart would have to have a great variety, which brings us back to the multiplicity of colors obtaining now.

### Adoption of a Standard Nomenclature for Colors

The second case of standardization is the adoption of a standard nomenclature for colors. Let us consider just a few names given to colors and see how close to a standard they run. There is primrose yellow for one instance. One dry-color maker puts out several shades of light yellow he calls primrose, one of which will match another maker's "lemon yellow." Another maker has a yellow with a high gloss that he calls primrose that is not of the same character as the first primrose in question. Then there are cerulean blues that are almost greens, and others that are a sky-blue. The author has seen colors called crimson in a range from a fire red to a deep magenta. Then there are geranium lakes which probably match some other maker's dahlia red, and so on and so on. In most cases the colors are named fancifully like Pullman cars or collars. The author knows, for he has been guilty of such enormities himself.

There might have been some excuse for this romantic nomenclature when the organic lake industry was young and colors were named so that no idea could be had of their chemical composition, but in these days when the color man will tell the ink maker into just what class a certain pigment falls, there is no necessity for the wide variety of names.

The colors that we use in our Cincinnati plant are these: Reds, 45; yellows, 13; browns, 4; oranges, 8; blues, 11; blacks, 4; greens, 10; purples, 8; whites, 11. This makes a total of 114 different pigments, so that really the standardization of ink in printing comes back to the standardization of the various colors made from it.

Some system of standardized naming ought to be adopted such as the "Standard Color Card of America" issued by the Textile Color Card Association of the U. S., Inc. On this card are dyed pieces of silk showing such colors as turquoise, ocean green, scarlet, geranium, etc., so that a very clear conception is had of just what each color is.

### Simplification and Standardization of Colors

The third case of standardization is simplification. There are probably far too many colors that are mutually replaceable or that could be obtained by mixing other colors. The chrome yellows are a case in point. They run all the way from the very light acid yellow commonly known as "canary" to the very orange basic yellow known as deep orange chrome or similarly designated. Tentative steps toward simplification have been taken by a committee appointed by the Federated Varnish Production Clubs. It was agreed by this committee to start first with this chrome yellow series. It has been estimated that there are two hundred distinct shades of chrome yellow put out by the various manufacturers of dry color. It is proposed that this number be reduced to twelve, varying from the light yellow to the orange. The committee feels that with these shades any desired combination can be obtained.

From the yellows to the iron blues and chrome greens is a fairly simple step, but with the wide variety of reds the difficulties might prove to be insurmountable. However, it will be extremely interesting to watch the progress of this committee. The Department of Commerce has set out to standardize in industry and has already, it is reported, reduced greatly the number of varieties of bricks and dishes made, so it is not improbable that some progress could be made along the same lines in colors, not only in the paint and varnish industry but also in the printing-ink field.

### Standardization of Colors by Measurement

Then finally in our consideration of the standardization of colors we come to standardization by measurement. The principle of the various schemes evolved is some index for each color determined in various ways, depending on the method used. For instance, one method is by spectrometric measurement of light reflected from a printed sheet of the color. The reflected light is broken down by the prism into its components, which are given a scale value. Therefore, by reproducing these values by a mixture of colors representing the scale "readings," one should be able to match exactly the original colored proof.

On the surface this method appears very logical and the author is in no position to condemn it of his own knowledge, but he has been informed that transmitted light, such as light passing through the solution of a dye, is accurately broken up, but reflected light, such as from a printed proof, does not give true values as not all the light rays are reflected but some are absorbed.

This lack of total reflection gives confusing results, and one incident was told in which a color was analyzed in one part of the country and the graphic results sent to a branch in another, but when it was attempted to duplicate the color the results were anything but identical.

While probably no one of these various methods of standardization may ever be adopted in its entirety, at least they are gropings toward some adequate system whereby artists, printers, pigment, and printing-ink makers, and users of color generally would be in agreement upon the subject of color.

One writer has even gone so far as to dream that a system of notation could be adopted which one could read as if a sheet of music, and reproduce the color, as the inspiration of a musician is reproduced on a musical instrument.

Certainly language alone is not sufficient to describe color, as witness this letter of a master stylist, Robert Louis Stevenson, from Samoa on October 8, 1892, to a friend of his in London:

> Perhaps in the same way it might amuse you to send us any pattern of wall paper that might strike you as cheap, pretty, and suitable for a room in a hot and extremely bright climate. It should be borne in mind that our climate can be extremely dark too. Our sitting room is to be in varnished wood. The room I have particularly in mind is a sort of bed and sitting room, pretty large, lit on three sides, and the colors in favor of its proprietor at present is a topazy yellow. But then with what colors to relieve it? For a little work-room of my own at the back, I should rather like to see some patterns of unglossy—well, I'll be hanged if I can describe this red—it's not Turkish and it's not Roman and it's not Indian, but it seems to partake of the two last, and yet it can't be either of them because it ought to be able to go with vermilion. Ah, what a tangled web we weave—anyway, with what brains you have left choose one and send me some—many—patterns of this exact shade.[2]

It might be interesting, as a study in color standardization to know just what Stevenson's friend did send him.

In conclusion, the author wishes to say that he has nothing definite to offer as a system for color standardization, but hopes that out of discussion of the subject some practical system may result.

## Discussion

Joseph M. Farrell.[3] I have heard so much about standardization for the past two years that I just about dream it, and this is the first time that I have listened to someone talk from an inkmaker's point of view offering something constructive. I cannot talk to you in theory, but I can give you a picture of the advertising business as it is today and tell you exactly where standardization stands. I do not know of anything that is more of interest in the production field of printing today or to the advertising trade than the standardization of colors. Some years ago the American Institute of Graphic Arts had a standardization committee. It worked on some colors, and they had some very able men on the committee, who definitely decided on some very excellent colors.

I am the buyer for a large advertising agency. When we work on a four-color advertisement, we proceed about as follows: We receive an art copy, and the advertisement is scheduled to appear in eleven or twelve of the largest circulated magazines in this country. The publisher tells us that we must give him original plates, and so we order certain plates, and the publisher tells us that we must use certain plates. Now, I believe that the advertising company in cooperating with the publisher and the engraver is tied down to all these things, which is a good thing as I see it. When we get the first set of plates, which is the first set which we would submit to our clients, a good deal of time and thought have been spent on them. This one set of plates would be what we would call satisfactory, but there might be only three out of ten that we would really be satisfied with. When we get to some other colors, a blue or green would be so entirely different that we could get nowhere near to our engraver; and I am sure that if you look at any of the art advertisements as they are today, you will understand what I am saying. We would go to the publisher and almost beg him to let us use another color because the engraver could not get a good job; and in some cases we would be successful, but it would go into other magazines and you would have a very unsatisfactory job.

Today I believe that standardization has progressed greatly. It is not 100 per cent right, but it has made good progress. Two years ago we went before the engravers and they approved our work, and then the advertising agency and our committee of the advertising agents association took up the great task of selling standardization to the publishers. Nobody else seemed to be able to do it, but we sat down and tried to convince them that it was necessary, and we also decided that the way to do it was to get the individual publisher's opinion. I have worked with 165 publishers of general magazines and 200 publishers of trade papers, and except in a very few instances I do not know of any case where standardization was not received as a great work. I think I am very conservative, and I hope the company I represent is conservative, and I think that if there was anything in standardization that was going to physically hurt our product we would never be for it.

For a year and a half the color work in our company's plant has gone out with these standard colors, and we do not have the problem any more of going to the publishers and asking them to use some other color; so this is what I mean by saying that I am sure that we are making some headway. I know that a great many advertising agencies are cooperating with each other on the standard colors.

Today practically all of the large magazines will accept our progressive policy in respect to our colors. Most of the old magazines are still on the old policy, but I think for good business reasons it is good policy to give the publisher what he wants, and that is all we are trying to do.

Comparing the advertisements or the advertising that comes through today with the advertising that went through a year and a half ago, it shows much improvement. We have the same shades of color, and we have certain inkmakers, and the engravers tell us they must use their ink, so that we have to check up. Now the inkmaker gives the same shade of ink all around. I think that is where the author has hit a vital point. We endeavor to have a uniform standardization of ink all around and to be as near right as we can make it, and I think that this is the kind of constructive work that inkmakers can do to cooperate with each other—work to turn out a uniform shade of color.

Standardization has done a lot of good. When we get one set of plates it helps to check the others. Now, I think that it is wrong to do it any other way, because the engraver sells the proof with a certain ink to an agency, and he gives it to the publisher, and somebody from Chicago sends in the ad with one color, and somebody from New York sends in another color, and from the Pacific Coast in another color, and then they start compromising, and there is trouble. There are always a certain number of printing superintendents and engravers that throw cold water upon standardization for some reason. On the other hand, we have dealt with a large number of magazine publishers and printers of magazines, and their remarks and their efforts are encouraging us to realize that standardization is the right thing, if each person goes about it in the right way and takes the interest in it that he should.

---

[2] "Vailima Letters," New York, Scribners, 1901.

[3] Chairman, Mechanical Production Department, American Association of Advertising Agents, New York, N. Y.

My own experience is that we have had no particular difficulty with reproducing our copy in certain colors. If by chance it turns out that we have an unusual piece of art from the artist so that we need a little different blue, I would not hesitate to go to our publisher and ask him if it is not possible to use that color. Now I am talking against my own people as much as anybody else, and against photoengravers, and no photoengraver should use any other color than that specified by the publisher. If they do use another color, they should only do so after requesting the publisher's consent.

Just to give you a certain example: The Curtis Publishing Company said to us: "I hope you can put over standardization, but we are a little dubious," and they specified that the photoengraver must use Levy inks and proving plates. They went to work with Levy inks and worked out that 1558, 1559, and 1560 were the inks that matched the colors that we wanted. Now we have notified every engraver that in making plates for the Curtis Publishing Company they should use Levy inks 1558, 1559, and 1560. If our engraver sends in anything else, we return it and say, "You must meet the requirements of the Curtis Publishing Company; no one should use other colors except the ones specified or by permission of the publishers," and we are checking up on our photoengravers.

I believe in this organization work which we have done with the publishers. The part that will help out is that if future work and technical work can be done among the ink manufacturers, it will assist us to do our work with the publishers.

Randolph T. Ode.[4] We have seen good results in using proper pigments in making the original, but in our case where we have pictures coming from all over the world, from the greatest painters of the world, should we attempt to secure standardization we would fall down ridiculously; in fact, it would be impossible. I think the statement as to what is the best way to handle the situation—that is, through publishers getting the engravers to use the inks that the publishers are going to use—is the only logical way to do it. Furthermore, if the publishers and the ink manufacturers will come together in connection with this matter of standardization and find out what they are talking about, that is an equally important step. The problem is just the same in lithography as it is in relief work, a very complex one, and it is becoming more so than ever before. Lithography today has come down from a multicolor proposition to that of a four- or five-color one.

There is a help in color work of which all printers do not take advantage, and that is to place on the printing cylinders of the press circumferentially the same picture, so that by varying the amount of ink at each ink fountain a balance of all the values may be secured and thus a much better final print be obtained. Two different pictures placed circumferentially on the cylinders do not readily permit this adjustment, for a light amount of a color required for one picture may not be suitable to the other.

A. J. Newton.[5] The inkmakers are the most reactionary "standpatters" I know of. We have had Mr. Priest, one of the great color experts in this country; we have Mr. L. A. Jones.

Now, the first man to consider is the man who pays for the advertisement. Supposing you have a big advertisement, such as the Proctor & Gamble advertisement, in 25 different publications. They pay an enormous sum for one picture, and you send out these advertisements, and you get different results in your color photography; not one of them is like the original in colors. Why not? Because all these publishers are using different inks, and not one of these advertisements is like the other, and not one of these inks is like the other. Each one says, "I am going to use my ink;" and they are never satisfied, and least of all the man who pays for the advertisement, the customer—he is the man who should be pleased in the first place. The publisher of "Life" magazine would bring up his magazine and show the illustrations they have put out and thought were fine; then they put the same advertisement in the "Woman's Home Companion" or the "Saturday Evening Post," and they are as different as chalk and cheese. Now, that does not satisfy the man who is paying for the advertisement. If he is paying for the advertisement, he wants it to appear as he gave it to the engraver; and it is absolutely impossible while the engraver is using one sort of ink, the publisher another, and while each publisher is using a different sort of ink.

The customer says, "We will not buy this space in your magazine unless we can get standard colors." Of course, it is better to use a standard set of colors. Each inkmaker uses a grade of ink of his own, and he says, "Now, that is my red, and this is my blue, and this is my yellow;" and they each use different shades. And so we get together with an advertising agency, and most of them will specify a standard set of color inks that have been agreed to by the advertising publishers and have been agreed to by the inkmakers, and they will correspond. There is some sense to that, of course, but it is difficult to alter your standards.

A man with an advertisement in 20 different magazines will get approximately equal results from every one. A couple of years ago this was not the case; they all were entirely different—some perfectly ghastly. I think we shall not only get things alike, but will improve our standards greatly. I am very pleased with the progress we have made. We have had opposition from everybody, especially from the engravers. The engraver says that he is going to use his ink, and no matter how he got it he does not care about the plates after they leave his hands. Now, you have the same problem with the publishers. They say, "I have been using these inks for years, and they are good enough, and my father used them before me, and they are good enough for me;" and if they will not conform to what he wants, he says that he will buy from someone else.

With regard to forming these standards, of course there has been a lot of work done on standardization, and the reason we have not made better progress is the inertia of the people most concerned. They will not take the trouble to understand or think about the subject or work it out. Of course you cannot do away with fashionable methods, but that has nothing whatever to do with scientific standards of color, if you use scientific methods of doing it. The author said he found that the results from the photometer do not correspond. Of course, it takes time; it takes practice; it takes experience to use a scientific instrument; and if the apparatus were used properly, then the results would be the same. If a man uses a photometer the first time, he does not read it so accurately, but when he gets used to it, his results in using the instrument here in New York are the same as in California; and if he gets the same result and the same shade of color from the transmitted light and reflected light, then the shades are the same. There is quite a difference in shade if you print a thing on a transparent medium and also on a perfectly white medium, and the same thing can be measured, recorded, imitated, and copied, and is perfectly definite.

A color has three components: hue—that is, the actual shade; saturation—that is the amount of density or intensity of the color; brightness, or brilliancy of the color. Munsell has another system which has the same three components. He calls them hue, which is the shade; chromo, the intensity; and the degree of that particular hue.

[4] Secretary, Providence Lithograph Company, Providence, R. I. Mem. A.S.M.E.

[5] Engineering Department, Eastman Kodak Company, Rochester, N. Y.

You can take it in a scientific way, but it all can be done and it should be done, and I figure that every inkmaker should see that the ink corresponds to the color. It is absolutely necessary that the complementary color he uses should be a yellow, a yellow of a certain shade, which absorbs all the blue and at the same time reflects all the green and the red. The trouble is that you cannot get him to see it at all. The ink that you use for the green record should be exactly complementary to that green record; that is, a magenta, a color which is minus green, a color which absorbs all the green, and at the same time reflects the red and the blue. It has been very difficult to get the inkmaker to see that. It is very difficult to get the absolutely ideal theoretical colors, but we can go, and indeed we have gone, a great deal farther than they used to go a good many years ago. And now we are getting the colors very much nearer what we want, and they are more or less alike from the various inkmakers who have been approached in this matter. So we are getting some improvement. When we get these steps carried out, it will be the greatest economy and satisfaction to have anything to do with the production of ink and with the use of color reproduction. I am heartily in favor of color standardization.

Charles L. Garner.[6] After listening to Mr. Newton's talk on the standardization of ink, I want to say that some firms that I know have adopted a uniform art standard, as adopted by this standardization committee. In support of that statement let me say that recently we received an order from a local house, in which the formula numbers specified were absolutely unknown to us. We furnished the Graphic Arts standard, and the customer said, "That is exactly what I want;" so I am sure that any institution and practically every printing concern in the United States of any moment will and can furnish Graphic Arts standards. If they have their own number, then they have adopted these standards as regular and correct and are prepared to furnish them to anyone who requests them.

Alexander Murray.[7] In regard to the artist's connection with standardized colors or the colors used in printing, it is possible, as the author has suggested, for the artist to paint with practically the same colors as the engraver uses; and in that case it simplifies the engraver's problem and it eliminates a good deal of extra work, but at the same time it limits the possibilities for the artist. It is largely in the hands of the advertiser as to what he wants to do. If the advertiser selects an original which has been painted without any artistic restriction, without any color restriction, he may or may not get a satisfactory reproduction. It depends upon what means the artist uses to suggest his effects. If his effects were obtained by various deep layers of color—transparent pigment, for instance—that cannot be duplicated by any printing process, because we print with a very thin layer of color, and the psychological effect of a very deep, transparent pigment cannot be so duplicated. In one case the engraver may be able to retain the spirit of an original, without facsimile reproduction, but in another case, only a perfect reproduction may retain enough of the spirit of it to make it worth while using the original. This question is connected with the ability of the advertising man to size up what there is in the picture and what the engraver can get out of it. It seems to me that if any attempt is made to limit artists to the use of a few standard colors it would make it very unlikely that there would be any rapid improvement in reproduction methods. Very largely, the amount of improvement and the progress that has taken place in the methods of photographic reproduction are due to the difficulty of reproducing works of art and the fact that these works of art are "over the heads" of the engravers. There is something to aim at which they would not have if the artist "painted down" to their process.

Mr. Newton. We must not forget that people endeavor to get a facsimile, but it is absolutely impossible to get a facsimile of a water color, an oil painting, or a pastel drawing. Customers overlook this. Any water color or oil painting or pastel is no facsimile of a landscape; it is merely a representation, a sort of suggestion of what the painter saw; it is merely an imitation. The first thing a customer asks for is a facsimile of what the artist gives you. Bear that in mind.

Now, the second thing is, as Mr. Murray just has stated, that it is impossible and would be fatal to tell the artist, a man of ideas, a man of temperament, a man of ideals, that he must paint a picture in just three colors and that he must paint it in just this way. My experience is that it is very difficult to reproduce a thing painted in just three pigments. I do not say that it is impossible. We have only three inks to use, and some combinations that an artist will use are outside the limits altogether. It is quite impossible to reproduce them unless you have a special printing in an ink of the exact shade. Now, some time ago they reproduced some of Turner's paintings which were rather close to the original; some of them had as many as 40 printings, and they got something like 40 colors; and it is impossible to get that by a mixture of only three colors. That, also, should be borne in mind. What we must attempt to do is to approximate as near as we can to the artist, and if you reduce the artist to using only three-color paintings, it will be very discouraging and unpleasant, and it would be a sort of step backward instead of a step forward. We should not try to restrict the artist—although we may ask him not to use impossible colors—but otherwise give as much freedom as we can. As Mr. Ode said, you get the originals from all over the world, but you cannot expect that you are going to get an exact facsimile of an oil painting; that is an impossibility.

Mr. Farrell. I believe that a great many artists, the ones that make paintings for the magazines, will gradually be educated along this line. My experience is that some of our work that is coming through is more popular with the general magazines, and I think that we will gradually improve in the type of work that is coming through. When I first went into the standardization work, we started to apply it in our own office, and we had to impress the engraver with the use of standard colors to keep in mind the reproducing of our piece of art right from the beginning. There was just one problem that we had in our office, and that was with the reproduction of a package. We could see that with the standard colors we were using we were not going to keep near the package, and of the magazines that we used every one had a different blue; so we experimented and we settled that, and we do not have any further trouble, except that we found it is different from a standard blue. In that we arrived at the color with a solid blue; I would say a middle tone of the black, using the standard colors, and it turned out our package all right. We had to impress upon our engraver that he must keep the standard colors in mind. I think every engraver must first bear that in mind. After a great deal of fussing around we have the same color package today that we had a year and a half ago, by using blue and adding red to it. There is no doubt about it that if you just reproduce a painting and work it in any way, you will not get as good results as if you keep the standard colors in mind and work it intelligently.

[6] Queen City Printing Ink Company, Rochester, N. Y.
[7] Eastman Kodak Company, Rochester, N. Y.

William C. Glass.[8] It seems to me that there are two distinct fields—one which may be called the commercial, and the other the artistic. A certain manufacturer of a nationally advertised product when he gave out an order specified that the inks should be purchased from a named manufacturer and must be in certain colors. It worked a hardship, because there is no question that this ink could have been matched by other ink manufacturers. The point was that the advertiser, the manufacturer of the product, wanted exactly the same product in San Francisco as was made in the East. In some cases he did not get it even under these specifications. There was a wide variation in packages purchased from different plants. However, there is a difference of opinion on the question.

It seems to me that the first of these two fields includes a large part of the commercial trade, which can be standardized and in which the artist can be held to a certain color chart. On the other side there is the question of reproducing oil paintings of old masters, the reproducing of art panels, etc., all of which is distinctly related to the artistic field. In this work standards certainly cannot be maintained if faithful reproductions are to be made.

Irving F. Niles.[9] Some time ago we had considerable difficulty in getting the proper color effect on a job moved from our Chicago plant to our New York plant. We shipped the ink and paper from a lot that had been used in Chicago to New York, but for some reason, we could not get the same color effect in New York that we could in Chicago, and finally we had to ship the whole job back to Chicago. We tried our best to get the same color effect, but we simply could not get the thing right; in fact, we had a man come from Chicago to New York, and even then we could not get it. No, we did not bring the presses.

Mr. Murray. I would like to ask those who are familiar with the selection of the three-color standard inks of the American Institute of Graphic Arts whether any work has been done on the establishment of specifications based on spectral measurements of these colors or whether the standards are selected from certain manufacturers by rule of thumb without any other specifications of a scientific nature being adopted. Has anything of that kind been projected for the future?

Mr. Newton. There has been considerable done by the Bureau of Standards, and that is the nearest that would come to that specification; of course, none of them does come to that specification, but it is something to shoot at. There is a great deal of work being done on it, and I think we have made a great step in advance in getting the printing ink manufacturer to agree to standardization of colors, and I think that none of them thinks they are perfect. If you get the publishers to print with you and if you get the engravers to work with them, I think it is a step forward. Now, I think we shall improve on that in time and get them to adopt fresh standards. At the present time we are a hundred times better off than we were a few years ago. We are not satisfied; we are a long way from being satisfied, but we are making a step forward. Everybody is much more comfortable than when they started in this standardization work.

L. Bashwiner.[10] I think that commercially a good many jobs now being done in six, seven, and eight colors can be reproduced in four. In order for the lithographers to be in line with some of the printers, they must reduce the amount of colors they use. Where they have control of their own artists, I think that standardization can be accomplished. They have more chance to compete with the other printers than they have had in the past. I fully advocate the idea that a subject be reproduced in the standard colors, three or four colors, that is now being done in six, seven, and eight colors.

Mr. Niles. Mr. Bashwiner is right; we have found subjects that are now being printed in three or four colors just as good as any we have ever seen, and other lithographers have said that it would take seven or eight colors for the same subjects that we have printed in four colors.

### Author's Closure

The practical inkmaker, as I have known him in the past, has been a man that has learned by his experience rather than by any scientific research. I am sure that today there is more of a tendency to keep in touch with the laboratory than ever before. One of the best ways to react upon the inkmakers is for the customer to get after him; he is usually responsive to what his customers want, especially so if they say they will get it from somebody else.

I would say that Mr. Glass has "hit the nail on the head." Have enough printings, in reproducing an oil painting, to get what you want, and try to confine your commercial artists to a commercial line of colors, if that can be done.

We have learned a lot since we came here. I have a very good idea now of the whole thing. When I started out, I knew very little about standardization, but I have learned quite a little.

# The Spirit of the Creative Age

By ROBERT W. DISQUE,[1] ROCHESTER, N. Y.

LET us go back to the middle of the fifteenth century and see what the savants of that period were thinking about. There are certain historical records which deal with the conflict of those who held sacred the original or humanistic art, popularly known as the hand-lettering art, with those proteges of Gutenberg, who advocated the new-found printing art.

It may be said that Gutenberg gave to mankind the inspiration which has marched on triumphantly through time and increased with fervor and force, each generation having been a contributor to the arts and inventions for the glory and advancement of civilization. Aldus Manutius, historically known as Aldus, took up the task as Gutenberg's life ebbed away, but it was a thorny path which he traveled.

But Aldus was determined. His was a great vision. The severity of the opposition of powerful patrons of humanistic art did not dampen his ardor in behalf of Gutenberg's invention. Aldus was more than a protege; he was a promoter of a new idea which he clearly understood, and which he regarded as revolutionary, yet highly important, not only as part of the evolution of book making, but most valuable "to illuminate," as he said, "a dark and troublesome age with the greater dissemination of knowledge."

One of Aldus' most severe antagonists was the Duke of Urbino, whose magnificent collection of humanistic art of the middle of the fifteenth century can be seen today in the Laurenzian Library at Florence, Italy. The Duke had this to say: "In that library the books are all beautiful in a superlative degree and all written by pen. There is not a single one of them printed, for it would have been a shame to have one of that sort."

It was Aldus' extraordinary physical endurance against persecution and bodily attacks which saved the day for Gutenberg's invention and really raised the curtain for the dramatic entry of the mechanical genius.

More than a third of a century of intimacy with the printing industry has permitted me to enjoy one thrill after another and many of them provided by the energy of the engineer.

I have seen an old Cottrell press, turning out 600 papers an hour, replaced by the web press printing 700 a minute. The old stereotype foundry that required 12 minutes to make a plate long ago passed into oblivion, to be succeeded by equipment making four plates in 3 minutes. The attache of the composing room would be amazed if he returned to life and visited his old haunts, for he would be bewildered by the complete change of scene, speed, and action. What a marvelous contribution to this great drama by the engineers of our present generation!

As recently as 10 years ago one would have been declared a madman even to hint a straight-line or progressive production for a composing room. But the genius has an uncanny way of anticipating difficulties and establishing certain fundamental principles to accomplish marvelous mechanical feats. And in this city of Rochester there is a straight-line production newspaper plant, probably the first success of its kind, at least in this part of the country.

Wander around a newspaper composing room and see what the mechanical engineer has contributed to progress. A third of a century ago all type was set or composed by hand. A first-class compositor would set about one line, column width, of news type a minute.

[1] Production Manager, Gannett Newspapers, Inc.

Presented at the First National Meeting of the A.S.M.E. Printing Industries Division, Rochester, N. Y., November 8 and 9, 1928.

A man named Mergenthaler, with a restless, tireless nature, felt the urge for invention. Others too, were afflicted with the same urge and made valuable discoveries and contributions toward the perfection of a typesetting machine. Mergenthaler's theory, however, seemed to be the most practical. Its simplicity of performance revolutionized the composing room overnight. The first Mergenthaler machine, for example, produced single column news lines four times more rapidly than could be accomplished by the speediest hand compositor. Furthermore, each line was cast on a solid slug, which made it possible for the printer to handle composition with greater ease and rapidity.

These first inventions of Mergenthaler were limited to the use of one size and style of type. The matrices, or molds, of type contained only a single letter and were known as one-letter matrices. Soon after the successful production of the single-letter matrices it was discovered that two letters could be cut into the matrix, and with a slight mechanical improvement, the printer could produce either a roman letter or an italic letter on the same line or slug. Of course, both letters had to be of the same size in order to pass through the type mold for perfect production of the letter and the type line. Therefore, the first type-setting machines produced four times more than the human hand, but only one size of letter and a line of news column width.

While the fundamental principles of machine-type composition have been retained, the genius of the engineer has been active in redressing the mechanism so that the performance of a modern typesetting machine is so diversified that it seems almost human. From four lines a minute the machine's speed of production has been increased to six lines. While the first machines cast an agate line about one-fourteenth of an inch in size, today a line nearly nine times larger is successfully produced. In the beginning a machine was equipped with one-letter matrices of a single size. Today the modern machines all have two-letter matrices, but the engineer has created a flexibility of mechanism which makes it possible for a single machine to produce as many as twelve styles and sizes of type. If Gutenberg and Aldus could come back to civilization today, what a glorious tribute the mechanical engineer of our time and generation could be accorded by those men who may be properly called the fathers of typographic invention.

The Intertype machine, too, has made notable contributions to the perfection of machine composition. The Intertype and the Mergenthaler employ practically the same fundamental principles of composition, casting, and distribution. While each machine has its own useful features of production and construction, both are accepted as standard equipment for the composing room.

Notwithstanding the remarkable accomplishments revealed in the typesetting machine, there are other mechanical geniuses who have made valuable and astonishing contributions to type-casting in order to facilitate the requirements of the newspaper composing room and to fill the demands of display advertising. The Ludlow type-casting machine makes it possible to produce type slugs ranging in size from one-fifth of an inch up to two inches. The Monotype machine's performance in type-setting and type-casting is really another wonder of the age. This machine extends its usefulness beyond type-casting and includes the production of dashes, rules, borders, and spacing material with a speed and accuracy which only the printer and the engineer can properly appreciate. The Elrod material-casting ma-

chine, also, has demonstrated its real value and worth in the newspaper composing room.

Today the compositor devotes all his time to production. Every letter and line of news or advertising appears each day in a fresh, new dress. No type is used the second time.

Every movement centered in the composing room of today reflects the thought and skill of the engineer; every device is a tribute to his genius, so that without the contribution of the mechanical engineer it would be utterly impossible for the newspaper to accommodate the reader and the commercial demands of our day.

But the untiring effort of the engineer penetrates every unit of the newspaper's mechanical departments. His work is again seen in the stereotyping foundry. As the type pages leave the composing room, the stereotyper greets them with an admirable simplicity of action and with the full assurance that with his skill and his mechanical devices he will fashion the page into a perfect reproduction within a few minutes.

In earlier days it required about 12 minutes to make a plate reproduction of a type page. Today a plate can be delivered to the pressroom in 3 minutes, if necessary. The improvements in molding machines, metal furnaces, casting boxes, cooling and finishing machines, automatic plate drops, startle the mechanical mind of yesteryear. What was then known as the wet mat, which required considerable time to prepare, is now replaced by the high-speed dry mat, delivered from the manufacturer and ready for instant service. Molten metal, which heretofore was carried in ladles by two men to casting boxes, is now electrically and automatically pumped into the boxes with but a touch of the hand. Casting boxes which in earlier days delivered one plate in three minutes now send to the finishing machine four perfect plates in three minutes. The hazards to men and product of the stereotype department have been greatly eliminated, and the speed has been increased fourfold by the mobilization of thought and action of the engineer and the foundryman.

Without the performance of a press, the last chapter of the newspaper drama could not be written. The whole civilized world pays tribute every day by its purchases of newspapers to the American press manufacturer. It is my belief that no civilized country is without an American-made newspaper press, so that the mechanical genius of the American engineer is far flung beyond the borders of his native land. Nor would I be mistaken in saying that Benjamin Franklin introduced American newspaper methods abroad, for it is a well-known fact that this extraordinary and historic character mobilized his resources, and several times the resources of others, to give our wonderful nation a place in the sun with the aid of the printed word.

One minute, and sometimes less, after the last plate or page is received, the press starts humming, singing its song of service to civilization. Racing against time, traveling at tremendous speed, yet issuing its product with accuracy and precision, these modern newspaper presses exalt the efforts of those who have made possible this marathon performance.

In days gone by, one unit, or a single press, operated independently of the other presses. Today a "hook-up" of any number of units has been made possible by the coordinated efforts of the mechanical and electrical engineers. The synchronization of motors enables productive expediency. The hook-up of units gives the publisher almost anything he wants to perfect a public service. The single-roll feed method of yesterday has been replaced by the triple-roll reel system of today. One roll of newsprint is fed into the swift-revolving cylinders with astonishing smoothness and accuracy. Replacement of rolls heretofore required a complete stop of the press; today the modern reel system has a fresh roll of newsprint in perfect position, ready to slip into its place of service while the press is in slow-down operation.

As the papers slide out to automatic conveyors in an endless stream, one is captivated by the neatly printed and folded copies, all counted and all ready to assist the circulation department in its exciting race to please and serve an interested and anxious public mind.

Rochester has a newspaper plant with a productive capacity which is perhaps the greatest in the world. The figures available lead me to say that the composing room doing the composition for The Times-Union and The Democrat and Chronicle probably turns out as many pages of news and advertising in a day as are produced by the largest newspaper plants in the world. Only the most modern equipment would permit such an enormous volume of composition.

The newspaper has been generously attended to, but inventive genius has been tireless in its labors to aid in the perfection of the printing art and industry. The commercial printer and the lithographer, the offset and intaglio printer, have all honored themselves with such contributions to the printing art as would have charmed Gutenberg and Aldus and softened the heart of the irreconcilable Duke of Urbino.

Students of philosophy and philosophers revel in the wisdom of Aristotle, Aurelius, Socrates and other giants of the early intellectual period. What a rich heritage we possess! And what a well of wisdom we have to draw from to stimulate and restrengthen our initiative. But theirs was only an intellectual age.

It seems to me that we are not lacking in appreciation of our inherited wisdom of the savants of earlier centuries, for the world today is proof of our energy and progress and of our performance, action, and achievements. We are not only thinking about things, but we are doing things. We can only maintain "the spirit of the creative age" by continued thinking, performance, action, and achievement.

# Modern Bronzing Problems and Methods

## Public Demand the Reason for Universal Use of Bronze for Decorative Purposes in Printing—The Vacuum Bronzer—Automatic Conveyors for Bronzing Machines—High-Speed Vacuum Bronzing Machines and Their Operation

By WILLIAM C. GLASS,[1] NEW YORK, N. Y.

BRONZING is one of the least popular and most important operations in certain branches of the printing and lithographic industries. It is often referred to as a necessary evil. Twenty years of personal experience in this field has, however, witnessed a phenomenal increase of the necessity and a reduction, amounting practically to elimination, of the evil.

Necessity for the bronzing operation is so obvious as to be overlooked, but this necessity is so thoroughly grounded in natural laws as to establish its permanency beyond any attempt or desire to modify or eliminate it. Gold and its visual substitutes hold a unique place in this world of ours for two reasons: first, gold is a precious metal, and second, it possesses color properties which are entirely lacking in any other vehicle used for decorative purposes.

From time immemorial man has intuitively considered gold as the standard of intrinsic value and the symbol of worth and merit. The Babylonians applied gold leaf to the mural decorations of their temples; the Egyptians used it in coating the mummy cases of their kings; the Greeks gilded the colossal statue of Athena which crowned the wondrous architecture of the Acropolis; the Romans used gold in the decoration of household furniture; the monks of the Middle Ages used it to illuminate their manuscripts; the old master painters used it to adorn the frescos of their cathedrals and abbeys; Louis XIV, "Le Grand Monarque," reveled in it, as did the art of the Near East from the Moors of Spain to the Moslems of Byzantium, and the countries of the Far East, India, China, and Japan.

Today gold is used everywhere for decorative purposes. A careful examination of any decorative or color scheme which makes a special appeal and commands unusual attention will invariably disclose gold as the element without which it would lose its individuality. And so through the ages the impelling lure of this wonderful metal has found its reflection in a demand for bronze as a decorative medium wherever the esthetic taste is relied upon to build up an appeal, whether that appeal is simply to satisfy the artistic temperament or to attract the prospective purchaser. This principle has successfully withstood the test of competitive endeavor.

In its chromatic value gold may be considered as both a neutral and a contrasting color. While it harmonizes with all colors it also serves to set them off and to enhance the value of every hue and tint. It is a perfect foil. Doubt that gold is a perfect foil for pictures in color will be at once dissipated by the inspection of any art gallery where the unanimity with which artists have adopted gilt or bronze for their frames will be at once apparent. As for the use of gold as an integral part of a decorative painting, we have only to point for authority to such master American painters as Sargent, Abbey, and Maxfield Parrish. Some years ago a small group of rebellious artists started a movement to supplant the traditional gold frame with frames of black or dark-finished wood. For paintings in color it was a failure. The public, which is always the ultimate judge, could not be won over; they recognized the appropriateness and the artistic color relation of gold.

### Public Demand the Reason for Universal Use of Bronze for Decorative Purposes

For the same reason it is public demand which has increased the use of bronze by many tons, until today even a guess at the total volume used would be hazardous. The successful use of bronze means the unhampered salesman, the emancipated artist, and the satisfied customer. Public demand is the one big reason for the universal use of bronze on practically every commodity which is offered for sale in package form. If there is any disposition toward skepticism, one has only to survey his own home and he will find bronze labels in use from the kitchen pantry through every room in the house. Bronze labels are used on canned goods, packages of foodstuffs of every description, bottle labels, cosmetic boxes, phonograph-record labels, playing cards, cigarette packages, cigar bands and boxes, hosiery and all kinds of textile labels, writing paper, decalcomania transfers, candy-box wrappers, chewing-gum wrappers, souvenir postal cards, and so on through the entire line wherever a label or wrapper is used on any type of merchandise or wherever a decorative scheme is relied upon to stimulate sales appeal.

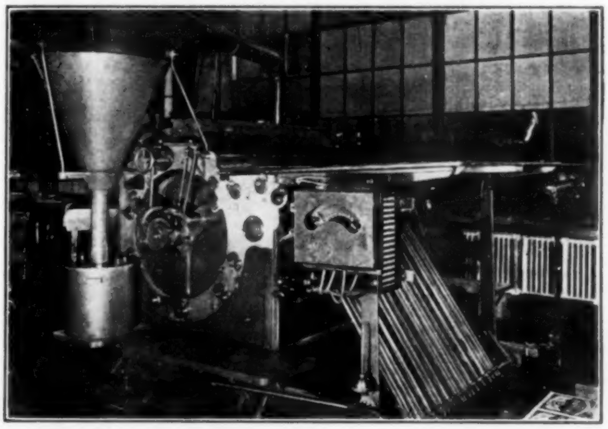

Fig. 1 Standard Fly-Delivery Vacuum Bronzer Arranged for Hand Feeding

(Note that the cyclone exhausts into the pressroom with no outdoor connection.)

This lengthy preface is not to be construed as an excuse for bronzing, but rather as a reason for its being and as a warning to those who may feel that it is not of sufficient importance to merit serious consideration from the standpoint of necessity for equipping with as up-to-date and efficient machines for this operation as for their other manufacturing processes.

The antipathy of the printers and lithographers toward the bronzing process is not without foundation, because the mere mention of bronze doubtless carries many of them back in retro-

Presented at the First National Meeting of the A.S.M.E. Printing Industries Division, Rochester, N. Y., November 8 and 9, 1928.

spect to their apprenticeship days when bronzing was done by hand. This meant rubbing bronze on a printed sheet with a wad of cotton batting, and then brushing the sheet again with another wad of cotton batting to remove the surplus bronze. In those days bronzing had to be done in an isolated part of the plant, because the powder spread rapidly through the room and covered every-

(This outfit is limited in speed by the bronzer to 1800 per hour, even though the press will run 3000. Note pulley blocks for raising conveyor from press when bronzer is not in use.)

thing in its path. The boys who did the work usually wore sponges over their noses to prevent inhaling too much of the bronze dust, and they were also supplied with a plentiful quantity of milk to drink as an antidote for the supposed injurious effects of the bronze dust. One can hardly be blamed for wanting to avoid such a condition. In spite of this condition, however, the demand for gold increased, and as a natural consequence machines were developed to take the place of this hand operation. The machines were a decided improvement, of course, but were far from satisfactory because they cured only some of the evils. It was not until 1907 that the first so-called "vacuum" bronzer with a positive delivery was introduced to the market. This machine met with instant and universal approval, and was adopted by the leading plants throughout the country.

## The Vacuum Bronzer

This vacuum bronzer consisted of two cylinders, each provided with grippers. (Fig. 1.) The sheet, which had been previously sized in a printing press, was brought to the bronzer and fed to gages similar to the press itself. The grippers in the larger cylinder engaged the sheet and carried it around past successive pads and rollers, then transferred it to grippers in the second cylinder, with the face of the sheet against this cylinder so that the back of the sheet could be dusted. The sheet was then delivered to a fly mechanism, similar to the well-known fly delivery on a printing press.

There is no intention in this paper to discuss differences in particular mechanisms between various types of bronzing machines, but rather to point out certain fundamental principles which in themselves have dictated ultimate results. It is a fact, however, that no fundamental change has been made in the principle of the vacuum bronzing machine in the last twenty-one years. The changes which have been made in vacuum bronzers have been dictated more by changing conditions in industry than by a necessity for improvement in the machine itself.

Attempts have been made to revert somewhat to the so-called flat bronzer which was discarded by the lithograph trade many years ago as inefficient, inadequate, and generally unsatisfactory. In this type of machine, generally speaking, the sheet is carried through on a belt or tape in a straight line instead of going around a cylinder. Practically all flat bronzing machines have no grippers to carry the sheet through, but depend entirely on friction. Such machines operate with fair results on heavy paper and cardboard, but when the paper is at all curly or uneven the leading edge is usually crumpled or torn, resulting in a total loss of the sheet. It is also a demonstrated fact that in this type of bronzer the sheet cannot be properly burnished and dusted. Experiments with bronzing machines of the flat type equipped with grippers have been equally unsuccessful. Bronzing machines of the flat type are comparatively inexpensive to build; they have been known to the trade for many years, and yet there are so few in use, except in very small sizes, as to practically eliminate them

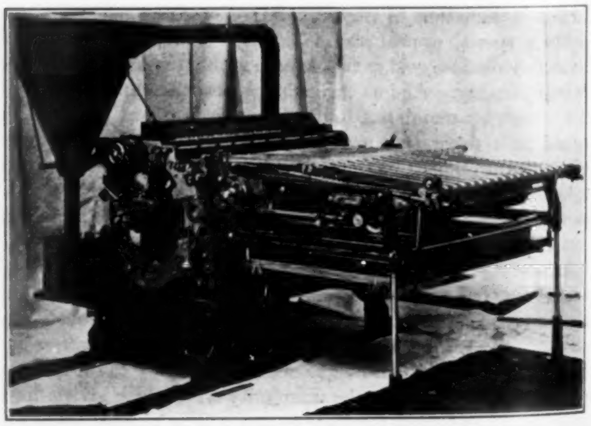

Fig. 4 Standard High-Speed Vacuum Bronzer of the Two-Cylinder Type, With Lowering-Pile Delivery

from serious consideration. They cannot be considered as at all efficient for mass production. They are short-run or special-purpose machines. On the other hand, when 80 to 90 per cent of all the bronze work in this country is being produced on a certain type of cylinder bronzer, that in itself is conclusive proof of its efficiency and constitutes a vindication of the underlying principles on which it is built.

### Automatic Conveyor for Bronzing Machines

When the vacuum bronzer was first introduced to the market, automatic feeders and high speed were not the watchwords as they are at the present time. Developments along these lines, however, soon led to the automatic conveyor for bronzing machines about the year 1911. (See Fig. 2.) This is a simple tape device which connects the delivery mechanism of the press with the bronzer so that the sheet can be fed directly and automatically from the press, after being sized, to the grippers of the bronzer and thence carried through the bronzing operation for delivery to the jogger board of the bronzer. When using a conveyor the bronzer is driven from the press-driving motor by means of a roller-chain connection so that both machines are synchronized. The conveyor can be readily disconnected when the bronzer is not required, so that the press may be used for other work independently of the bronzer.

The conveyor made possible service and improvements which could not have been anticipated before its introduction. The practice in hand feeding was to carry several sheets from the press over to the feed board of the bronzer and then feed them through the bronzer by hand. Obviously the last sheet out of the press would be the first sheet into the bronzer, and the first sheet out of the press would be the last into the bronzer. There would be a noticeable difference in the quality of work between these extremes, making it necessary to carry a sufficient body of size on the sheets so that the last one into the bronzer would still take bronze.

This hand feeding also required considerably more labor and resulted in a great amount of spoilage, besides the loss of time and decreased production.

With the automatic conveyor, the sheets go into the bronzer at a predetermined time after being printed with size, so it is possible to reduce the amount of size to the minimum and still obtain a satisfactory bronzed job. There is no loss in production, because the bronzer is timed absolutely with the press; there is no excess of labor, because the bronzer is fed automatically from the press.

With the rapid increase in popularity of the offset press new problems arose in bronzing requirements, and these problems were not confined entirely to the necessity for increased speed. With printing presses, the usual practice was to confine the bronze work to one press and have the bronzer connected to this press with a conveyor. There were many differences of opinion

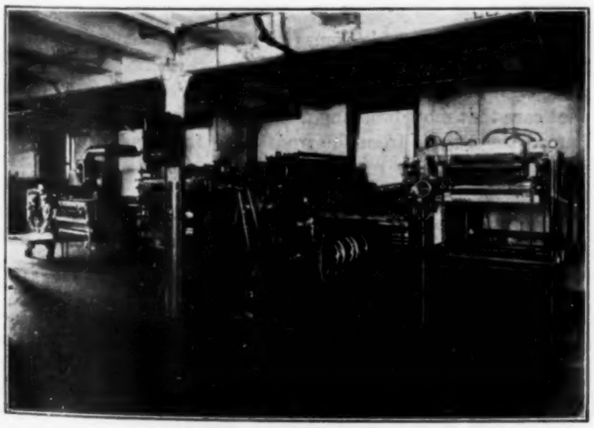

Fig. 5 Standard High-Speed Vacuum Bronzer Connected to an Offset Press by Means of an Automatic Drive and Conveyor Mechanism

(The sheet is not touched by hand after being put into the automatic feeder of press until it is removed from the pile delivery of the bronzer, speed, 3000 sheets per hour.)

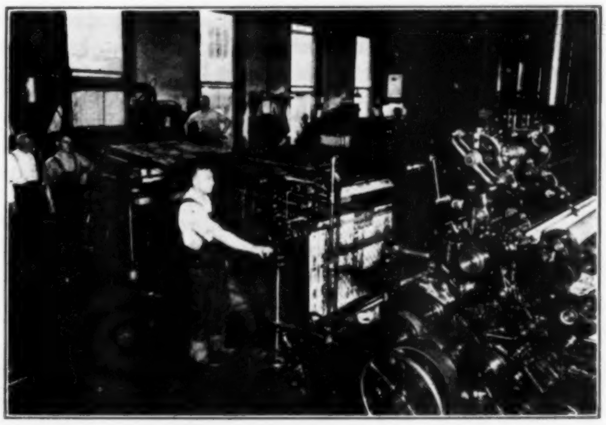

Fig. 6 Standard High-Speed Vacuum Bronzer Connected to an Offset Press, Showing Course of Sheet From Delivery Mechanism of Press to Feeding-in Tapes on Bronzer

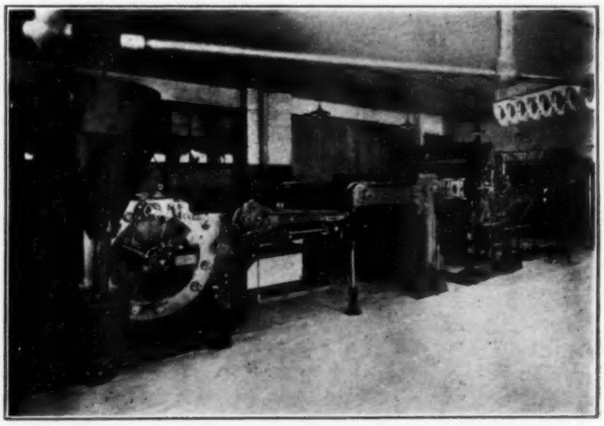

Fig. 7 Standard High-Speed Vacuum Bronzer Connected to an Offset Press

(This is a special installation because of limited space available in which to install the bronzer. The bronzer is mounted on special wheels and tracks set into the floor. As shown, the bronzer is rolled up to the press delivery into operating position, leaving a passageway behind the bronzer. When not in use it is rolled back against the wall, leaving a passageway between the press and bronzer.)

Fig. 8 Standard High-Speed Vacuum Bronzer Connected to a Direct Rotary Press

(This is a special installation. The press is used for bronze work exclusively and the machines are arranged with the delivery mechanism of the press directly above the feeding-in tapes of the bronzer. Neither the press nor the bronzer can be used independently of each other. Speed 2500 per hour.)

on this same question in regard to offset presses, because it was felt that all the colors, including bronze sizing, had to be printed on the same offset press in order to assure accurate register. It seems, however, that this objection has been fairly met, because the benefits of printing colors on several presses, and especially in large plants, have been so great as to merit careful attention. The bronzing operation was benefited thereby, so that at the present time, except under unusual conditions, a bronzer can be connected up to one offset press in a group and all of the bronze work can be diverted to this one outfit, regardless of the offset press or presses on which the preceding colors were printed.

### High-Speed Vacuum Bronzing Machines

The problem which the bronzer manufacturer had to solve was that of increased speed, and this has been accomplished by high-speed vacuum bronzing machines which are capable of maintaining guaranteed speeds of 3000 sheets per hour.

These high-speed machines are the same in principle and in all essential mechanisms as the original vacuum fly-delivery bronzer, except that the fly-delivery mechanism has been replaced by a lowering-pile-delivery mechanism. (Fig. 4.) In some cases the bronzing cylinder has been provided with two sets of grippers diametrically opposed so that two sheets can be bronzed for each revolution instead of one as in the case of the fly-delivery machine. (Fig. 5.) This feature permits of 3000 sheets per hour with the bronzer actually running only 1500 per hour, which was the average speed for hand feeding.

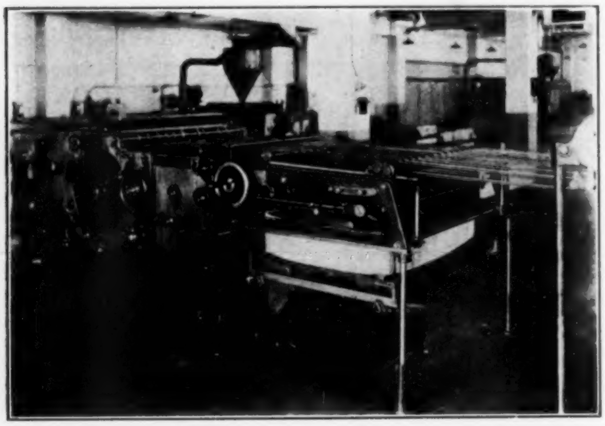

Fig. 9 Four-Cylinder High-Speed Vacuum Bronzer Connected to an Offset Press by Means of an Automatic Drive and Conveyor Mechanism

(This is the latest development in high-speed bronzing, producing absolutely clean sheets at the rate of 3000 per hour.)

The all-important objective is, of course, the cleanest possible sheet. Before the introduction of the vacuum bronzer there were dusting machines on the market through which bronzed sheets were fed for an additional dusting. The introduction of the vacuum bronzer solved this problem of bronzing and dusting in one operation in a highly satisfactory manner, except for certain unusual requirements. There are some classes of work which have to be dusted again because of subsequent operations. This dusting, however, is not necessarily due to the failure of the bronzer to dust the sheet properly. Bronzing consists of impinging a coating of bronze flakes on a somewhat tacky surface of sizing. When this surface under the bronze dries it will be found that there are many unattached flakes of bronze lying free or between other attached flakes on this surface. Running the hand over the sheet dislodges these flakes or breaks off the tops of others which may be simply held by a point in the sizing.

Therefore, for such bronze work as had to be subsequently calendered or varnished, it was found advisable, if not always necessary, to dust the sheets again. For this operation also the old-fashioned dusting machine gradually gave way to the bronzer because the latter could be readily cleaned out and the sheets put through a second time for an additional burnishing and dusting. Many concerns equipped themselves with an additional bronzer to be used exclusively as a duster. Then in case of an emergency the duster could also be used as a bronzer. The most efficient dusting machine consists of a bronzer with an automatic feeder attached to eliminate the hand feeding operation. It is advisable to allow bronzed sheets to stand for several hours between the bronzing and dusting operations. On the other hand, good results can be obtained by running the sheets through the bronzer immediately after being bronzed, provided the bronzing has been done on a machine equipped with an automatic conveyor so that the minimum amount of sizing has been used.

Combining these thoughts produced the obvious result of a still further improvement in the vacuum bronzer in a four-cylinder machine which has recently been introduced to the trade. (Fig. 9.) This machine is practically two machines combined in one. It has two distinct vacuum attachments, one for the bronzing unit proper and one for the dusting unit. The sheets can be taken from this new bronzer and run through a varnishing machine without redusting which is the most severe test that can be applied. It represents the ultimate of perfection in bronzing equipment, because it combines speed with quality and an absolutely clean sheet in one operation. It would be far-fetched to say that the two-cylinder bronzer has outlived its usefulness, but it is not exaggeration to say that the four-cylinder combination bronzing and dusting machine is the ultimate answer to the bronzing question.

As has been suggested, bronzing is somewhat of an unpopular operation, and has therefore suffered greatly by lack of attention from executives who have been satisfied to leave this part of the work to more or less indifferent supervision. This is an expensive policy, however, because bronzing is usually a finishing operation after an expensive sheet of paper has been made more valuable by the addition of many printings of color and the expenditure of much labor. A sheet wasted in the bronzing operation represents considerably more in expense than one wasted at the press, and yet in many cases the bronzing operation is indifferently supervised and left to unskilled and uninterested operatives.

### Points to Be Observed in Operating Bronzing Machines

There is no reasonable excuse for bronzing to be unpopular. If a printing press, paper cutter, folding machine, or any other piece of mechanical equipment had the inadequate and unintelligent care that most bronzing machines receive there would be an immediate crusade from the front office to fix the responsibility and discipline those responsible for the condition. A bronzer can be kept clean, and the bronzing operation can be made no more obnoxious than any other in the trade. Obviously, if the amount of bronze fed into the machine could be confined to exactly the quantity required for the sheet being bronzed, then there would be no surplus to require an extra brushing, and there would be no surplus to dirty the machine and escape into the pressroom. Various mechanisms and adjustments have been provided so that the quantity of bronze can be regulated toward a minimum according to the particular job being run. The difficulty is that most operatives never pay any attention to feed except to see that there is enough, working on the basis that the surplus is reclaimed by the vacuum system. Most of it is reclaimed under normal conditions, but the vacuum system is designed to meet certain conditions, and when overtaxed it simply will not take care of the excess, which is then free to escape into

the pressroom or lodge in the recesses of the machine itself.

Another important point in connection with the bronze feed is that the job should be started with too little bronze, because this will then show up low spots in the make-ready on the press. It is better to bring up a few spots here and there on the press than to flood the sheet with bronze to make up for them.

The question of separate rooms or compartments for the bronzing operation is also deserving of comment. The author is opposed in principle to segregating the bronzer. It is at once an admission of the belief that the bronzing operation cannot be clean, and produces the wrong psychological effect on those responsible for this operation. The great majority of vacuum bronzers are being operated in the open pressroom near other machines and paper stock, with no likelihood of damage to either except through carelessness.

The question of connecting the cyclone of the vacuum system with the outer air is one which can best be met in the individual installation. Where it can be connected out of doors it is best to do so because a considerable volume of air issues from the top of the cyclone, and if this exhausts into the pressroom it will set up a current of air through the pressroom and this current will carry with it not only the loose bronze which may be around the machine but any other dust which may accumulate. With the proper outdoor connection no bronze will escape from the machine, but on the contrary it will be returned to the receptacle supplied for this purpose. With an outdoor connection improperly installed there is every likelihood of a back pressure, which will result not only in bronze issuing from the outlet out of doors but also through the fountain door and other openings in the machine itself.

The use of pure aluminum bronze should be carefully supervised, because pure aluminum is highly inflammable and is susceptible to flash fires and possible explosions. The motors operating in close proximity to bronzing machines should be of the fully enclosed type or provided with enclosing covers, especially when on direct current. All electric wiring about the bronzer should be carefully done to insure against short-circuits and the possibility of flash fires. This refers, of course, only to aluminum bronze, because gold bronze is not inflammable.

It is many times found necessary to powder sheets with magnesia, especially in a lithograph plant, if it is desired to run gold or subsequent colors without allowing the necessary interval of time for natural drying. This is usually done on a bronzing machine. This practice should be discouraged, however, as much as possible, because magnesia ruins rolls and pads very rapidly. If the operation must be performed, then it is advisable to have a special bronzer set aside for this purpose. If this plan is not practicable, then there should be an extra set of rollers and pads kept for powdering only.

### Best Results Obtained With High-Grade Bronze

The subject of bronzing machines would be incompletely covered without some reference to bronze itself. There are many qualities and grades of bronze: some are fine, almost a powder, while others are coarse and more or less sandy. Some bronzes are dry, others are greasy. Some bronzes are heavy and solid, while others are light and fluffy. There is no single rule which applies except the rule of common sense according to requirements. In general it is safe to say that the bronze which is cheapest in price is usually the most expensive when it comes to the cost sheet. In case of unsatisfactory results with bronze, the wisest policy is to solicit the advice and counsel of the bronze manufacturer. No particular quality or grade of bronze will produce equally good results on all kinds of paper any more than will the same kind of ink produce satisfactory results on all kinds of paper. The requirements should be studied intelligently. The same sort of reasoning applies with equal force to the sizing. There is no universal sizing which will answer for all kinds of paper and all kinds of bronze. Many printers have thought they could mix up all their old ink and use it for sizing because it is hidden under a coating of gold, but they were never further from being right. It pays to give careful attention to the sizing and thus avoid unsatisfactory, and in many cases disastrous, results in the finished job.

It pays to buy a consistently high-grade bronze, because it has greater covering capacity per pound than cheaper and lighter bronze. When mixed with new bronze it can be used over and over without impairing its luster beyond the usable point, and

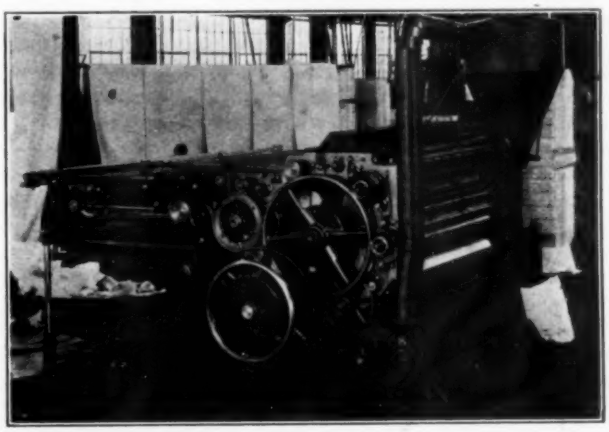

Fig. 10 Rear Doors and Guards Removed From Standard High-Speed Bronzer, Showing Particularly the Reciprocating Bronzing Pads and Cams for Operating Them

(This mechanism is the same also on the fly-delivery and four-cylinder high-speed bronzer.)

still give practically as satisfactory results as the use of entirely new bronze. As a matter of fact, it is preferable to mix a small quantity of used bronze with new bronze because it gives practically as good results as to quality and makes it much easier for dusting. This, however, should be thoroughly and carefully done outside of the machine, and the bronze put into the fountain in a mixed state. The use of the bronze-receptacle vacuum system is strongly urged because this brings the unused bronze into the receptacle where it can be sifted, weighed, and worked in with new bronze before being used again in the machine.

Too much attention cannot be given to these apparently minor details, because the sum total of these details usually spells the difference between quality and efficiency on the one hand, and poor work and inefficiency on the other.

Bronzing is here to stay, and is increasing rapidly from year to year. It might be well in closing, therefore, to repeat and to again state definitely that this operation is of sufficient importance to merit the most serious consideration and investigation from the standpoint of equipment and supervision.

## Discussion

H. A. Bernhardt.[2] I do not agree with the author when he claims that the average lithographic plant manager is very careless when bronzing a job. It is my experience that the man in charge of the bronzing is really more careful with the bronzing of a job than with any one of the other colors of the same job. Bronze is usually the last printing, and therefore any spoilage at this stage is relatively more costly. Also the bronze is very often

[2] Manager, Latham Lithograph Company, Long Island City, N. Y.

a greater single factor than any other single color, and therefore would normally command greater attention in its application.

Regarding the wisdom of using bronze, recently a customer (who is among the largest advertisers in this country) was in a great hurry to get out a folder which was to be embellished with a bronze border. He suggested that we omit the bronze border, hoping thereby to gain several days in the delivery time. We therefore submitted a proof, substituting a gray border for the bronze one, which gave a very displeasing effect and therefore was not approved by the customer, who then cheerfully granted the necessary time to apply bronze, as originally planned in the design. The job in question was a fine Christmas greeting in eight colors and bronze. By omitting the bronze it would have suffered in artistic beauty.

I agree with the author that bronze, if applied with artistic judgment in the original design, is very much desired today, and with the modern bronzing machinery and improved methods, bronzing presents an added profit-producing operation that is too often overlooked by the average lithographer.

Randolph T. Ode.[3] What does the author think of printing on top of bronze or bronze ink?

Mr. Glass. That is an open question. Only in instances where plates are made in the old way is the bronzing usually done first, because the gloss is lost as a rule in going through the presses several times. It is preferable to put the bronze on last as a finishing operation.

A great deal of attention is being given to the matter of printing a varnish size over the bronze, which keeps it from coming off. I think it is open to some discussion, but it is certainly all right with some classes of work.

Mr. Bernhardt. As to applying bronze and then printing or lithographing over it, we have done it on several occasions. We have an especially beautiful effect in the picture of a bronze Indian where we have done the bronze in the first printing and then have added the various colors to the picture of the Indian, and we have obtained a very beautiful effect which could not have been secured had we put the bronze on in the last operation, because the portions that did not receive any ink were the lustrous eyelashes that were absolutely a gold effect, and the picture resembled a bronze statue. All of this requires foresight, because that bronze has to be thoroughly dried, for a week at least, and in applying those printings we double-printed one or two of those colors in order to get the effect, but the result was something worth while. Whether that can be practiced commercially I do not know. I have seen some sample labels with one color put over solid bronze.

R. F. Reed.[4] There is a matter that seems to be vague in the minds of some of the lithographers. Some of them print the gold size on the sheet from electrotypes, others from stone or from metal, by direct lithography, while still others use the offset process. Of course, if you use the offset press, you secure a thinner film of size on the sheet than by the other methods. It is a question as to whether bronzing can be done as satisfactorily by printing the size on the offset press as by the other methods. I would like to ask whether in the opinion of the author it can be done more satisfactorily on the offset press than by means of electrotypes? With reference to the matter of explosions in the use of aluminum bronze, I know that explosions have taken place in bronzing machines. Has it ever been proved that static electricity would cause such an explosion? Of course, in dry weather there is considerable static electricity generated in the bronzing machine.

Mr. Glass. Answering the first question, I would say that there is no doubt that the body of size from the offset press is less than from the electrotype plate, and care has to be taken so that the colors underneath do not show through. I say frankly that, given the opportunity to do it, I lean very much to bronzing from electrotype plates with a high-speed rotary press, whether the previous colors have been put on by offset or by stone or electrotype or any other process. The answer to that depends very largely upon what the various lithographers and printers are doing. I have been called in by requests for information as to what was wrong with the bronzing machine because the customer was not getting the proper covering of gold from the offset presses, whereas the real difficulty was in the offset press itself in not giving the proper amount of sizing. It is sometimes necessary on the offset press to print a color and then print the gold size over that. The extra color can be avoided many times in making plates for the other colors. The way to get the most satisfactory job is to print the bronze from the electrotype plates.

With reference to the second question about explosions, I know of only two instances where there have been explosions, and in neither of these cases were experts able to determine exactly what caused the explosion. It might have been static. I rather doubt it. I do not think it would be possible to build up a sufficient amount of static going through a bronzing machine to explode aluminum dust because if that were true we would have had many more explosions than we have had. Enough static is generated many times to make it difficult to deliver the sheet, for the reason that in a bronzing machine the sheet is held against a metal cylinder and is burnished by pads and rolls. It seems to me that if static had been the cause generally, there would have been many more static explosions. Two have occurred within the last ten years; the percentage is very small. It is my opinion that static has not caused the explosions. I think it was caused by a short circuit in one case and perhaps by a spark in the motor in the other case.

W. T. Edgell.[5] Is the explosion due to the static or to a spark in the commutator?

Mr. Glass. One of the ordinary tests for pure aluminum powder is to take a sheet of paper with aluminum powder sprinkled on it and to tap it so that the powder will go up in the air as a cloud, and then touch a match to it. If it burns freely, you will know that you have pure aluminum; what is left is lead. It proves to a certain extent also that some proportion of air is necessary. A spark from static is a momentary discharge that cannot be easily measured. It is doubtful if it could cause such an explosion except under certain conditions.

Walter E. Sooy.[6] I would like to ask a question of the author with reference to printing. The job may have several colors printed on a sheet, for example; it may be printed on a single-color press. The sheet is dried between each color; it shines where these colors lap. Is there anything in the bronzer or dusting machine to eliminate the bronze clinging to that portion of the sheet that shines or has a glossy finish due to the overlapping of the colors, or do you consider that a material or a production problem?

Mr. Glass. Having got into the difficulty, there are two half-

ways out. The first one is to magnesia the sheets; the second is to dope the bronze. Now, there is a question that has not been touched—the question of doping the bronze. There have been many ideas for doping bronze. Aluminum hydrate seems to be about as satisfactory as any and appears to have the effect of acting as a magnesia operation as well. Many times it acts as a vehicle for carrying the bronze as well as powdering the sheets. I am frank in saying that that is a manufacturing problem before you get to the bronzing operation.

Doping the bronze has to be done very carefully so far as proportions are concerned, because if too much is used it will dull the luster. There is a point which you can approach which will not affect the luster appreciably.

George C. Van Vechten.[7] I think that it is possible to develop an installation of a bronzing equipment that is not what would be called dirty. The conventional method is to use a centrifugal-type separator in conjunction with a fan, creating a vacuum in the machine. This system produces a pressure type of separation so that the bronze will fly or be distributed in the room from every aperture or crack. At present we have an installation of twelve machines in which we connected the air discharge from the centrifugal separators to a vacuum line, and then we developed an additional separator, which was also under vacuum, and thus we collect the bronze which the first separator does not remove; this is a second operation. In addition to that, in order to capitalize the air, which is being wasted, for refrigeration purposes, we had to have a rotary viscous air filter. With that it is possible to discharge the air back into the room perfectly clean. By utilizing the vacuum system we have very little bronze in the room. I think probably that would be the solution of the problem for future installations.

### Author's Closure

In thinking over the presentation of my paper, I wondered how much discussion could be started on the question of "bronzing." The reason for this statement is that there seems to be such an antipathy to the process of bronzing that it is difficult to get anyone to think seriously about it until he is faced with the necessity of bronzing, and only then does he become partially interested in the subject. It is sort of an "orphan" process and has not been given the necessary attention.

Bronzing is one of the least popular and most important operations in certain branches of the printing and lithographic industries. It is not popular, principally because many executives look upon it as a dirty operation that has to be endured. It is important, however, because we all know that gold is the one thing that adds value and beauty to anything, whatever it might be, and it is a strange thing that gold, which is the one color that acts as a foil, is the only color that will harmonize with any other color, and it also represents intrinsic value. This attracts the eye and ultimately attracts the sale, and that is what we are all aiming at.

Gold ink cannot be made to give the same color value and luster as bronze. Gold ink is composed of varnish and gold bronze mixed together, and therefore produces a surface of gold and varnish in which the luster is immediately destroyed. Gold bronze consists of a bronze powder dusted over a varnish and accordingly gives the full luster and quality of gold bronze.

A good many people seem to think that working on a bronzing machine is a killing operation. It is no more killing or dangerous than any other operation on any industrial machine; it is no more dangerous than any other dust you might mention or might sweep up on the workroom floor.

[7] Superintendent, Stecher Lithograph Company, Rochester, N. Y. Assoc-Mem. A.S.M.E.

The old way with the vacuum bronzer was to hand-feed it, but hand-feeding is now out of date and inefficient, and is accompanied by spoilage and waste, and the work also is not so good. For instance, you take fifteen or twenty sheets from the printing press over to the bronzing machine. Obviously the first sheet off the press is the last sheet into the bronzer and vice versa. You can take those twenty sheets and spread them out and see a difference in quality from one to the other. Aside from the question of waste and spoilage from the handling of the sheets through this operation, there is enormous waste of bronze and even of time. There is a considerable percentage of bronze which goes through the machine and which does not touch the paper at all.

Eighteen years ago the question of feeding bronzing machines automatically was taken up, and a mechanism was developed for feeding the sheets automatically from the press into the bronzer. That helped a very great deal. I talk conveyors because I realize that they help the printer and help the bronzer. Sometimes too much emphasis was put on the first cost of the conveyor. The average man saw the price of the conveyor without the returns he would get from it. Then there was the question of connecting up the bronzer with the conveyor to a certain press of a group. Some argued, and still do, that it is impracticable and sometimes impossible to run all the colors on one press and the bronze sizing on another press. I think it is only in the exceptional case that the lithographer actually has to run all his colors and the bronze on one press. I understand certain makers of offset presses go so far as to guarantee register from one press to another. If we do not face these questions squarely we will go on in the same old rut. However, with the rapid increase of popularity of the offset press new problems are ever occurring, not confined entirely to the necessity for increased speed.

Now comes the question of high-speed bronzing. The question of increased speed is one that is open to a great deal of discussion. What do we mean by high speed? There are no rules to cover speeds of offset presses. Speed depends on the job, depends on the paper, on the ink, on the amount of ink on the paper, and on many other variables.

What is the maximum speed required of a bronzer from the viewpoint of the lithographer or the printer? It seems to be the unanimous opinion that 3000 an hour would be ample. Some offset printers guarantee 4500 on certain classes of work. Well, if you can size a sheet at 4500, we will give you a bronzer that will bronze at that speed, but I think we ought to come down to brass tacks. I say frankly that I am not a lithographer or a printer, but I have yet to see a bronze job that can be run at 4500 an hour on large size sheets.

High-speed bronzing, of course, means automatic feeding from the press to the bronzer. That is being done today in many plants in this country, as high as 3600 an hour, but 3600 an hour is not an average speed; 2800 is an average speed; a guaranteed speed under most conditions is 3000. I have seen them go anywhere from 3000 to 3600; 3600 on a very good sheet, straight edge, heavy stock, very little bronze on the sheet. The all-important thing in bronzing machines is the clean sheet, and therefore we come to the question that is the most difficult of all to answer, what is a clean sheet? A clean sheet on a certain kind of wrapper or label will not answer at all on certain other kinds of wrappers or certain other kinds of labels. We run into that question continually, so we must arrive at some basis on which to judge the average. A cigarette-package wrapper presents a fairly good example of a commercial bronze job. At the same time it is not comparable to some of the high-grade candy wrappers, which are printed in many colors. It is rather difficult to answer when asked whether we are able to guarantee that the bronzer will give an absolutely clean sheet. When I truthfully say "No, we do not guarantee an absolutely clean sheet," the prospect

immediately loses interest, feeling that he wants an absolutely clean sheet. Then if I show him a commercially clean sheet and say, "That is what we guarantee," I find him rather surprised at the quality of the work. So you see, that is an unsatisfactory procedure.

Now, up to this time, in order to get commercially clean sheets, it has been necessary to run the sheets through a dusting operation after the bronzing. Of course, that means an extra operation and thereby another chance for increased waste, inefficiency, and increased cost. Some of our larger lithographers and printers have taken their old bronzing machines and put automatic feeders on them, thereby increasing their production on the dusting; however, that is not entirely satisfactory. Some have even installed high-speed bronzing machines with a feeder in order to get the speed desired. Something had to be done about it, and the result has been a further development in the high-speed bronzing line, with the dusting unit built into the bronzing machine. In other words, instead of taking the sheet from the bronzer and then over to the dusting machine the sheet goes into the bronzer, then into the dusting unit and then into the delivery. That raises a question as to whether that gives a clean sheet. If you take a pile of sheets from a bronzing machine and let them stay over night or two or three days and then dust them, you will get a cleaner job than by dusting them immediately after they are bronzed; but what we are faced with in the industry is not a striving for perfection alone but for perfection along the lines of efficiency. By putting this dusting unit into the bronzing machine, we can get much cleaner work, and the next day it can be run through the varnishing machine without showing any bronze even on dark greens or blues, which would show it up if it were there. So the four-cylinder vacuum bronzer answers the question of high speed and a clean sheet in the bronzing machine in the same operation.

Executives have been satisfied to leave the bronzing work to more or less indifferent supervision. If one went out into the pressroom and saw dollar bills lying around on the floor, someone would hear about it. On the other hand, in the pressroom one sees sheets of paper costing a good many dollars, with several colors on them that have cost money, and if asked about it, they would say, "Why, of course, we must allow for some spoilage, some waste." If that department was given the same care that the presses are given, the results would compare favorably. Bronzing machines are not given the same attention from the mechanical departments as the other machines.

Then there is the question whether it is advisable to put the bronzing operation in a separate room. In many instances, especially in building new plants, provision is made to put the bronzing machine in a little "coop" by itself. That is a mistake because the impression is created that it is a dirty machine, and that it is put there so that it will not get the rest of the room dirty.

I believe the bronzing operation is perhaps the most important of any of the operations in the plant, and it ought to have the same care and the same supervision as the other equipment.

# The Art of Photo Composing, or Photo-Mechanical Imposition

By WILLIAM C. HUEBNER,[1] BUFFALO, N. Y.

THE advertiser or other customer who buys color-printing work demands a faithful reproduction of the object or painting or whatever it is that he furnishes as "copy." The printed representation of this advertised product or other article in color is intended to convey a favorable impression, and if it is a commercial article, to create a desire for ownership through effective sales appeal. The color reproduction accomplishes its purpose only when the finished edition is in precise register, with the component images united to tell the story accurately.

Commercial printers know well the general methods of printing, which are relief, intaglio, and lithographic or planographic.

Reproduction in quantity, or mass production, requires the making of duplicate plates in the desired number, these plates bearing the image or subject to be printed.

In relief printing these duplicates are made by using an intermediate means such as stereotyping and electrotyping between the original plate and the duplicate. In both of these methods the detail of the subject on the original plate is so changed by the transposition or transference through the matrices that it is not reproduced with fidelity. The expense and other accompanying economic factors make the use of either of these old methods of duplication commercially impractical for multicolor quantity reproduction under present-day requirements.

Intaglio printing has no satisfactory intermediate means for producing duplicate plates, because its technical requirements involve either flat plates or continuous-surface cylinders with the designs or images etched below the surface. The practical difficulties of making uniform and exact duplicates of these images, placing them in the desired positions on the form, and then preparing them for intaglio printing have prevented satisfactory commercial results. The lack of fidelity to the color "copy" and the lack of uniformity in the finished product have proved a disappointment to the large buyers of intaglio color advertising and to the producers of such color printing.
